tree peaks at 2 to 4 hours after IV injection but can be seen as early as 10 to 15 minutes after injection. FC offers a potentially detailed anatomic mapping of extrahepatic biliary structures and can be a useful adjunct to the critical view of safety technique. Dynamic, real-time NIR light capability is built into many modern laparoscopic and robotic cameras. It has the added benefit of not requiring cannulation of the biliary tree, such as with IOC, but can also be used in conjunction with IOC to help identify anatomy. No substantial contraindication for use of ICG exists, and it has been used safely in patients with iodine allergy. Anaphylactic reaction has been reported at a rate of 0.003%. ICG dye in patients with a history of anaphylactic reaction to shellfish is avoided. ICG is safe for use in pregnancy as maternal-to-fetal transfer is limited by the placental barrier. This is a tool that is growing in popularity. Its use is still actively being studied, but early systematic reviews show a trend toward reducing operative time, conversion to open, and injuries.[35]

Firm recommendations for routine use of ICG are limited by published study sizes. Early published data suggest both reduced operative time and conversion to open surgery in FC cases for both inflamed and noninflamed pathology. Additionally, there is a high success rate for identification of extrahepatic biliary structures. There are limited data on whether fluorescence cholangiography helps reduce major CBD injuries compared with historic techniques. Examples of ICG use in practice are seen in Fig. 88.32.

Laparoscopic Common Bile Duct Exploration

A survey of general surgery residents from 2000–18 demonstrated a precipitous decrease in the experience with both open and laparoscopic CBDE. At the turn of the millennium, the average general surgery resident participated in three open and one laparoscopic CBDE by graduation. Two decades later, the average experience was less than one procedure per resident.[36] This correlates with an overall decline in open and laparoscopic CBDE with concomitant increase in ERCP utilization for the management of choledocholithiasis. Common reasons surgeons choose not to perform CBDE include access to ERCP, lack of equipment, lack of comfort with the procedure, time constraints, and lack of trained staff.

Despite current practice patterns, numerous studies have demonstrated the benefits of one-stage management of choledocholithiasis with CBDE at the time of cholecystectomy over two-stage management with ERCP and cholecystectomy. The two techniques have equivalent stone clearance rates, but one-stage management is associated with decreased length of stay, decreased costs, and decreased rates of complications including pancreatitis.[37] Given these benefits, there has been a shift in the surgery community to reclaim the bile duct and to return to surgical management of choledocholithiasis as the standard of care.

The two laparoscopic approaches to CBDE for stone removal include a transcystic and transcholedochal approach. Techniques to clear the CBD via the cystic duct include sphincteroplasty under fluoroscopic guidance and choledochoscopy with basket retrieval of stones. Both approaches use the Seldinger technique and start with introducing a flexible guidewire through the cystic duct into the CBD. For sphincteroplasty, after the guidewire is positioned into the duodenum, a balloon is positioned across the ampulla and dilated. Stones are then cleared from the CBD into

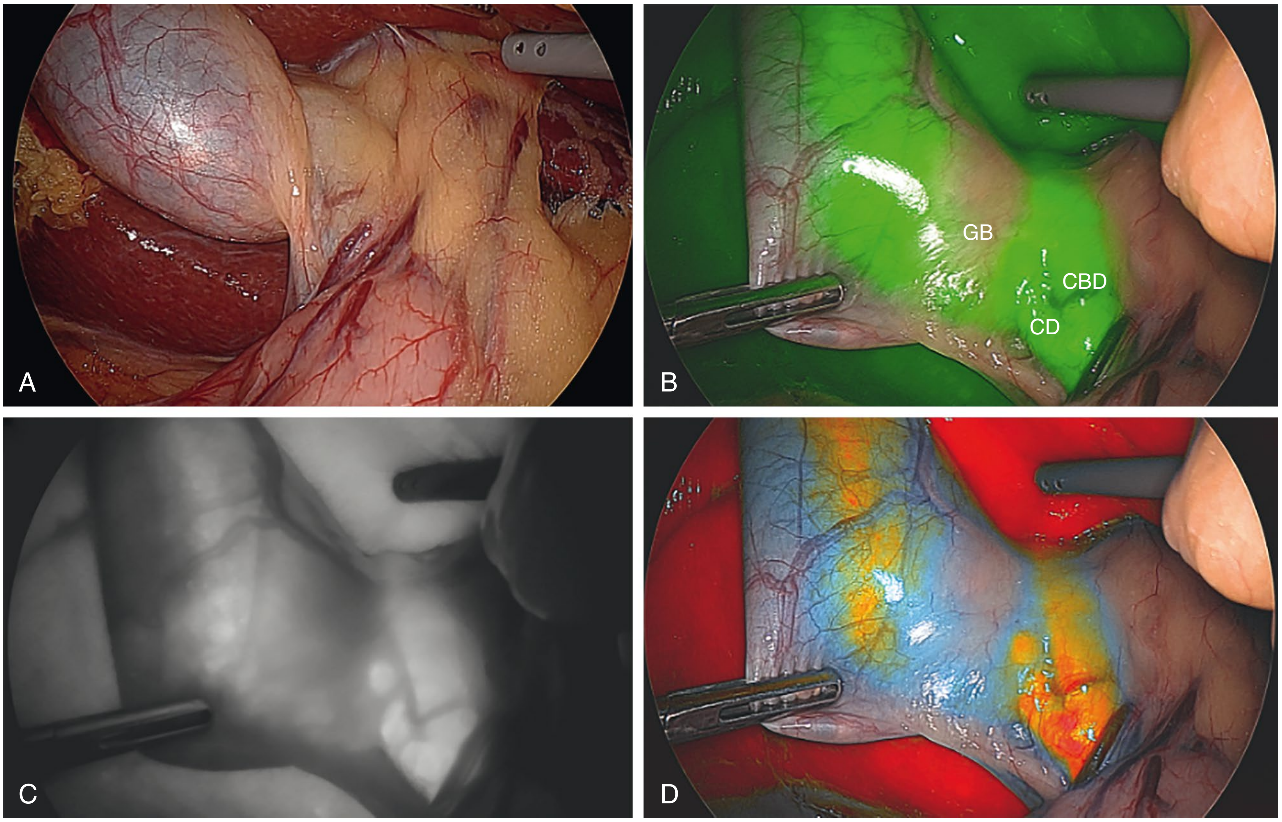

FIGURE 88.32 (A) Bright light/traditional laparoscopic view before peritoneal dissection. (B) Fluorescence cholangiography with "overlay" mode for the same image/patient as (A). (C) Fluorescence cholangiography with grayscale mode. (D) Fluorescence cholangiography with color segmented fluorescent mode. *CD,* Cystic duct; *CBD,* common bile duct; *GB,* gallbladder.

the duodenum with flushing maneuvers. Choledochoscopy requires CBD dilation of at least 6 to 8 mm to allow for passage of a flexible choledochoscope or ureteroscope. After the guidewire is passed through the cystic duct into the CBD, the valves of Heister along the cystic duct are lysed with balloon dilation. Choledochoscopy facilitates direct visualization of the bile duct and stones can either be pushed into the duodenum or captured with a basket under direct visualization and retrieved via the cystic duct.

For larger stones (>1 cm) or stones that are too big to be retrieved via the cystic duct, options for duct clearance include electrohydraulic lithotripsy or a transcholedochal approach. Electrohydraulic lithotripsy uses high-voltage electrical impulses, discharged in fluid, to produce hydraulic pressure waves, and these waves are able to fragment solid objects. Unlike extracorporeal shock wave lithotripsy, which uses sparks and shock waves generated outside the body to fragment stones, electrohydraulic lithotripsy requires close contact with the gallstone with a choledochoscope or endoscope. Once the stone is broken into fragments, they can be retrieved via the cystic duct in a wire basket.

In the transcholedochal approach, a longitudinal incision is made in the CBD after two stay sutures are placed on either side of the planned choledochotomy (Fig. 88.33). The size of the incision should be at least as large as the diameter of the largest stone. The choledochoscope can then be fed down into the distal bile duct and stone extraction performed as described earlier. At the completion of the exploration, larger diameter bile ducts (i.e., 1 cm and larger) can be closed primarily with interrupted 4-0 absorbable suture. For smaller diameter ducts, when there is a concern for stricture, or the CBD obstruction has not been entirely cleared, a T-tube should be placed through the choledochotomy and the bile duct closed with 4-0 absorbable sutures. Completion cholangiography should be routinely performed to document clearance of the CBD.

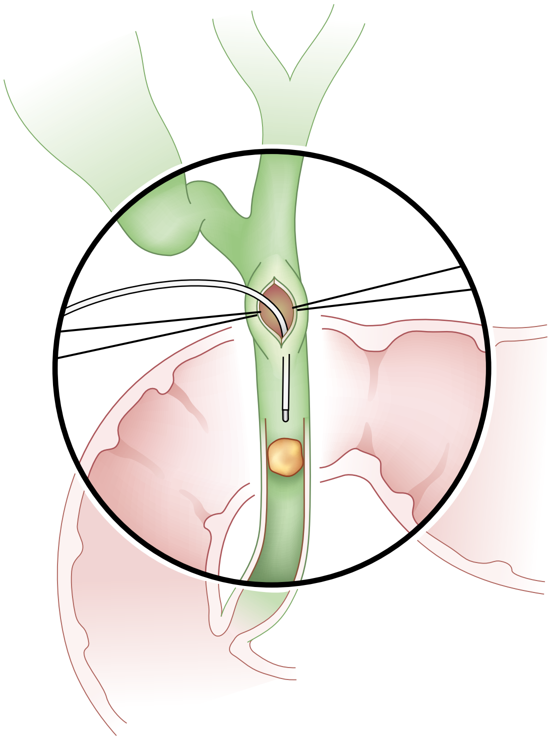

FIGURE 88.33 Laparoscopic choledochotomy for common bile duct exploration.

When feasible, the transcystic approach is preferred as it is technically easier and does not require advanced laparoscopic suturing. However, with the advent of the robotic platform, difficult dissection and advanced suturing in a minimally invasive fashion are within reach for the general surgeon. Relative contraindications to the transcystic approach include numerous (more than eight) stones, a stone larger than 1 cm, intrahepatic stones, and a cystic duct that does not permit dilation and choledochoscope passage.

Bailout Procedures

As the grade of cholecystitis increases from I to II or III, a laparoscopic procedure becomes increasingly difficult to complete safely. The Tokyo Guidelines on recommendations for surgical management of cholecystitis recommended a few bailout options, and a surgeon must be prepared to perform these, especially with a higher grade cholecystitis. As surgical training features fewer open cholecystectomy operations, it is becoming more common to see laparoscopic bailout options used.

Although crucial for safe anatomic dissection, grasping the fundus and infundibulum of an acutely inflamed, distended gallbladder may prove difficult. Decompression of the gallbladder with a laparoscopic needle aspirator (most common) or a 14-gauge angiocatheter can help suction the gallbladder contents and alleviate tension. A very inflamed gallbladder, even with decompression, may not be amenable to grasping with routine laparoscopic devices. In this scenario, claw or rat-tooth graspers may prove useful, but an early conversion to open surgery may be required. Alternatively, a dome-down (or retrograde) approach may be possible, but very close care and attention must be directed to gallbladder anatomy during this dissection. Loss of bearings medially can lead to high injury of the common hepatic duct, so early dissection away from the cystic plate is critical.

If the cystic structures cannot be safely dissected from the portal structures, a subtotal cholecystectomy can be performed. The gallbladder is surgically divided high on the infundibulum, all stones are removed, and the infundibulum is left in situ. Subtotal cholecystectomy such as this can be "fenestrating" or "reconstituting." Fenestrating leaves the cystic duct stump open and reconstituting is closure of the stump with stapler or suture. Data are limited on the whether fenestrating or reconstituting has better outcomes as sample size is low; however, patient anatomic factors often influence the decision (e.g., in a gangrenous gallbladder the tissue may be too friable for a suture). A drain is left in place to help evaluate and manage a bile leak, which is a somewhat common occurrence in these cases. If any of the previously mentioned techniques are not successful in aiding dissection, there should be no hesitation to convert to open cholecystectomy.

Open Cholecystectomy

Although open cholecystectomy is considered a safe alternative or bailout procedure for the difficult laparoscopic cholecystectomy, experience with it has drastically declined, making this procedure not necessarily the safer technique. Open cholecystectomy is generally performed after conversion from the laparoscopic approach, for patients who have a contraindication to the laparoscopic approach, or as a step during another operation, such as a pancreaticoduodenectomy. Open cholecystectomy can be performed through a midline or right subcostal incision. Early identification and ligation of the cystic artery limit the blood loss during the procedure but may prove difficult because of inflammation. This approach must be used with caution as the extension of the dissection continues inferiorly, putting portal vein and other portal structures at risk.[38] When it is performed for severe cholecystitis, the dissection of the gallbladder of the liver bed may be associated with substantial blood loss, but with removal of the infected gallbladder and packing of the area, the bleeding is usually well controlled.

Open Common Bile Duct Exploration

Clearance of choledocholithiasis or any other reason for CBDE is typically performed by open technique. Most surgeons prefer right upper quadrant incision; however, an upper midline incision can be used as well. Gentle palpation of the distal bile duct will frequently find the offending stone, which may be milked backward. Stay sutures are then placed and a choledochotomy is performed in the supraduodenal bile duct. Flushing of the duct with a soft rubber catheter will frequently remove the offending stones. Balloon catheters and, with fluoroscopic guidance, wire baskets may be useful to withdraw the stone. Flexible choledochoscopes are used to visualize the distal bile duct. With complete removal of stones, a T-tube is placed, and a cholangiogram obtained before closure to document clearance.

With dilated bile ducts, multiple distal impacted stones, a distal duct stricture with stones, intrahepatic stones, or primary bile duct stones drainage procedures provide more successful long-term outcomes. Options in this setting include choledochoduodenostomy (Fig. 88.34) or Roux-en-Y hepaticojejunostomy (Fig. 88.35). A side-to-side or end-to-side choledochoduodenostomy allows future endoscopic intervention of the upper biliary tree, if necessary. An alternative to duodenostomy is a Roux-en-Y choledochojejunostomy.

Transduodenal sphincteroplasty must be the procedure of choice when impacted stones at the ampulla cannot be removed through choledochotomy or several stones are impacted in a *nondilated tree* (Figs. 88.36 and 88.37). After completion of the Kocher maneuver, a longitudinal duodenotomy is made on the lateral wall. Compression of the lateral wall against the medial

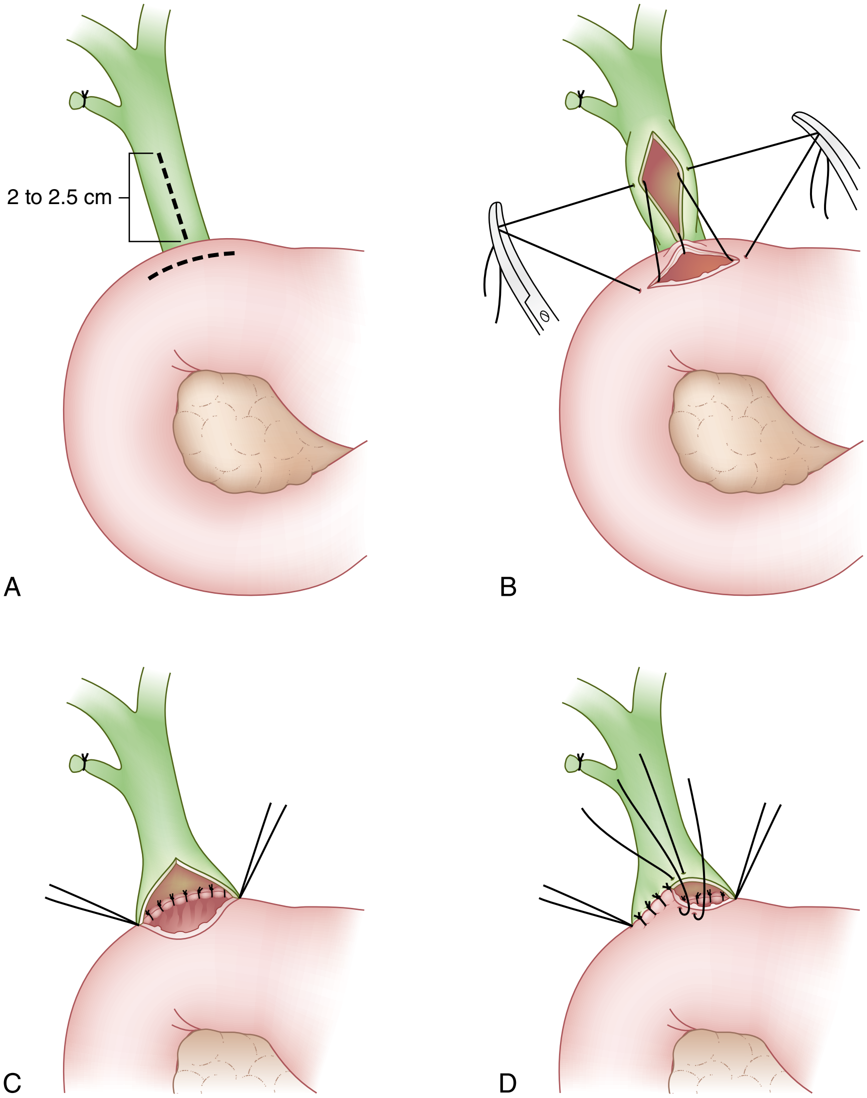

FIGURE 88.34 Choledochoduodenostomy. In the setting of a dilated common bile duct (CBD) with inability to clear all the stones from the distal duct, an anastomosis can be performed between the CBD and adjacent duodenum. Although maintaining the possibility of future endoscopic therapy, this arrangement risks sump syndrome in the undrained distal duct. (A) Vertical incision on CBD and horizontal incision on duodenum. (B) Stay sutures on corners, creating open anastomosis. (C) Suturing posterior wall. (D) Suturing anterior wall.

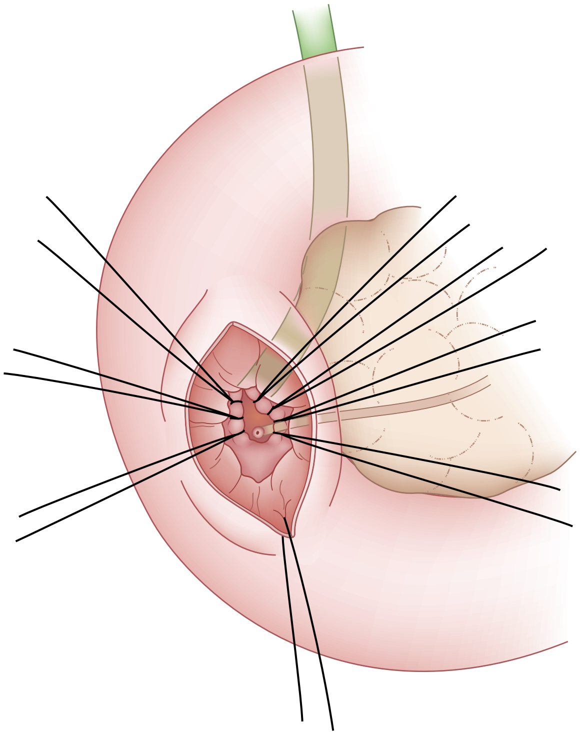

FIGURE 88.37 Transduodenal sphincteroplasty.

wall will allow palpation of the ampulla to plan placement of the duodenotomy appropriately. With identification of the ampulla, an incision is made at the 11 o'clock position, and each wall is elevated with stay sutures. The pancreatic duct usually enters at the 5 o'clock position on the ampulla and must be avoided. It is also imperative to remember that the inferior pancreaticoduodenal arcade is adjacent to the distal part of the ampulla and can be injured during sphincterotomy. Sequential straight clamps are placed along the planned incision of the ampulla to guide visualization through hemostasis. With each step, the duodenal mucosa is sewn to the bile duct mucosa with absorbable 4-0 or 5-0 sutures. A 1.5-cm sphincterotomy is usually sufficient to allow stone removal and subsequent drainage. Closure of the longitudinal duodenotomy in transverse fashion avoids a future duodenal stricture.

Open exploration carries a low morbidity (8%–15%) and mortality (1%–2%), with a low rate of retained stones (<5%). The downside of choledochoduodenostomy is that the bile duct distal to the anastomosis may drain poorly and may collect debris that obstructs the anastomosis or the pancreatic duct, a process known as *sump syndrome*. Anastomosis to the jejunum in a Roux-en-Y arrangement provides excellent drainage of the biliary tree without a risk of sump syndrome but does not allow future endoscopic evaluation of the biliary tree (see Fig. 88.35).

With intrahepatic stones, the transhepatic approach to cholangiography is generally more successful. Percutaneous drainage catheters may be left in place and upsized to perform percutaneous stone extraction. Long-term management of intrahepatic stones must be carefully tailored to the disease but frequently requires hepaticojejunostomy for optimal biliary drainage. Liberal use of choledochoscopy at the time of a drainage procedure ensures removal of all current stones. This approach allows a stone clearance rate of more than 90%.

Complications of Cholecystectomy

Postcholecystectomy Syndromes

First described in 1947, postcholecystectomy syndrome, recurrence of heterogeneous symptoms similar to those experienced before a cholecystectomy, such as upper abdominal pain and dyspepsia, with or without jaundice, occurs in 10% to 15% of all cholecystectomies worldwide. These symptoms may manifest from days to years after cholecystectomy and are more common in females. The etiology ranges from surgical complications (in more severe forms) to primary unrelated etiology such as esophagitis, GERD, and more. Biliary etiologies specifically include, but are not limited to, a retained stone, bile salt–induced diarrhea, biliary leak, long remnant cystic duct, or functional problems with biliary tree and/or sphincter of Oddi.

Bile Duct Injury

More than 80% of bile duct injuries occur during cholecystectomy. Variable anatomy, porta hepatis inflammation, inappropriate exposure, inadequate experience or skill, and aggressive hemostasis have been cited as risk factors. Studies have suggested that misperception of the anatomy is a much more common factor in iatrogenic injury than surgical skill.[34] With sufficient cephalad retraction of the gallbladder fundus, the cystic duct overlies the common hepatic duct, running in a parallel path. Without inferolateral traction of the gallbladder infundibulum to dissociate these structures, dissection of the apparent cystic duct may actually include the common hepatic duct, placing it in jeopardy. By retraction of Hartmann pouch inferolaterally and opening of the triangle of Calot, the cystic duct is displaced from the porta, no longer collinear with the hepatic duct. The use of a 30-degree laparoscope provides adequate visualization of the critical view of safety during laparoscopic cholecystectomy. Also, in many of these cases, a confirmation bias occurs in which surgeons tend to rely on evidence that supports their perception while discounting visual cues that suggest an alternative explanation. Confirmation bias helps explain why most bile duct injuries are identified in the postoperative setting, not intraoperatively. Cholangiography does not completely avoid bile duct injury but may reduce the incidence and extent of injury and allow immediate recognition and management. The original analysis of biliary reconstruction was based on the Bismuth classification and has been modified by Strasberg. Classification of bile duct injuries is determined by location and helps guide later surgical reconstruction (Fig. 88.38).[39] Injury to the bile duct that does not leak bile will usually be manifested with jaundice, with or without pain. Among postoperative bile duct strictures, occurring roughly in less than 1% of all cases, types E1 and E2 involve the common hepatic duct but not the bifurcation, with type E1 maintaining more than 2 cm of common hepatic duct below the bifurcation and type E2 being within 2 cm of the confluence. Type E3 strictures occur at the confluence, preserving the extrahepatic ducts, and in type E4, the stricturing process includes the extrahepatic biliary tree. Type E5 strictures involve aberrant right hepatic duct anatomy, with injury to the aberrant duct and common hepatic duct.

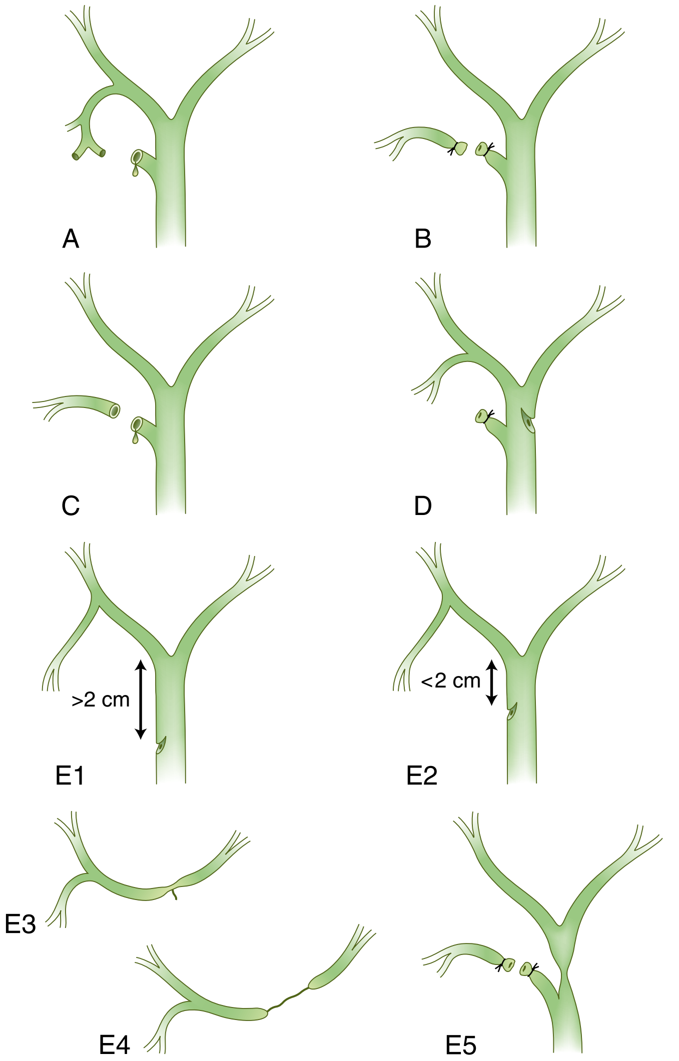

FIGURE 88.38 Strasberg classification of postoperative bile duct strictures. (A) Injury to small ducts in continuity with the biliary system with a leak in the duct of Luschka or the cystic duct. (B) Injury to a sectoral duct, causing obstruction of portion of the biliary system. (C) Injury to a sectoral duct with bile leak; the leak is from a duct and is not continuous with the biliary system. (D) Lateral injury to the extrahepatic biliary ducts. (E1) Bismuth type 1: injury more than 2 cm from the confluence. (E2) Bismuth type 2: injury less than 2 cm from the confluence. (E3) Bismuth type 3: injury at the confluence; confluence intact. (E4) Bismuth type 4: destruction of the biliary confluence. (E5) Complete occlusion of all bile ducts, including sectoral ducts.

Presentation. Bile duct injury can result in bile leakage or stricture. Leakage into the peritoneal cavity followed by peritonitis tends to manifest earlier than stricture. Less than 10% of strictures are found in first week postoperatively, and more than 70% are diagnosed within 6 months. In the setting of bile leakage, patients may present with fever, increasing abdominal pain, jaundice, or bile leakage from an incision. Regardless of timing or presentation, adequate repair and subsequent outcome depend on diagnosis, sufficient delineation of anatomy, creation of a tension-free anastomosis, and liberal use of transanastomotic stents.

Treatment

Recognized at the time of cholecystectomy. When bile duct injury is suspected intraoperatively, conversion to an open operation and use of cholangiography help delineate management. Goals for the immediate treatment of bile duct injury include maintenance of ductal length, elimination of any bile leakage that would affect subsequent management, and creation of a tension-free repair. If the injury occurs to a larger than 3-mm duct but is not caused by electrocautery and involves less than 50% of the circumference of the wall, a T-tube is placed through the injury. This choledochotomy with T-tube usually will allow healing without the need for subsequent biliary-enteric anastomosis. Ducts smaller than 3 mm that by cholangiography drain only a single segment or subsegment of the liver and simple ligation may suffice for management. Any thermal injury in which the extent of thermal damage may not be manifested immediately or an injury involving more than 50% of the duct circumference requires resection of the injured segment with anastomosis to reestablish biliary-enteric continuity. Defects smaller than

1 cm and not near the hepatic duct bifurcation can be repaired by mobilization and end-to-end anastomosis of the bile duct. This approach should be accompanied with transanastomotic T-tube placement. The tube should be inserted through a separate choledochotomy and not exit the bile duct through the anastomosis. To ensure a tension-free anastomosis, a generous Kocher maneuver, mobilizing the duodenum and the head of the pancreas out of the retroperitoneum, is necessary.

More commonly, injuries occur adjacent to the bifurcation or involve more than a 1-cm defect between the ends of the bile duct, requiring reanastomosis to the gastrointestinal tract. In this setting, the distal end is oversewn and the proximal end debrided to normal tissue. The choice of reconstruction depends on the location and extent of injury, history of previous attempts at repair, and preference of the surgeon. Low injuries to the bile duct can be reimplanted into the duodenum, although the new choledochoduodenostomy anastomosis risks a duodenal fistula, especially considering that these anastomoses may require significant mobilization to avoid anastomotic tension. The Roux-en-Y approach to reconstruction is substantially more versatile and can be applied to injuries throughout the biliary tree. In addition, most injuries to the bile duct occur higher in the biliary tree, close to the hilum, thus not allowing tension-free anastomosis to the duodenum. Therefore, in almost all cases of bile duct injury, a resection of the injured segment with mucosa-to-mucosa anastomosis using a Roux-en-Y jejunal limb is preferred. Transanastomotic stenting has been shown to improve anastomotic patency, with longer duration of stenting providing a more favorable outcome. As concomitant vascular injuries are common, Doppler ultrasonography can confirm adequate hepatic arterial and portal venous flow to the hepatic parenchyma.

Because most bile duct injuries and, therefore, most immediate repairs occur at centers where biliary reconstruction is performed infrequently, most immediate repairs go unreported in the literature. However, the importance of surgical judgment and experience in biliary reconstruction cannot be overemphasized. Reports of previous failed attempts at reconstruction highlight the value of experience in the treatment of bile duct injuries. Therefore, when one is confronted with a bile duct injury and no surgeon with experience in biliary reconstruction is available, the most appropriate management strategy is placement of one or multiple drains in the right upper quadrant and immediate referral to an experienced center.[34]

Identified after cholecystectomy. The diagnosis of iatrogenic bile duct injury should be suspected in any patient who presents with new or increasing symptoms after a laparoscopic cholecystectomy. Leakage may be manifested as bilious drainage into a subhepatic drain placed at the time of operation or bilious drainage from a surgical incision. Without a site for external drainage, bile leakage can be manifested as a biloma, whether sterile or infected, or with biliary ascites. Persistent or worsening postprandial pain, shoulder pain, malaise, and/or fever must raise the suspicion of a bile duct injury.

Patients suspected of having an iatrogenic bile duct injury should undergo imaging to assess for a fluid collection and to evaluate the biliary tree. Ultrasonography can achieve both these goals, but because percutaneous drainage may be required and anatomic delineation is valuable, cross-sectional imaging by CT will generally provide more useful data. Some surgeons advocate the use of radionuclide scanning to confirm bile leakage, but with any documentation of a leak, CT will be necessary to plan management. Also, ischemia is a common cause of bile duct stricture. In the setting of a bile duct injury, 20% or more of patients will have concomitant unrecognized vascular injuries.

In the delayed presentation of a bile duct injury, three major goals guide therapy (Box 88.1). First, control of infection with drainage of any fluid collections will minimize the inflammatory process. Inflammation in the porta hepatis leads to fibrosis, which acts only to increase stricture formation. Broad-spectrum antibiotics, decompression of the biliary tree, and drainage, whether percutaneous or operative, of any fluid collections will achieve this goal. With control of sepsis, there is no urgency for biliary reconstruction. In fact, with time, resolution of the periportal inflammation helps with the execution of a durable reconstruction. In addition, the retraction of an injured bile duct into the hilum of the liver, as well as inflammation in this region, makes successful repair in the immediate postoperative setting unlikely. Therefore, although immediate reexploration to manage the injury as expeditiously as possible is tempting, successful long-term management of bile duct injuries identified postoperatively depends on clear and deliberate preoperative planning of the reconstruction.

A second goal of management is clear and thorough delineation of the biliary anatomy with cholangiography. Without preoperative cholangiography, any attempts at repair are unlikely to be successful. The cholangiogram must indicate the intrahepatic anatomy and bile duct bifurcation. For patients with bile duct continuity, ERCP may be possible. However, PTC will demonstrate the intrahepatic biliary tree, identify the location of the injury, provide drainage of bile, and possibly even allow the leak to close (Fig. 88.39). Percutaneous biliary catheters can also be left in place during reconstruction to assist in dissection and to provide drainage perioperatively. PTC can be combined with ERCP as necessary, depending on the site and extent of injury. Small bile leaks with bile duct continuity and cystic duct stump leaks can be successfully managed by endoscopic stenting and sphincterotomy.

The third goal of management is to reestablish durable biliary-enteric drainage. Although a combination of percutaneous and endoscopic biliary dilations and stenting may establish continuity, surgical reconstruction has the highest patency rates. To achieve a successful and durable repair, the anastomosis must be performed between a minimally inflamed bile duct to intestines in a tension-free, mucosa-to-mucosa fashion. When the anastomosis is within 2 cm of the hepatic duct bifurcation or involves intrahepatic ducts, some evidence suggests that long-term stenting may improve patency. If the bifurcation is involved, stenting of both right and left ducts should be performed. When the reconstruction

BOX 88.1 Goals of Therapy in Iatrogenic Bile Duct Injury

1. Control of infection, limiting inflammation
    - Parenteral antibiotics
    - Percutaneous drainage of periportal fluid collections
2. Clear and thorough delineation of entire biliary anatomy
    - Magnetic resonance cholangiopancreatography or percutaneous transhepatic cholangiography
    - Endoscopic retrograde cholangiopancreatography (especially if cystic duct stump leak is suspected)
3. Reestablishment of biliary-enteric continuity
    - Tension-free, mucosa-to-mucosa anastomosis
    - Roux-en-Y hepaticojejunostomy
    - Long-term transanastomotic stents if bifurcation or higher is involved

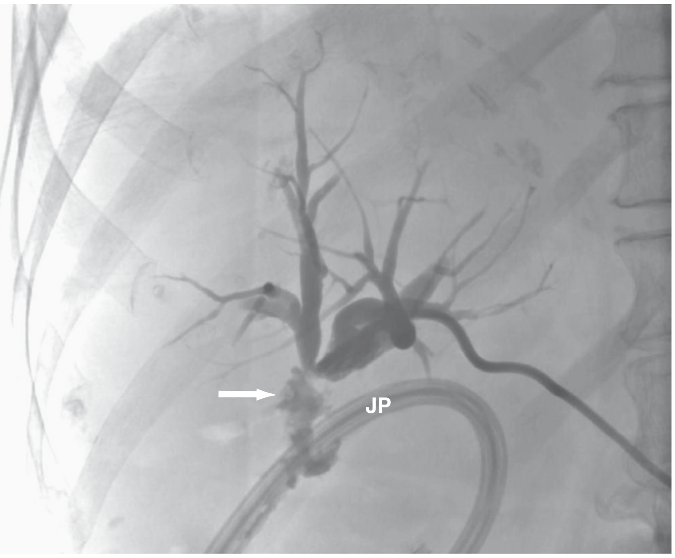

FIGURE 88.39 Percutaneous transhepatic cholangiogram of bile duct injury. Note the extravasation of contrast material *(arrow)* and the Jackson-Pratt *(JP)* drain placed at the time of initial operation.

involves the CBD or common hepatic duct more than 2 cm from the bifurcation, stenting is not necessary; therefore, a preoperatively placed transhepatic drain or intraoperatively placed T-tube will provide adequate decompression in the immediate postoperative period.

At the time of operation, the adhesions of the duodenum and colon to the liver should be separated. The porta hepatis can be encircled with a Penrose drain. Although the bile duct should lie on the lateral border of the porta hepatis, preoperatively placed percutaneous biliary drainage catheters can assist in the dissection, as the marked fibrosis and inflammatory process may make its identification difficult. If necessary, a small-caliber needle attached to a syringe can be used to aspirate and to identify the bile duct while avoiding inadvertent injury to a vascular structure. Once identified, above the stricture, only a limited segment of bile duct (<5 mm) is dissected free. Any further dissection of normal duct risks vascular compromise of the segment to be used in the anastomosis. Preservation of as much normal biliary tree as possible remains a goal of the reconstruction. Next, the bile duct can be opened and the percutaneously placed catheters advanced through the incision. At this point, a wire can be used to exchange the catheters for long-term Silastic stents, if appropriate, or the catheters can be left in place for transanastomotic decompression. The mucosa-to-mucosa anastomosis can be created in an end-to-side fashion to the Roux-en-Y jejunal limb. In the setting of substantial inflammation at the bifurcation, another reconstruction option involves anastomosis of the Roux limb to the left hepatic duct. As noted, the left hepatic duct retains a substantial extraparenchymal length, allowing an anastomosis in this portion of normal duct. Before this section is used for drainage of the entire liver, cholangiography must confirm that the biliary bifurcation is widely patent, thus ensuring drainage of the right lobe across the bifurcation to the left duct system.

Interventional radiologic and endoscopic techniques. Fluoroscopic-guided management using percutaneous access to traverse the stricture can be used when the duct continuity of the duct is preserved. Balloon dilation can treat strictures, and this approach is successful in up to 70% of patients.[40] Complications, although frequent, are generally manageable and include cholangitis, hemobilia, and bile leaks requiring repeated intervention. Endoscopic balloon dilation of bile duct strictures is generally reserved for those with primary bile duct strictures or patients who have undergone choledochoduodenostomy for reconstruction because the Roux limb does not usually allow endoscopic strategies. Therefore, series are limited, but results are encouraging, with 88% of patients responding to therapy and a complication rate of 8% from pancreatitis and cholangitis.

Outcomes. Successful outcomes can be achieved in patients undergoing biliary-enteric reconstruction after bile duct injury, with many series showing more than 90% of patients free of jaundice and cholangitis. High success rates are generally achieved when injuries are identified early, and patients are referred immediately to experienced centers. In several studies, referral to centers performing complex biliary surgery routinely was associated with better long-term success.[34] Surgical reconstruction provides a durable long-term management strategy. Management of these injuries requires a multidisciplinary management and may need percutaneous techniques as well as surgical reconstruction. Sepsis at the time of reconstruction and biliary cirrhosis are predictors of stricture. In some studies, results were generally better if transanastomotic stents were used during reconstruction.[41] Chronic liver disease and hepatic fibrosis are associated with higher operative mortality and lower success rates. Although a devastating complication, management is highly successful and restores health-related quality of life scores to preinjury levels.

Biliary Leak

After a cholecystectomy, patients may suffer a leak from the cystic duct or an unrecognized duct of Luschka. Fevers, chills, right upper quadrant pain, jaundice, leakage of bile from an incision or into a drain, or persistent anorexia or bloating are common signs and symptoms. Although it can be seen after any cholecystectomy, those performed for acute cholecystitis carry the greatest risk. With inflammation and fibrosis around an obstructed cystic duct, clips placed on the duct may not fully occlude it or may be dislodged as the inflammatory process resolves. Patients will generally present within 1 week of cholecystectomy as the bile collects. A CT, when performed, will show ascites or a right upper quadrant fluid collection consistent with a biloma. After drain placement and controlling the leak and infection, ERCP can be performed if the leak is high output (>300–500 mL/day). Some of these leaks may dry up on their own with sufficient external drainage. If there is high output or persistent bile leak, ERCP with sphincterotomy with stenting of the common duct will allow the leak to seal without need for surgical management.[41] Reexploration in this setting is rarely indicated, especially in patients with evidence of septic shock or those in whom the leakage is not percutaneously accessible. If percutaneous drainage is not feasible because of overlying bowel or the fluid is not localized and thus not amenable to percutaneous drainage, a laparoscopic washout of the abdomen and placement of subhepatic drains can be considered. No attempt should be made to fix the leak; any such intervention is almost always unsuccessful and risks further biliary tree injury. Persistence of a bile leak longer than 6 weeks should raise the suspicion of an unrecognized bile duct injury. Similar to CBD injuries, surgical treatment of a duct leak is most successful once the inflammatory process has resolved.

Lost Stones

Accidental opening of the gallbladder with spillage of stones occurs in 20% to 40% of cholecystectomies. Pigmented stones, a high number of stones, less experienced surgeons performing the surgery, and severe cholecystitis are all risk factors. Unfortunately, stones lost during a cholecystectomy can have significant and even substantially delayed consequences, such as chronic abscess, fistula, wound infection, and bowel obstruction. Most dropped stones settle into the Morison pouch or the retrohepatic space along the abdominal wall, which may develop into a chronic abscess in this location. The likelihood for the development of complications from lost stones is difficult to quantify because surgeon documentation of gallbladder perforation is variable and a substantial delay frequently exists between cholecystectomy and complication from lost stones. On the basis of available studies, lost stones do not necessitate conversion to an open operation; treatment should include extensive irrigation, significant attempt to retrieve lost stones, course of antibiotics, documentation of the perforation in the operative notes, and clear communication with the patient of the small possibility of delayed presentation from erosion or abscess.

Postcholecystectomy Pain

Although unusual, pain similar to biliary colic may persist or recur after cholecystectomy. A thorough evaluation of the biliary tree should be undertaken after cholecystectomy if the pain recurs. Recurrence of pain, if it is associated with other system findings of jaundice, fever, or chills within days to weeks after cholecystectomy, suggests a secondary choledocholithiasis or a bile leak. Other biliary tree phenomena may cause a similar picture, such as SOD. Postoperative bile duct strictures, which usually are manifested with jaundice, are generally identified within the first year after cholecystectomy and may be manifested with pain or fever if only one lobar duct is obstructed. In the setting of normal liver chemistries, other causes of right upper quadrant pain should be investigated.

Retained Biliary Stones

Retained stones or secondary stones, originating in the gallbladder and passing into the common duct, are usually cholesterol stones and frequently become symptomatic within weeks of a cholecystectomy but may be identified for up to 2 years after cholecystectomy. Hyperbilirubinemia and an elevated ALP level should raise the suspicion of a retained stone. US may not show intrahepatic biliary ductal dilation if the stone does not fully occlude the duct or the obstruction is early. Endoscopic removal of these stones through a generous sphincterotomy has very high success rates.

Other Postoperative Complications

The most common intraabdominal complications following laparoscopic cholecystectomy for acute cholecystitis are abscess formation, bleeding, and bile leak. These complications can usually be managed with the assistance of IR rather than return to the operating room; although in the setting of a bile leak causing diffuse peritonitis, operative washout and drain placement is indicated. Bile and gallstone spillage are common in cases of acute inflammation. Bile should be irrigated and aspirated and efforts should be made to retrieve all dropped gallstones. Larger dropped stones can result in abscess formation so every effort should be made to retrieve them.

Most bile leaks postoperatively are not related to major CBD injury, but due to leakage from the cystic duct or small subcapsular ducts (ducts of Luschka). When a patient is deemed to be higher than average risk of leak, a closed suction drain should be left in the operative field. Examples of when to leave a drain include that the gallbladder is exceptionally adherent to the liver parenchyma, poor cystic duct quality, or when bailout techniques are employed. Leaks may not be immediately apparent in many instances. If a small leak is present, it will usually heal on its own. In patients who present postoperatively with imaging findings of a fluid collection in the surgical bed, one must determine whether a drain should be placed. If the patient is demonstrating signs of sepsis or concerning lab and imaging findings, the fluid should be drained. If the patient appears well, has normal labs, and has simple fluid on CT scan, then the fluid may represent seroma, and drainage may not be necessary. Although it is true that many bile leaks following cholecystectomy are cystic stump leaks, bile duct injury should be considered unless clinical findings prove otherwise. Patients with abnormal LFTs, high-volume leaks, upward trending drainage volumes, and those with signs of sepsis should undergo ERCP for delineation of the anatomy and possible stent placement.

Biliary Neoplasms

Gallbladder Polyps

Benign masses of the gallbladder are common, occurring in up to 12% of the population. Polyps are nonmobile protrusions into the gallbladder lumen that can be divided into pseudopolyps and true polyps. Most polyps are pseudopolyps and can be further divided into cholesterol polyps, focal adenomyomatosis, hyperplastic polyps, and inflammatory polyps, none of which have malignant potential. Cholesterol polyps appear as pedunculated echogenic lesions of the gallbladder, are usually smaller than 1 cm, and are frequently multiple. Adenomyomatosis is seen as a sessile lesion, commonly in the fundus, with characteristic microcysts within the lesion, and is frequently larger than 1 cm (Fig. 88.40). True polyps are neoplastic growths in the wall of the gallbladder that have the potential to harbor or become gallbladder cancer. The risk of malignancy increases with polyp size, and expert consensus is that cholecystectomy should be recommended to all patients with polyps 10 mm or greater or symptoms potentially attributable to the gallbladder.[42] For patients with smaller polyps (6–9 mm), clinical risk factors, such as Asian race and PSC, and radiographic features, such as sessile morphology and vascularity,

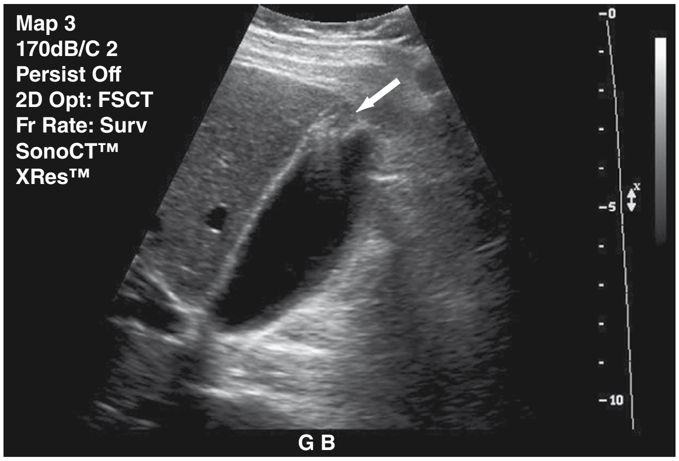

FIGURE 88.40 Ultrasound image of adenomyomatosis. Seen in the fundus of the gallbladder is a sessile thickening *(arrow)* with smaller microcysts within it, consistent with adenomyomatosis.

should also influence recommendation for cholecystectomy. Polyps smaller than 10 mm with no other risk factors and no ultrasonographic features suggesting malignant disease can be observed with serial ultrasonography.

Benign Biliary Masses

Benign intraluminal lesions of the biliary tract have been an evolving field. The most accepted categorization of benign biliary lesions distinguishes biliary intraepithelial neoplasms from intraductal papillary neoplasms.[43] Intraepithelial neoplasms are flat lesions that are not evident grossly and are usually incidental findings on resection for other indications. Their epidemiology and molecular features strongly suggest that they are precursors of bile duct malignancy (cholangiocarcinoma). In contrast, intraductal papillary neoplasms are grossly visible polypoid lesions that are the rarer counterparts to intraductal papillary mucinous neoplasms (IPMNs) of the pancreas and are also considered premalignant. The presentation is typically that of biliary obstruction with jaundice and sometimes right upper quadrant pain. Treatment consists of complete resection with a small rim of normal epithelium because incomplete excision of affected epithelium carries a high risk of recurrence. Like IPMNs of the pancreas, intraductal papillary neoplasms of the bile duct can affect multiple parts of the biliary tree synchronously or nonsynchronously.

Inflammatory lesions of the biliary tree, known as pseudotumors or benign fibrosing disease, may be mistaken for cholangiocarcinoma. When this process follows surgical intervention on the biliary tree, the masslike stricture may be the result of ischemia to the duct, with subsequent inflammation and fibrosis. Alternatively, pseudotumors may occur de novo; these commonly affect the extrahepatic biliary tree above the bifurcation.

Malignant Biliary Disease

Gallbladder Cancer

Gallbladder cancer is an aggressive malignant disease and carries an extremely poor prognosis. Patients have no specific presenting symptoms; therefore, presentation with late-stage disease is common. The poor prognosis corresponds to the high proportion of patients presenting with advanced disease. For patients with earlier stage disease, a more aggressive surgical approach is warranted.

Incidence

Gallbladder cancer generally occurs in the sixth and seventh decades of life and is two to three times more common in females than in males. Ethnicity plays an important role in the development of gallbladder cancer, with the highest incidences in South America and parts of Asia. Among North American populations, Native Americans and immigrants from Latin America have the highest rates. In the United States overall, gallbladder cancer is the most common cancer of the biliary tract and the fifth most common gastrointestinal cancer.[44]

Cause

The prevailing theory of gallbladder cancer focuses on chronic inflammation with subsequent development of neoplasia. The presence of gallstones is considered to be the primary risk factor, and risk of cancer development increases with longer history of gallstone disease. More than 70% of patients with gallbladder cancer have cholelithiasis, and gallbladder cancer is approximately five times more common in patients with gallstones than in those without stones. Extensive calcification of the wall of the gallbladder, termed *porcelain gallbladder,* has historically been considered an indication for cholecystectomy due to the risk of cancer development. Whereas the risk of gallbladder cancer is higher in patients with focal gallbladder wall calcification, the finding of diffuse calcifications with modern CT imaging is common compared with the finding of calcifications on plain films, and is not associated with such a high risk of gallbladder cancer that resection in asymptomatic patients is required.[45] Other risk factors include entities that may also cause inflammation in the gallbladder wall, such as APBJ, choledochal cysts, and PSC. Genetic profiling of gallbladders with chronic cholecystitis and cancer, as well as preclinical models, strongly suggest that chronic inflammation leads to an accumulation of mutations (most commonly P53) in a metaplasia-dysplasia-neoplasia sequence.[46]

Pathology and Staging

Gallbladder cancer is generally adenocarcinoma. It is staged by the standard tumor-node-metastasis (TNM) staging system (Table 88.1[47]). Gallbladder cancer spreads via lymphatics, hematogenously, and notoriously into the peritoneal cavity or along biopsy or surgical wound tracts.

Gross descriptions of gallbladder cancer have been grouped into infiltrative, nodular, papillary, and combined forms. Most tumors have an infiltrative pattern and spread in a subserosal plane and can invade the entire gallbladder wall and even into the porta hepatis. Nodular types tend to grow as a more circumscribed mass and can invade the liver. A small subset of gallbladder cancers are of the papillary subtype and carry a better prognosis because they tend to have an indolent course and are commonly limited to the gallbladder wall at the time of diagnosis (Fig. 88.41).

The first draining nodal basin for gallbladder cancer includes the cystic and pericholedochal nodes. From these, the primary drainage areas are the retroportal and pancreaticoduodenal notes. Progressing from these lower portal areas, the lymphatics course to the celiac, superior mesenteric, and finally to aortocaval notes. Involvement of these more distant lymph node stations portends a poor prognosis. Suspicious lymph nodes outside the portal region seen on imaging can be sampled preoperatively by EUS or they should be explored intraoperatively before resection.[48] The gallbladder wall is thin, contains a narrow lamina propria, and is only a single muscular layer with no serosal covering between it and the liver. Thereby, gallbladder malignancies can invade the liver early in their progression. In addition, because the venous drainage of the gallbladder includes direct venous tributaries into the liver parenchyma, these tumors may spread directly into segment IV of the liver. Transperitoneal spread is also common and can progress to carcinomatosis.

Clinical Presentation

Because 90% of gallbladder cancers originate in the fundus or body of the gallbladder, most do not produce symptoms until the disease is advanced (Fig. 88.42). Most gallbladder carcinomas have systemic disease at the time of presentation, with grossly enlarged lymph nodes and/or visible distant metastases in over 50%. Symptoms of acute cholecystitis, with obstruction of the neck of the gallbladder, may portend a better prognosis because patients with these symptoms may present with earlier stages of disease. Some patients describe symptoms of chronic cholecystitis in which the pain has recently changed in quality or frequency. Presentation with jaundice can be difficult to distinguish from hilar cholangiocarcinoma and is a powerful negative prognostic

TABLE 88.1 **AJCC Staging Systems for Biliary Tract Cancers**[47]

	GALLBLADDER CANCER	INTRAHEPATIC CHOLANGIOCARCINOMA	PROXIMAL/HILAR CHOLANGIOCARCINOMA	DISTAL CHOLANGIOCARCINOMA
TX	Primary tumor cannot be assessed			
T0	No evidence of primary tumor			
Tis	Carcinoma in situ			
T1	Tumor invades the lamina propria or muscular layer	Solitary tumor without vascular invasion, $\leq$5 cm or $>$5 cm	Tumor confined to the bile duct, with extension up to the muscle layer or fibrous tissue	Tumor invades the bile duct wall with a depth $<$5 mm
T1a	Tumor invades the lamina propria	Solitary tumor $\leq$5 cm without vascular invasion		
T1b	Tumor invades the muscular layer	Solitary tumor $>$5 cm without vascular invasion		
T2	Tumor invades the perimuscular connective tissue	Solitary tumor with intrahepatic vascular invasion or multiple tumors, with or without vascular invasion	Tumor invades beyond the wall of the bile duct to surrounding adipose tissue, or tumor invades adjacent hepatic parenchyma	Tumor invades the bile duct wall with a depth of 5–12 mm
T2a	Tumor invades the perimuscular connective tissue on the peritoneal side without involvement of the visceral peritoneum		Tumor invades beyond the wall of the bile duct to surrounding adipose tissue	
T2b	Tumor invades the perimuscular connective tissue on the hepatic side with no extension into the liver		Tumor invades adjacent hepatic parenchyma	
T3	Tumor perforates the visceral peritoneum and/or directly invades the liver and/or one other adjacent organ or structure	Tumor perforating the visceral peritoneum	Tumor invades unilateral branches of the portal vein or hepatic artery	Tumor invades the bile duct wall with a depth $>$12 mm
T4	Tumor invades the main portal vein or hepatic artery or invades two or more extrahepatic organs or structures			
NX	Regional lymph nodes cannot be assessed			
N0	No regional lymph node metastasis			
N1	Metastases to one to three regional lymph nodes	Regional lymph node metastasis present	One to three positive lymph regional nodes	Metastasis in one to three regional lymph nodes
N2	Metastases to four or more regional lymph nodes		Four or more positive regional lymph nodes	Metastasis in four or more regional lymph nodes
M0	No distant metastasis			
M1	Distant metastasis

factor. Weight loss, abdominal mass, and ascites are associated with later stages of disease.

Diagnosis

Laboratory examination generally is not helpful except to identify signs of advanced disease, such as anemia, hypoalbuminemia, leukocytosis, and elevated ALP or bilirubin levels. Carcinoembryonic antigen and CA 19-9 may be elevated in gallbladder cancer.

Ultrasonography is generally the first examination used in the evaluation of right upper quadrant pain. Ultrasonographic findings of gallbladder cancer include an irregularly shaped lesion in the subhepatic space, heterogeneous mass in the gallbladder lumen, and asymmetrically thickened gallbladder wall (Fig. 88.43). The finding of a polyp larger than 10 mm should also raise the suspicion of gallbladder cancer.

Cross-sectional imaging with CT or MRI is an important part of the preoperative assessment of gallbladder cancer and can provide critical information on the local extent of disease and whether distant metastases are present. CT and MRI may demonstrate peritoneal metastases, hepatic parenchymal metastases, lymphadenopathy, and adjacent vascular involvement (Fig. 88.44). Invasive diagnostic cholangiography has largely been replaced by MRI cholangiography in most high-volume centers. PET can also be a valuable adjunct in searching for metastatic disease or when CT or MRI provides limited information about the primary tumor.

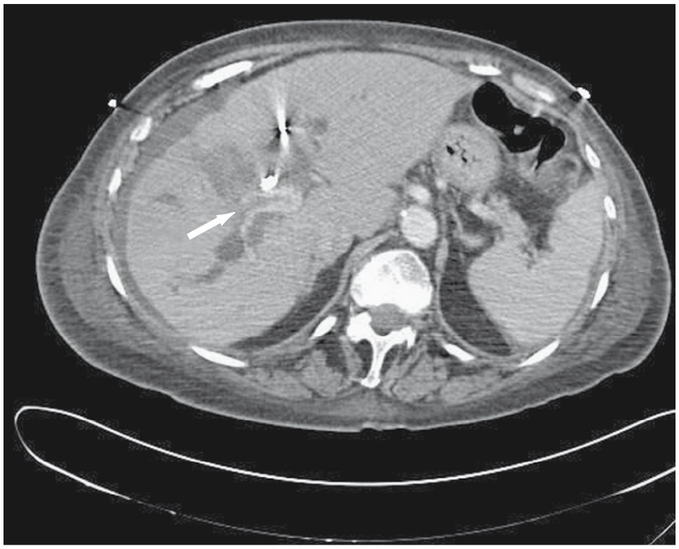

FIGURE 88.44 Computed tomography scan showing gallbladder mass with local invasion into portal vein *(arrow)*.

Gallbladder cancer has a tendency to seed biopsy tracts, and unnecessary biopsies simply increase this risk. If the diagnosis is suspected, the surgeon and patient must be prepared for a definitive operation. In the setting of unresectability (vascular encasement or extensive hepatic involvement) or incurability (hepatic or peritoneal metastases), a biopsy for confirmatory tissue diagnosis should be performed.

Treatment

Resection of gallbladder cancer remains the only potential for cure. Patients with gallbladder cancer can be divided into three specific subgroups of presentation: patients with an incidental finding of gallbladder cancer at the time of or after cholecystectomy, patients suspected of having gallbladder cancer preoperatively, and patients with advanced disease at presentation.

Gallbladder Cancer After Cholecystectomy

With the finding of carcinoma after cholecystectomy, subsequent treatment depends on depth of penetration of the gallbladder wall and surgical margins. With T1a lesions, in which the carcinoma penetrates the lamina propria but does not invade the muscle layer, cholecystectomy suffices for therapy. The likelihood of nodal disease in this setting is less than 3% and cholecystectomy cures 85% to 100% of patients. The cystic duct margin should be reviewed to ensure a negative margin, and sometimes, it is necessary to resect the CBD to obtain a negative margin. For T1b lesions, which penetrate the muscularis but not the deeper connective tissue or serosa, the likelihood of residual liver bed and/or nodal disease begins to increase significantly. Therefore, extended cholecystectomy is generally recommended for all patients who are medically fit with T1b or greater level of invasion but remains controversial.[48] Although re-resection has been associated with improved survival, patients with residual disease have such a poor prognosis that some surgeons regard it more as a staging than a therapeutic procedure.[49]

The extended cholecystectomy is directed at obtaining an R0 resection of the disease, including the draining lymph node basins. Therefore, removal of the hepatoduodenal, gastrohepatic, and retroduodenal lymph nodes should be included. Resection of the cystic duct margin to uninvolved mucosa may require resection of the CBD with Roux-en-Y reconstruction. Because local extension into the hepatic parenchyma is common, approximately 2 cm of apparently normal hepatic parenchyma from the gallbladder fossa is resected. As port site recurrences have been reported for patients with even early-stage disease, some surgeons previously recommended port site excision. However, port site recurrences rarely occur in isolation and generally represent aggressive disease. Port site resection has not been associated with improved survival and is no longer recommended as a routine practice. In patients with T2 lesions, in which the cancer extends past the muscularis but not beyond the serosa, a similar approach with radical cholecystectomy is indicated because more than 40% of these patients have lymph node metastases and up to 25% have positive margins when treated with standard cholecystectomy alone. Patients suspected of having gallbladder cancer preoperatively

Patients in whom preoperative evaluation suggests possibly resectable gallbladder cancer without metastatic disease should be offered an attempt at resection, even though survival is poor compared with those found incidentally. These patients tend to present with advanced locoregional disease and may require an extended liver resection. Because surgical intervention provides the only potential for cure or prolongation of life, radical resection should be considered for adequate operative candidates. The operation begins with a staging laparoscopy to identify small-volume peritoneal or hepatic metastases that would preclude a resection, thereby avoiding an unnecessary laparotomy. Staging laparoscopy should be considered in all patients due to its high yield, even for patients with suspected early stage disease (>10%), but especially for patients with suspected locally advanced disease (>25%).[50]

In the setting of metastatic disease, nonoperative strategies should be used to palliate symptoms. Radical resection in the setting of T3 and T4 lesions includes at least segments IVB and V but more often requires a central hepatectomy, including all of segments IV, V, and VIII. To achieve R0 margin status in large tumors, a right trisegmentectomy may be required. Direct extension of tumor into adjacent structures, such as the hepatic flexure, is not a contraindication to resection as long as negative margins can be obtained. Debulking without the possibility of complete resection has no role in the management of gallbladder cancer.

Patients With Advanced Disease at Presentation

Many patients with gallbladder cancer will present with advanced, incurable disease. The goal of therapy should be palliation of common symptoms, which include jaundice, pain, and intestinal obstruction. Jaundice can be managed by endoscopic biliary stenting, and self-expanding endobiliary metal stents can provide a durable solution, with less need for repeated interventions than with plastic stents. Pain is generally treated with oral narcotics but may progress to require parenteral opioids in the hospice setting. Percutaneous neurolysis of the celiac ganglion can help with the palliation of pain. Intestinal obstruction is usually gastric outlet obstruction from local extension of tumor and is generally managed by an endoscopic duodenal wall stent. In 2010, the landmark ABC-02 study established the combination of gemcitabine and cisplatin as standard of care for systemic therapy of advanced biliary cancer, including gallbladder cancer.[51] The survival benefit of chemotherapy is relatively less for gallbladder cancer than for cholangiocarcinoma, and molecular profiling also demonstrates fewer actionable mutations for targeted therapy in gallbladder cancer than in cholangiocarcinoma (see the following section).

Adjuvant Therapy

The majority of gallbladder cancer recurrences include distant sites as part of the recurrence pattern, highlighting the importance of systemic therapies. Several studies have attempted to extrapolate the benefit of gemcitabine-based chemotherapy from the metastatic setting to the adjuvant setting without success. The large BILCAP trial in 2019 was the first to demonstrate a significant survival benefit of capecitabine (oral 5-fluorouracil) in an adjuvant setting following resection of biliary cancers, including gallbladder cancer (T1b or higher).[52] Adjuvant capecitabine was therefore established as standard of care following complete (radical) resection of gallbladder cancer. However, the optimal sequencing of chemotherapy and radical re-resection in patients with incidentally identified gallbladder cancer remains controversial.

Survival

Survival of patients diagnosed with gallbladder cancer is dependent on the stage of disease at presentation and whether surgical resection is performed. Independent factors affecting survival include T status, N status, histologic differentiation, CBD involvement, and R0 resection. Advances in surgical management and extent of resection have led to improvements in survival in surgical patients, although most patients present with late-stage disease and are not candidates for resection. Patients with T1a lesions, limited to the mucosa and lamina propria, have an excellent prognosis. Complete resection of T1b lesions to negative margins also affords an excellent prognosis. Survival of patients with T2 lesions depends on nodal status and ability to achieve complete resection, with 5-year survival rates that range from 20% to more than 60%. The 5-year survival of patients with T3 tumors is less than 20%, and patients with T4 lesions or metastatic disease have a survival measured in months. Because most patients with gallbladder cancer present with advanced disease, the overall survival of gallbladder cancer is approximately 20%.

Bile Duct Cancer

Cholangiocarcinoma is a rare disease entity that carries a dismal prognosis. Cholangiocarcinoma can arise anywhere along the biliary tree and are best classified according to their anatomic location. Tumors arising beyond the second-order bile ducts within the liver are called intrahepatic or peripheral cholangiocarcinoma, whereas tumors involving the periampullary region are called distal cholangiocarcinoma. Tumors involving the extrahepatic proximal biliary tree near the bifurcation are referred to as proximal or hilar cholangiocarcinoma and as Klatskin tumors. The incidence of cholangiocarcinoma is rising worldwide, especially intrahepatic cholangiocarcinoma, which is the second most common primary cancer of the liver behind hepatocellular carcinoma. Some of this increase may be due to the previous misdiagnosis of intrahepatic cholangiocarcinoma as carcinoma of unknown primary.

Risk Factors

Although most patients with cholangiocarcinoma have no identifiable cause, the risk of development of cholangiocarcinoma appears to correlate with chronic inflammation in the biliary tree and compensatory cellular proliferation. Therefore, many predisposing disease states carry an increased risk for development of cholangiocarcinoma. Congenital lesions, such as choledochal cysts, predispose to the development of cholangiocarcinoma from exposure of the biliary epithelium to toxic pancreatic secretions (see earlier). Cholangiocarcinoma is more prevalent in Southeast Asia, where infection with the liver flukes *C. sinensis* and *Opisthorchis viverrini* creates chronic biliary inflammation, with obstructions and strictures. Recurrent pyogenic cholangitis is characterized by primary bile duct stone formation with infections and carries a risk of cholangiocarcinoma development. PSC, with its autoimmune multifocal strictures of the intrahepatic and extrahepatic biliary trees, also carries an increased risk of cholangiocarcinoma. PSC is the most common identified risk factor for cholangiocarcinoma in the West. PSC carries a cumulative annual risk for cholangiocarcinoma of 1.5% per year, and this risk is increased in those with associated inflammatory bowel disease. Although sporadic cases of cholangiocarcinoma tend to occur at the bifurcation, patients with PSC may have multifocal disease not amenable to resection. Medications and chemical carcinogens have been associated with the development of cholangiocarcinoma, including Thorotrast, oral contraceptives, asbestos, and cigarette smoke. Finally, cirrhosis, infection with hepatitis B and C, choledocholithiasis, and, to a lesser extent, diabetes mellitus are important risk factors for cholangiocarcinoma that may explain the rising incidence.[53]

Staging and Classification

The three distinct pathologic subtypes include nodular (or mass forming), sclerosing (or periductal infiltrating), and papillary cholangiocarcinoma. Intrahepatic cholangiocarcinoma is most commonly mass forming, and advanced tumors may develop satellite lesions. Most proximal (extrahepatic) cholangiocarcinomas are the sclerosing subtype causing periductal fibrosis in a concentric pattern and a circumferential duct occlusion. Both papillary and nodular subtypes occur in distal cholangiocarcinomas and are manifested with intraluminal growths. In the nodular subtype, a firm mass based in the duct wall can be seen growing into the duct lumen, whereas the more common papillary subtype appears as a polypoid lesion that is soft with less periductal fibrosis and a better prognosis.

The staging of cholangiocarcinoma relies on the TNM staging system but is slightly different based on anatomic location.[47] The three staging subdivisions include intrahepatic, proximal/hilar, and distal bile duct (see Table 88.1). Similar to many adenocarcinomas, direct local invasion and local lymph node spread are common and have a worse prognosis. Tumors confined to the bile duct (T1) and those extending outside the bile duct but not invading adjacent structures such as the hepatic artery or portal vein (T2) carry a significantly better prognosis than those invading any nearby structure. The two most important prognostic factors after resection are ability to achieve complete (R0) resection to negative margins and the presence or absence of lymph node metastases.

Clinical Presentation

The presentation of cholangiocarcinoma depends on the anatomic site of origin. Intrahepatic cholangiocarcinoma does not usually cause biliary obstruction and more typically presents with abdominal pain, weight loss, or as an incidental finding. Painless jaundice is a common symptom of proximal and distal cholangiocarcinoma, but patients with unilobar obstruction of a bile duct may present without jaundice but with unilateral lobar atrophy and subsequent contralateral lobar hypertrophy (Fig. 88.45). The resultant hepatic compensation can delay presentation until the later stages of disease. Therefore, cholangiocarcinoma causing obstruction at or below the hepatic bifurcation tends to be manifested at earlier stages than intrahepatic cholangiocarcinoma. The common manifestations of biliary obstruction and hyperbilirubinemia, such as pruritus, dark urine, and acholic stools, can be seen. Other markers of hepatic synthetic function, such as prothrombin time and albumin level, are generally unaffected until later in the disease or when the biliary obstruction is longstanding. Cholangiocarcinoma tends to extend in a submucosal route, with associated perineural invasion, but constant pain on presentation suggests more advanced disease.

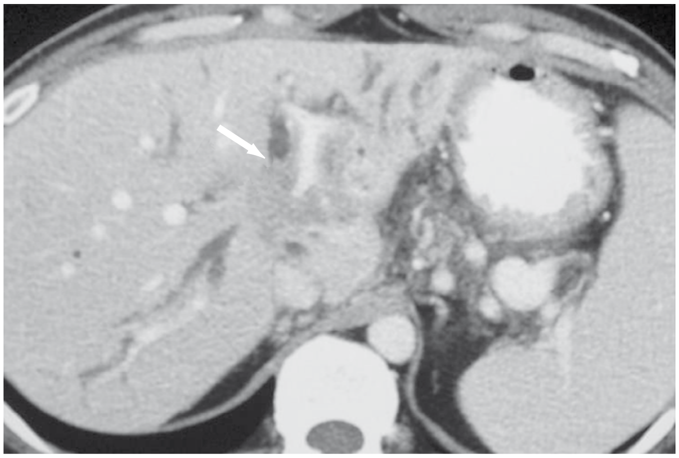

FIGURE 88.45 Computed tomography scan of cholangiocarcinoma with left lobar atrophy caused by obstruction of the left duct. Noted in the atrophied left lobe are dilated biliary radicals *(arrow)*.

Diagnosis and Assessment of Resectability

The radiologic evaluation of jaundice includes a right upper quadrant US examination, which may show intrahepatic biliary ductal dilation but does not usually identify the actual site of obstruction. With hilar cholangiocarcinomas, the gallbladder and visualized extrahepatic biliary tree are usually decompressed, whereas distal lesions will have extrahepatic biliary ductal dilation and gallbladder distention. For intrahepatic and extrahepatic cholangiocarcinoma, cross-sectional imaging by triphasic CT allows not only assessment of metastatic disease but also initial evaluation of resectability. The location of the tumor can be identified, and its relationship to vascular structures also can be assessed. Identification of aberrant anatomy and determination of segmental or lobar involvement by CT are helpful for preoperative planning. Tumor markers, including carcinoembryonic antigen and CA 19-9, are unreliable for diagnosis of cholangiocarcinoma but, if elevated, may be useful postoperatively in the surveillance of recurrence.

Typically, CT alone is insufficient for the assessment of feasibility and appropriateness of resection for proximal (perihilar) cholangiocarcinoma. Cholangiography by MRCP, PTC, or ERCP helps determine the proximal extent of resection. For patients who are potential candidates for resection, PTC with percutaneous biliary drainage has advantages over ERCP in its ability to easily target specific ducts, drain longer stenoses, and maintain access to the biliary tree for repeated intervention. Endoscopic cholangiography also carries the additional risk of cholangitis by the introduction of enteric bacteria into an undrained portion of

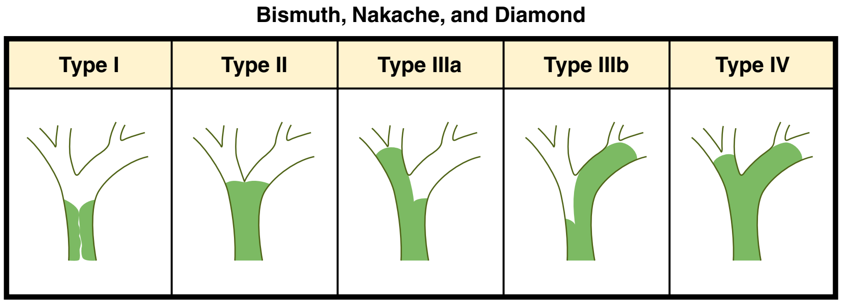

FIGURE 88.46 Bismuth-Corlette classification of tumor involvement.

the biliary tree but has obvious appeal over percutaneous drainage in the palliative setting. Bilobar intrahepatic metastases and any extrahepatic disease are contraindications to resection. Because complete (R0) resection is the only strategy that affords the possibility of cure, other contraindications to resection include encasement of the main portal vein (Fig. 88.46), bilateral hepatic lobar artery involvement, involvement of bilateral secondary biliary radicals, and lobar atrophy with involvement of the contralateral portal vein or biliary radicals. Involvement of unilobar vascular structures is managed with resection of the primary and affected lobe in continuity and therefore is not a contraindication.

Tissue diagnosis before resection in operative patients is unnecessary. With obstructive jaundice, bile cytology and brushings are unreliable, and a negative cytology report does not exclude malignant disease. Fluorescence in situ hybridization (FISH) for chromosomal polysomy increases the sensitivity of cytology and may be helpful in indeterminate lesions, but establishment of a tissue diagnosis is important only when the patient is not a candidate for resection. However, preoperative biliary drainage may be useful in select cases. In patients with distal cholangiocarcinoma, preoperative biliary drainage increases the rate of infectious complications of resection but is generally useful for those with preoperative hyperbilirubinemia (bilirubin level >10 mg/dL) and those with a prolonged time interval between presentation and resection. For patients with hilar cholangiocarcinoma, hepatic resection remains an important feature of the operative strategy. In the setting of complete biliary obstruction, hepatic resection carries an additional risk of bleeding, sepsis, and hepatic failure. Drainage of the obstructed but unaffected segments can enhance the postresection hypertrophy of the remaining liver but may increase perioperative infectious complications.

Patients with intrahepatic cholangiocarcinoma, in contrast, do not require cholangiography. Furthermore, a resectable solid liver mass in a noncirrhotic patient with no evidence of a primary malignancy outside of the liver does not require biopsy. However, preoperative biopsy and tumor markers (such as CA 19-9) can be useful in distinguishing intrahepatic cholangiocarcinoma from hepatocellular carcinoma and metastatic lesions, which are much more common than primary malignancies.

Treatment

Operative management. With the clinical suspicion of cholangiocarcinoma in adequate operative candidates without contraindications to resection, exploration should proceed, even in the absence of a confirmed tissue diagnosis. Up to 15% of patients undergoing resection for suspected biliary malignant disease will prove to have benign disease. More than 50% of patients undergoing exploration have historically had findings precluding resection, such as peritoneal metastases, hepatic metastases, or locally advanced lesions. With advances in the quality of preoperative imaging, this rate is decreasing. However, staging laparoscopy still can be an important initial step at the time of resection to reduce the incidence of nontherapeutic laparotomy.

Distal cholangiocarcinoma. Distal cholangiocarcinoma is managed by pancreaticoduodenectomy. Because these lesions tend to grow in a submucosal plane, a frozen section of the proximal bile duct margin helps ensure an R0 resection. An R0 resection remains one of the most important prognostic factors for this disease, with 5-year survival rates of up to 50% in node-negative patients with an R0 resection.

Proximal cholangiocarcinoma. Surgical management of proximal cholangiocarcinoma involves resection of regional nodal tissue and en bloc resection of the CBD with hepatic parenchyma as necessary to achieve negative margins. The Blumgart preoperative staging system incorporates the longitudinal involvement of biliary radicals (the Bismuth-Corlette classification) as well as extent of vascular involvement and hepatic lobar atrophy to help with operative planning and prognosis (see Fig. 88.46).[54] Small mid-duct tumors can sometimes be completely resected with common duct resection and cholecystectomy, but most proximal cholangiocarcinomas also require partial hepatic resection, which commonly includes resection of the caudate lobe. Resection of the bile duct and nodal tissue requires skeletonization of the hepatic artery and portal vein. Reconstruction is performed using a Roux limb of jejunum. More advanced tumors may involve complex resection and reconstruction of the portal vein, hepatic artery, or both. With resection to secondary biliary radicals, transanastomotic stenting may allow healing and confirmation of anastomotic integrity. Improvements in long-term survival over time have correlated with the increasing use of hepatic resection to achieve negative margins. Intraoperative assessment of margins by frozen section is important, as negative margin status is the most important variable associated with outcome after resection. Five-year survival rates greater than 50% have been reported in selected series, and, with vascular resection and reconstruction techniques, resectability rates have also increased. Although the importance of achieving an R0 resection is clear, the role of routine lymph node dissection is debated. There has been no demonstrable therapeutic benefit of routine lymph node dissection. However, lymph nodes are one of the most important prognostic factors in cholangiocarcinoma and may help direct adjuvant therapy.

With high rates of local unresectability and its frequent association with primary sclerosis cholangitis, liver transplantation has been explored for proximal cholangiocarcinoma since the 1980s. An extensive neoadjuvant therapy protocol that includes high-dose chemoradiation followed by transplantation has shown excellent results (>60% 5-year survival) in highly selected patients that have small (<3 cm) but unresectable tumors without evidence of lymph node metastases.[29] In spite of these findings, the role of transplantation in the management of cholangiocarcinoma remains controversial, and there is substantial debate over the routine use of an extremely limited resource in this disease process.

Intrahepatic cholangiocarcinoma. Intrahepatic cholangiocarcinoma is managed with partial hepatectomy with the goal of negative margins. Multifocal disease is common and associated with poor prognosis as are regional lymph node metastases. Preoperative evidence of multifocal disease and/or regional lymph node metastases should be considered contraindications to resection except in selected patients. With more effective systemic agents (see the following), there is increasing interest in neoadjuvant therapy for such high-risk patients. In patients that undergo resection, portal lymph node dissection (with goal of at least six lymph nodes) is recommended for adequate staging and may help guide the use of adjuvant therapy.[55]

Palliation. In patients found to have unresectable or incurable disease preoperatively, all attempts to palliate their symptoms nonoperatively should be used. The goals of palliation should include relief of jaundice, alleviation of pain, and relief of duodenal obstruction, if necessary. Surgical palliation has not been shown to prolong survival or to reduce complication rates and thus should be reserved for candidates found to be unresectable or metastatic at time of operation. Depending on the location of the biliary obstruction, endoscopic or percutaneous routes of drainage can be used, and placement of a self-expandable metallic stent provides a durable solution. When plastic stents are used, additional manipulation or placement of subsequent stents may be required. For distal cholangiocarcinomas, ERCP is the preferred route of nonoperative biliary drainage, whereas PTC is more useful for proximal lesions. Drainage of atrophic lobes with stents does not improve palliation of disease. Percutaneous destruction of the celiac plexus has demonstrated some benefit for pain relief. For distal cholangiocarcinomas, in which duodenal obstruction may occur, endoscopic duodenal stenting can relieve obstruction in this preterminal condition.

Medical treatment. As described earlier, the ABC-02 study established the combination of gemcitabine and cisplatin as standard of care for systemic therapy of advanced biliary cancer, with the greatest benefit seen in patients with intrahepatic cholangiocarcinoma. Cholangiocarcinoma has a high incidence of somatic genetic alterations, including isocitrate dehydrogenase (IDH) and fibroblast growth factor receptor (FGFR), which are considered actionable with associated targeted therapies. The high tumor mutational burden of cholangiocarcinoma likely explains its relative responsiveness to immunotherapy. In 2022, the TOPAZ-1 trial demonstrated a significant benefit of adding a programmed cell death ligand 1 (PD-L1) checkpoint inhibitor to gemcitabine and cisplatin for unselected patients with advanced biliary cancer, establishing checkpoint inhibition as part of first-line therapy.[56]

In the adjuvant setting, as described previously, the BILCAP trial established capecitabine (oral 5-fluorouracil) as the preferred agent following resection of biliary cancers.[52] Radiation therapy has not been proven in prospective randomized studies to affect survival in cholangiocarcinoma in any setting. However, some nonrandomized studies have suggested that adjuvant radiation may provide a small survival advantage as an adjunct to resection when microscopic residual disease remains, such as patients with R1 resections. Furthermore, radiation therapy is often used in the palliative setting, especially for proximal cholangiocarcinoma, since many patients will experience pain and other local symptoms from unresectable or recurrent tumors

Survival

Long-term survival is highly dependent on stage at presentation and complete surgical resection to negative margins. Most patients present with advanced disease that is not amenable to resection, but the anatomic location of cholangiocarcinoma greatly affects presentation and ability to achieve negative margins. Intrahepatic cholangiocarcinoma is more likely than extrahepatic cholangiocarcinoma to present with distant metastatic disease. Patients with intrahepatic and distal cholangiocarcinoma are more likely to undergo R0 resection than patients with proximal cholangiocarcinoma. Although postoperative morbidity rates of 35% to 50% are still common, mortality rates are generally low (<5%) in modern series. Five-year overall survival rates following resection of cholangiocarcinoma range from 20% to 50% in most series. Variability in overall survival appears to be the related to the incidences of lymph node metastases and R1 resections in various studies, which in turn are likely related to differences in patient selection and surgical technique. However, the landscape of systemic therapy for cholangiocarcinoma is changing so rapidly that these overall survival outcomes are moving targets that will certainly improve in the coming years.

HISTORICAL PERSPECTIVE

The surface anatomy of the liver was described as early as 2000 BCE by the ancient Babylonians. Even Hippocrates understood and described the seriousness of liver injury. In 1654, Francis Glisson was the first physician to describe the essential anatomy of the blood vessels of the liver accurately. The beginnings of liver surgery are described as rudimentary excisions of eviscerated liver from penetrating trauma. The first documented case of a partial hepatectomy is credited to Berta, who amputated a portion of protruding liver in a patient with a self-inflicted stab wound in 1716.

In the late 1800s, the first gastrectomies and cholecystectomies were being performed in Europe. At that time, surgery on the liver was regarded as dangerous, if not impossible. European surgeons began to experiment with techniques of elective liver surgery on animals in the late 1800s. The credit for the first elective liver resection is a matter of debate, and many surgeons have been given credit, but it certainly occurred during this period.

The early 1900s saw some small but significant advances in liver surgery. Techniques for suturing major hepatic vessels and using cautery for small vessels were applied and reported. The most significant advance of that time was probably that of J. Hogarth Pringle. In 1908, he described digital compression of the hilar vessels to control hepatic bleeding from traumatic injuries. The modern era of hepatic surgery was ushered in by the development of a better understanding of liver anatomy and formal anatomic liver resection. Credit for the first anatomic liver resection is usually given to Lortat-Jacob, who performed a right hepatectomy in 1952 in France. Pack from New York and Quattelbaum from Georgia performed similar operations within the next year and were unlikely to have had any knowledge of Lortat-Jacob's report. Descriptions of the segmental nature of liver anatomy by Couinaud, Goldsmith, and Woodburne in 1957 opened the door even wider and introduced the modern era of liver surgery.

Despite these improvements, hepatic surgery was plagued by tremendous operative morbidity and mortality from the 1950s into the 1980s. Operative mortality rates over 20% were common and usually related to massive hemorrhage. Many surgeons were reluctant to perform hepatic surgery because of these results, and understandably, many physicians were reluctant to refer patients for hepatectomy. With the courage of patients and their families, as well as the persistence of surgeons, safe hepatic surgery has now been realized. A complete list is not possible here, but courageous hepatic surgeons such as Blumgart, Bismuth, Longmire, Fortner, Schwartz, Starzl, and Ton deserve mention.

Advances in anesthesia, intensive care, antibiotics, and interventional radiologic techniques have also contributed tremendously to the safety of major hepatic surgery. Total hepatectomy with liver transplantation and live donor partial hepatectomy for transplantation are now performed routinely in specialized transplantation centers. Partial hepatectomy for many indications is now performed throughout the world in specialized centers, with mortality rates of 5% or less. Partial hepatectomy on normal livers is now consistently performed, with mortality rates of 1% to 2%.

Safely performed open hepatic surgery, with its liberal use in the management of a wide variety of diseases, is now a reality. Moreover, minimally invasive approaches to liver surgery have been developed and are now being used in significant numbers. However, the learning curve remains steep, and the indications for this technique are being carefully defined. Using robotics in liver surgery may help address the issues with the learning curve with laparoscopy. The addition of robotics offers advanced suturing and articulation that closely approximate open surgery. This allows a greater proportion of cases to be performed in a total, minimally invasive fashion.[1] The role of robotics in liver surgery is rapidly evolving. Thermal ablative techniques to treat hepatic tumors, including radiofrequency and microwave ablation, have exploded in popularity. Finally, techniques to improve the safety of liver resection, such as portal vein embolization to induce preoperative hypertrophy of the future liver remnant (FLR), are being developed and used.

ANATOMY AND PHYSIOLOGY

Anatomy

Gross Anatomy

Precise knowledge of the liver anatomy is a prerequisite to performing surgery on the liver or biliary tree. Over the last several decades, a greater appreciation for complex anatomy beyond the misleading minimal external markings has been realized. The anatomic contributions of Couinaud (see later) and the description of the segmental nature of the liver should be embraced and studied by students of hepatic surgery.

General description and topography. The liver is a solid gastrointestinal organ whose mass (1.2–1.6 kg) largely occupies the right upper quadrant of the abdomen. The costal margin coincides with the lower margin of the liver, and the diaphragm drapes over its superior surface. The thoracic cage covers most of the right and left liver. The posterior surface straddles the inferior vena cava (IVC). A wedge of the liver extends to the left of the abdomen. The liver is invested in the peritoneum except for the gallbladder fossa, porta hepatis, and posterior aspect of the liver on either side of the IVC in two wedge-shaped areas. This region of the liver to the right of the IVC, devoid of peritoneal coverage, is called the *bare area.* The peritoneal duplications on the liver surface are referred to as *ligaments*. The diaphragmatic peritoneal duplications are referred to as the *coronary ligaments,* whose lateral margins are the right and left triangular ligaments on either side. From the center of the coronary ligament emerges the falciform ligament, which extends anteriorly as a thin membrane connecting the liver surface to the diaphragm, abdominal wall, and umbilicus.

The ligamentum teres (the obliterated umbilical vein) runs along the inferior edge of the falciform ligament from the umbilicus to the umbilical fissure. The umbilical fissure is on the inferior surface of the left liver and contains the left portal pedicle. In early descriptions of hepatic anatomy, the falciform ligament, the most apparent surface marker of the liver, was used as the division of the right and left lobes of the liver. However, this description is inaccurate and not useful to the hepatobiliary surgeon (see later for detailed segmental anatomy). On the posterior surface of the left liver, running from the left portal vein in the porta hepatis toward the left hepatic vein and the IVC, is the ligamentum venosum (obliterated sinus venosus) that also runs in a fissure (Fig. 89.1). Hepatic arterial blood and portal venous blood enter the liver at the hilum and branch throughout the liver as a single portal pedicle unit, which also includes a bile duct. These portal triads are invested in a peritoneal sheath that invaginates at the

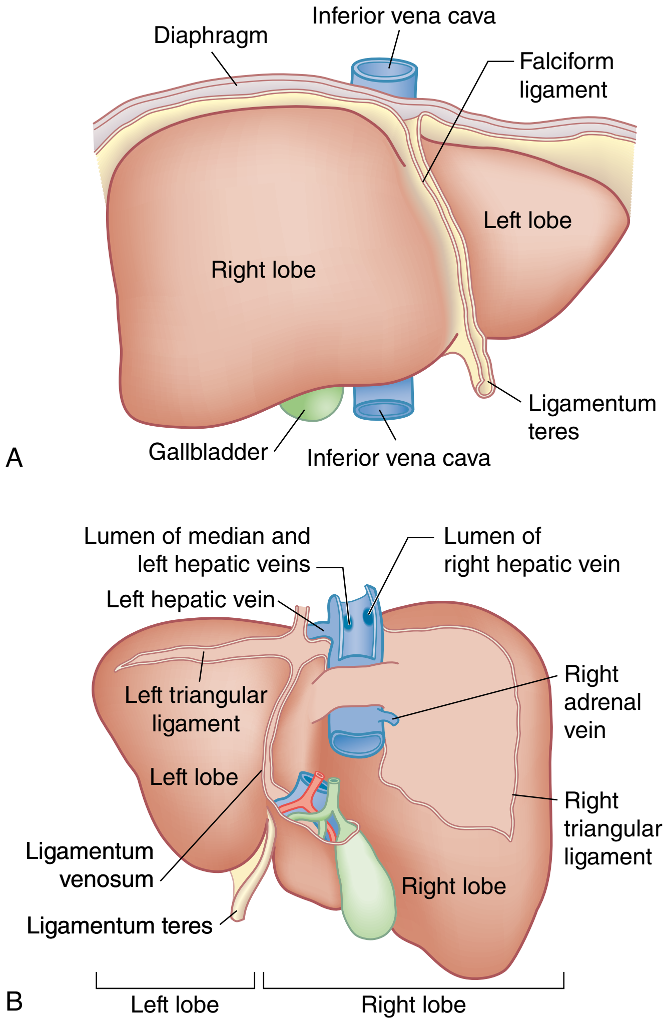

FIGURE 89.1 (A) Historically, the liver was divided into right and left lobes by the external marking of the falciform ligament. On the inferior surface of the falciform ligament, the ligamentum teres can be seen entering the umbilical fissure. (B) The posterior and inferior surface of the liver is shown. The liver embraces the inferior vena cava (IVC) posteriorly in a groove. The lumens of the three major hepatic veins and right adrenal vein can be seen directly entering the IVC. The bare area, bounded by the right and left triangular ligaments, is illustrated. To the left of the IVC is the caudate lobe, which is bounded on its left side by a fissure containing the ligamentum venosum. The lesser omentum terminates along the edge of the ligamentum venosum, and thus, the caudate lobe lies within the lesser sac and the rest of the liver lies in the supracolic compartment. A layer of fibrous tissue can be seen bridging the right lobe to the caudate lobe posterior to the IVC, thus encircling it. This ligament of tissue must be divided on the right side in mobilizing the right liver off the IVC. (From Blumgart LH, Hann LE. Surgical and radiologic anatomy of the liver and biliary tract. In: Blumgart LH, Fong Y, eds. *Surgery of the Liver and Biliary Tract.* London: WB Saunders; 2000:3-34.)

hepatic hilum. Venous drainage is through the right, middle, and left hepatic veins that empty directly into the suprahepatic IVC.

Normal development and embryology. The developing liver shares a common progenitor with the biliary tree and pancreas. During embryogenesis, signals are transmitted from the cardiac mesenchyme and septum transversum. The molecules regulating this (e.g., fibroblast growth factor, bone morphogenetic protein, Wnt, transforming growth factor-β) are being elucidated. The liver primordium begins to form in the third week of development as an outgrowth of endodermal epithelium, known as the *hepatic diverticulum* or *liver bud.* The connection between the hepatic diverticulum and the future duodenum narrows to form the bile duct, and an outpouching of the bile duct forms into the gallbladder and cystic duct. Hepatic cells develop cords and intermingle with the vitelline and umbilical veins to form hepatic sinusoids. Simultaneously, hematopoietic cells, Kupffer cells, and connective tissue form from the mesoderm of the septum transversum that connects the liver to the ventral abdominal wall and foregut. As the liver protrudes into the abdominal cavity, these structures are stretched into thin membranes, forming the falciform ligament and lesser omentum. The mesoderm on the surface of the developing liver differentiates into visceral peritoneum, except superiorly, where contact between the liver and mesoderm (future diaphragm) is maintained, forming a bare area devoid of visceral peritoneum (Fig. 89.2).

The primitive liver plays a central role in fetal circulation. The vitelline veins carry blood from the yolk sac to the sinus venosus, forming a network of veins around the foregut (future duodenum) that drain into the developing hepatic sinusoids. These vitelline veins eventually fuse to form the portal, superior mesenteric, and splenic veins. The sinus venosus empties into the fetal heart and becomes the hepatocardiac channel and then the hepatic veins and retrohepatic IVC. The umbilical veins, paired early on, carry oxygenated blood to the fetus. Initially, the umbilical veins drain into the sinus venosus, but at week 5 of development, they drain into the hepatic sinusoids. The right umbilical vein ultimately disappears, and the left umbilical vein later drains directly into the hepatocardiac channel, bypassing the hepatic sinusoids through the ductus venosus. In the adult liver, the remnant of the left umbilical vein becomes the ligamentum teres, which runs in the falciform ligament into the umbilical fissure, and the remnant of the ductus venosus becomes the ligamentum venosum at the termination of the lesser omentum under the left liver (Fig. 89.3).

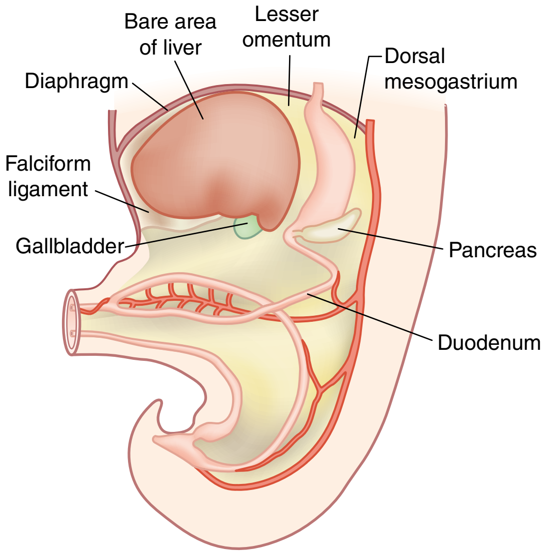

FIGURE 89.2 An approximately 36-day-old embryo is shown. The extensions of the septum transversum can be seen developing as the liver protrudes into the abdominal cavity, stretching out and forming the lesser omentum and the falciform ligament. The liver is completely invested in visceral peritoneum, except for a portion next to the diaphragm known as the bare area. (From Sadler TW. *Langman's Medical Embryology.* 5th ed. Baltimore: Williams & Wilkins; 1985.)

The adult liver is a complex system of numerous cell types, including hepatocytes, cholangiocytes, neuroendocrine cells, hepatic progenitors (oval cells), myofibroblastic mesenchymal cells (hepatic stellate cells and portal myofibroblasts), resident macrophages (Kupffer cells), and vascular endothelial cells.

Functional Anatomy

Historically, the liver was divided into left and right lobes by the obvious external landmark of the falciform ligament. Not only was this description oversimplified, but it was anatomically incorrect in relation to the blood supply to the liver. Our understanding of functional liver anatomy has become more sophisticated.

The functional anatomy of the liver (Figs. 89.4 and 89.5) is composed of eight segments, each supplied by a single portal triad (also called a *pedicle*) composed of a portal vein, hepatic artery, and bile duct. These segments are further organized into four sectors separated by scissurae containing the three main hepatic veins. The four sectors are even further organized into the right and left liver. The terms *right liver* and *left liver* are preferable to the terms *right lobe* and *left lobe* because there is no external mark that allows the identification of the right and left liver. This system was originally described in 1957 by Goldsmith and Woodburne and by Couinaud. It defines hepatic anatomy because it is most relevant to surgery of the liver. The functional anatomy is more often seen as cross-sectional imaging (Fig. 89.6).

The main scissura contains the middle hepatic vein, which runs in an anteroposterior direction from the gallbladder fossa to the left side of the vena cava. It divides the liver into right and left hemilivers. The line of the main scissura is also known as the *Cantlie line.* The right liver is divided into anterior (segments V and VIII) and posterior (segments VI and VII) sectors by the right scissura, which contains the right hepatic vein. The right portal pedicle is composed of the right hepatic artery, portal vein, and bile duct. It splits into right anterior and right posterior pedicles, which supply the segments of the anterior and posterior sectors.

The left liver has a visible fissure along its inferior surface called the *umbilical fissure.* The ligamentum teres, containing the remnant of the umbilical vein, runs into this fissure. The falciform ligament is contiguous with the umbilical fissure and ligamentum teres. The umbilical fissure is not a scissura and does not contain a hepatic vein; it contains the left portal pedicle, which contains the left portal vein, hepatic artery, and bile duct. This pedicle runs in this fissure and branches to feed the left liver. The left liver is split into anterior (segments III and IV) and posterior (segment II, the only sector composed of a single segment) sectors by the left scissura. The left scissura runs posterior to the ligamentum teres and contains the left hepatic vein.

At the hilum of the liver, the right portal triad has a short extrahepatic course of approximately 1 to 1.5 cm before entering the substance of the liver and branching into anterior and posterior sectoral branches. The left portal triad, however, has a long extrahepatic course of up to 3 to 4 cm and runs transversely along the

FIGURE 89.3 (A) Umbilical and vitelline vein development of a 5-week-old embryo. The hepatic sinusoids have developed, and although there are channels that bypass these sinusoids, the vitelline and umbilical veins are beginning to drain into them. (B) In the second month, the vitelline veins drain directly into the hepatic sinusoids. The ductus venosus has formed and accepts oxygenated blood from the left umbilical vein, bypasses the hepatic sinusoids, and directly enters the hepatocardiac channel. (C) By the third month, the vitelline veins have formed into the portal system (splenic, superior mesenteric, and portal veins). The right umbilical vein has disappeared, and the left umbilical vein (future ligamentum teres) drains into the sinus venosus, bypassing the hepatic sinusoids. Note the development of the inferior vena cava and hepatic veins. (From Sadler TW. *Langman's Medical Embryology*. 5th ed. Baltimore: Williams & Wilkins; 1985.)

FIGURE 89.4 Schematic depiction of the segmental anatomy of the liver. Each segment receives its own portal pedicle (triad of portal vein, hepatic artery, and bile duct). The eight segments are illustrated, and the four sectors, divided by the three main hepatic veins running in scissurae, are shown. The umbilical fissure (not a scissura) is shown to contain the left portal pedicle. (From Blumgart LH, Hann LE. Surgical and radiologic anatomy of the liver and biliary tract. In: Blumgart LH, Fong Y, eds. *Surgery of the Liver and Biliary Tract*. London: WB Saunders; 2000:3-34.)

base of segment IV in a peritoneal sheath, which is the upper end of the lesser omentum. This connective tissue is known as the *hilar plate* (Fig. 89.7). The continuation of the left portal triad runs anteriorly and caudally in the umbilical fissure and gives branches to segments II and III on the left and recurrent branches to segment IV on the right side.

The caudate lobe (segment I) is the dorsal portion of the liver. It embraces the IVC on its ventral surface and lies posterior to the left portal triad inferiorly and the left and middle hepatic veins superiorly. The main bulk of the caudate lobe is to the left of the IVC, but inferiorly it traverses between the IVC and left portal triad, where it fuses to the right liver (segments VI and VII). This part of the caudate lobe is known as the *right portion* or the *caudate process*. The left portion of the caudate lobe lies in the lesser omental bursa and is covered anteriorly by the gastrohepatic ligament (lesser omentum) that separates it from segments II and III anteriorly. The gastrohepatic ligament attaches to the ligamentum venosum (sinus venosus remnant) along the left side of the left portal triad (Fig. 89.8).

The vascular inflow and biliary drainage to the caudate lobe come from both the right and left pedicles. The caudate process largely derives its portal venous supply from the right portal vein or the bifurcation of the main portal vein. The left portion of the caudate derives its portal venous inflow from the left main portal vein. The arterial supply and biliary drainage are generally through the right posterior pedicle system for the right portion and through the left main pedicle for the left portion. The hepatic

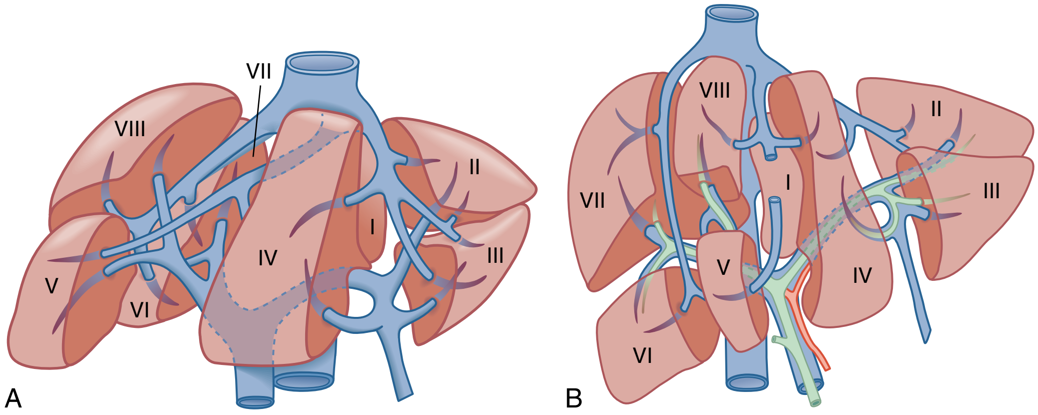

FIGURE 89.5 Segmental anatomy of the liver. (A) As seen at laparotomy in the anatomic position. (B) In the ex vivo position. (From Blumgart LH, Hann LE. Surgical and radiologic anatomy of the liver and biliary tract. In: Blumgart LH, Fong Y, eds. *Surgery of the Liver and Biliary Tract*. London: WB Saunders; 2000:3-34.)

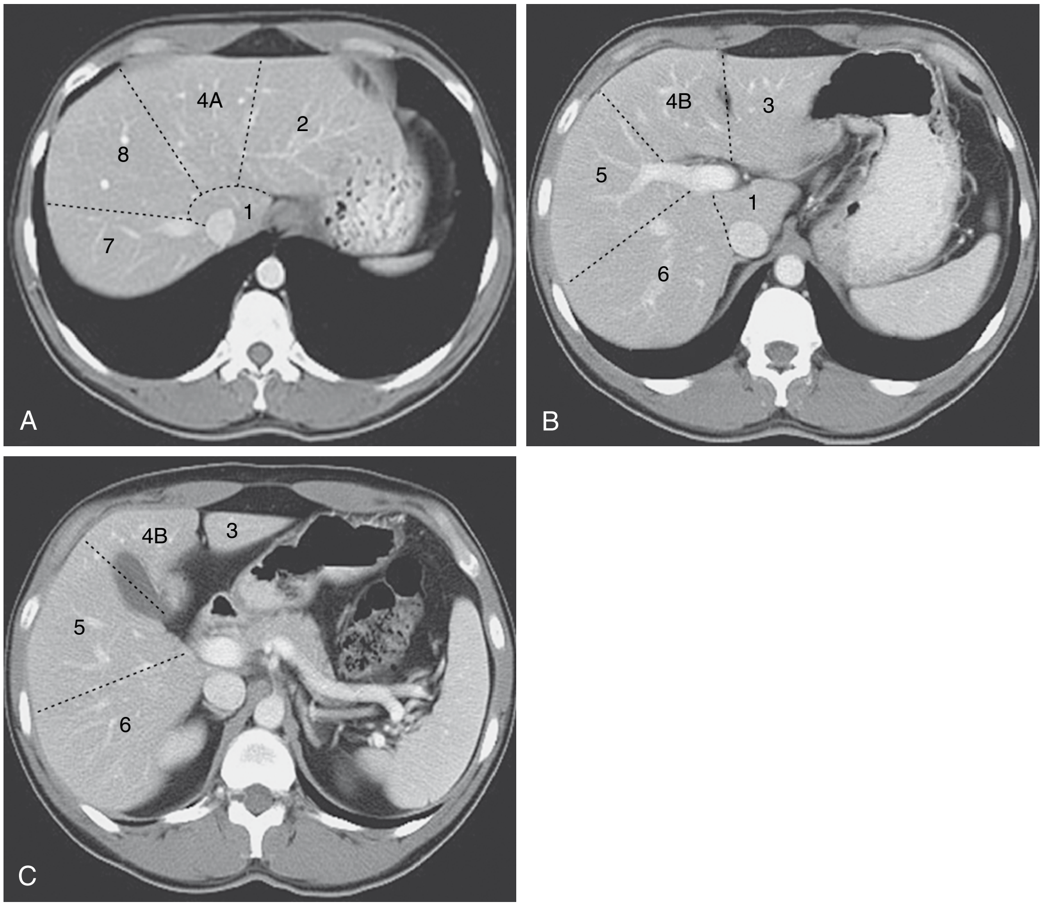

FIGURE 89.6 Segmental anatomy of the liver is demonstrated at three levels on contrast-enhanced computed tomography images. (A) At the level of the hepatic veins, the caudate lobe (segment 1) is seen posteriorly embracing the vena cava. Segment 2 is separated from segment 4A by the left hepatic vein. Segment 4A is separated from segment 8 by the middle hepatic vein, and segment 8 is separated from segment 7 by the right hepatic vein. (B) At the level of the portal vein bifurcation, segment 3 is visible as it hangs inferiorly in its anatomic position and is separated from segment 4B by the umbilical fissure. Note that segment 2 is not visible at this level. Terminal branches of the middle hepatic vein separate segment 4B from segment 5, and terminal branches of the right hepatic vein separate segment 5 from segment 6. Note that segments 4A, 8, and 7 are not visible at this level. Segment 1 is seen posterior to the portal vein and embracing the vena cava. (C) Below the portal bifurcation, one can see the inferior tips of segments 3 and 4B. The terminal branches of the middle hepatic vein and the gallbladder mark the separation of segment 4B from segment 5. Segments 5 and 6 are separated by the distal branches of the right hepatic vein. Note how the right liver hangs well inferior to the left liver.

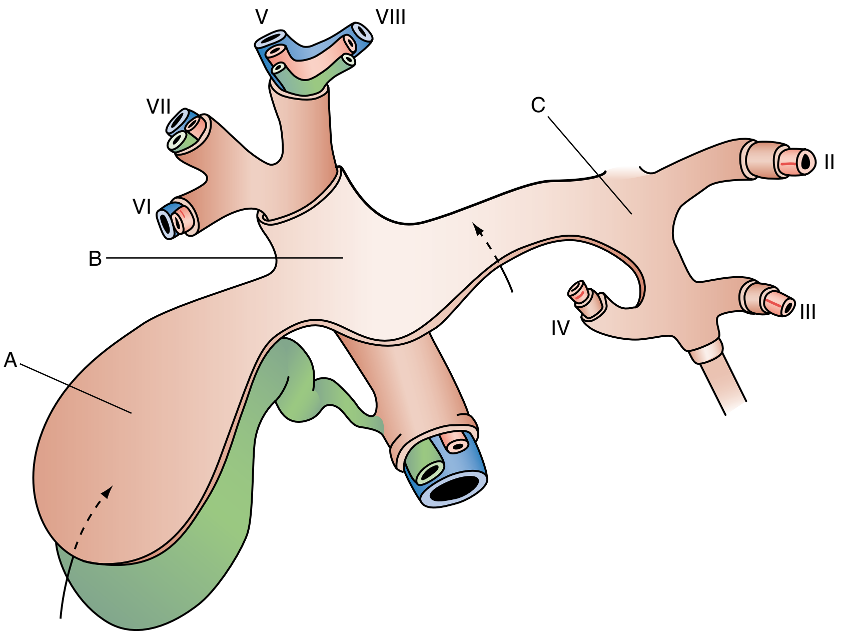

FIGURE 89.7 The plate system: The cystic plate between the gallbladder and liver *(A)*, the hilar plate at the biliary confluence at the base of segment IV *(B)*, and the umbilical plate above the umbilical portion of the portal vein *(C)*. Shown are the plane of dissection of the cystic plate for cholecystectomy and the hilar plate for exposure of the hepatic duct confluence and main left hepatic duct *(arrows)*. (From Blumgart LH, Hann LE. Surgical and radiologic anatomy of the liver and biliary tract. In: Blumgart LH, Fong Y, eds. *Surgery of the Liver and Biliary Tract*. London: WB Saunders; 2000:3-34.)

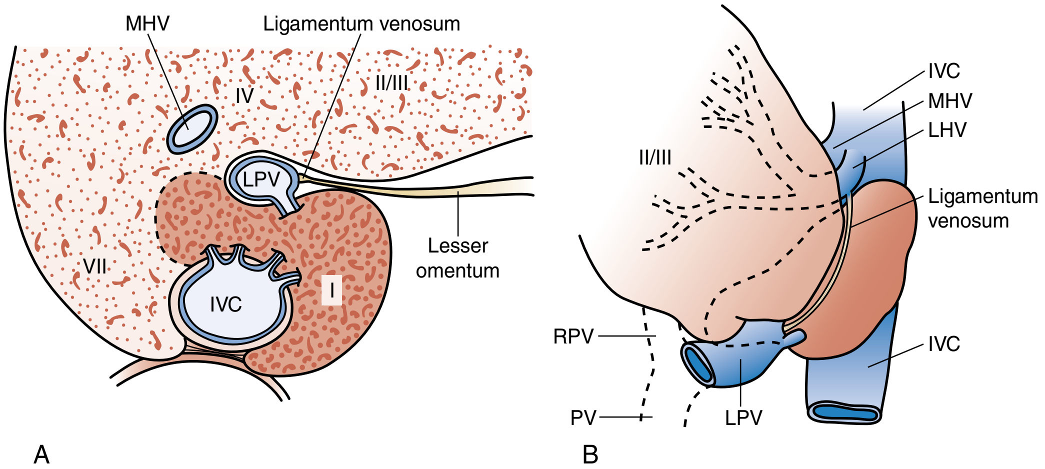

FIGURE 89.8 Anatomy of the caudate lobe (segment I). (A) Seen in cross-section, most of the caudate is to the left of the IVC and lies posterior to the lesser omentum, which separates the caudate from segments II and III. The termination of the lesser omentum at the ligamentum venosum is demonstrated. The caudate lobe traverses to the right, insinuating itself between the IVC and the LPV, where it attaches to the right liver. Note the proximity of the MHV to these structures. (B) Segments II and III have been rotated to the patient's right, exposing the left side of the caudate. *IVC,* Inferior vena cava; *LHV,* left hepatic vein; *MHV,* middle hepatic vein; *PV,* portal vein: *RPV,* right portal vein. (From Blumgart LH, Hann LE. Surgical and radiologic anatomy of the liver and biliary tract. In: Blumgart LH, Fong Y, eds. *Surgery of the Liver and Biliary Tract*. London: WB Saunders; 2000:3-34.)

venous drainage of the caudate is unique because several posterior small veins drain directly into the IVC.

The posterior edge of the left side of the caudate terminates as a fibrous component that attaches to the crura of the diaphragm and runs posteriorly, wrapping behind the IVC and attaching to segment VII of the right liver. In up to 50% of people, this fibrous component is composed partially or entirely of liver parenchyma. Thus, liver tissue may completely encircle the IVC. This structure is known as the *caval ligament* and is important to recognize in mobilizing the right liver or the caudate lobe off the vena cava.

Anomalous development of the liver is uncommonly encountered. Complete absence of the left liver has been reported. A tongue of tissue extending inferiorly off the right liver has been described (Riedel lobe). Rare cases of supradiaphragmatic liver in the absence of a hernia sac have been noted.

Portal vein. The portal vein provides approximately 75% of the hepatic blood inflow. Despite being postcapillary and largely deoxygenated, its high flow rate provides 50% to 70% of the liver's oxygen requirement. The lack of valves in the portal venous system provides a system that can accommodate high flow at low pressure. This also allows the measurement of portal venous pressure at any point along the system.

The portal vein forms behind the neck of the pancreas at the confluence of the superior mesenteric and splenic veins. The length of the main portal vein ranges from 5.5 to 8 cm, and its diameter is approximately 1 cm. Cephalad to its formation behind the neck of the pancreas, the portal vein runs behind the first portion of the duodenum and into the hepatoduodenal ligament, where it runs along the right border of the lesser omentum, usually posterior to the common bile duct and proper hepatic artery. The left gastric or coronary vein can variably drain into the portal vein, splenic vein, or the junction of the two.

The portal vein divides into main right and left branches at the hilum of the liver. The portal vein is the only vein with both tributaries and branches. The left branch of the portal vein runs transversely along the base of segment IV and into the umbilical fissure, where it gives off branches to segments II and III and feedback branches to segment IV. The left portal vein also gives off posterior branches to the left side of the caudate lobe. The right portal vein has a short extrahepatic course; it usually enters the substance of the liver, where it splits into anterior and posterior sectoral branches. These sectoral branches can occasionally be seen extrahepatically and can come off the main portal vein before its bifurcation. There is usually a small caudate process branch off the main right portal vein or at the right portal vein bifurcation that comes off posteriorly to supply this portion of liver (Fig. 89.9).

There are several connections between the portal and systemic venous systems. Under conditions of high portal venous pressure, these portosystemic connections may enlarge secondarily to collateral flow. This concept is reviewed in more detail later in the chapter, but the most significant portosystemic collateral locations are the following: the submucosal veins of the proximal stomach and distal esophagus receive portal flow from the short gastric veins and the left gastric vein and can result in varices, with the potential for hemorrhage; the umbilical and abdominal wall veins recanalize from flow through the umbilical vein in the ligamentum teres, resulting in caput medusae; the superior hemorrhoidal plexus receives portal flow from inferior mesenteric vein tributaries and can form large hemorrhoids; and other retroperitoneal communications yield collaterals that can make abdominal surgery hazardous.

The anatomy of the portal vein and its branches is relatively constant and has much less variation than the biliary ductal and hepatic arterial systems. The standard configuration, where main portal vein divides into the left and right branches and the right portal vein then divides into right anterior and right posterior portal vein, is found in up to 70% of individuals. The most common variant of this configuration is the so-called portal vein trifurcation where the main portal vein divides into three branches: the left portal vein, the right anterior portal vein, and the right posterior portal vein. The second most common variant is the right posterior portal vein, which originates as the first branch of the portal vein. This can also be envisioned as the right anterior portal vein arising from the left portal vein. These two variations account for most of the variations from the so-called normal anatomy. The portal vein is rarely found anterior to the neck of the pancreas and duodenum. Entrance of the portal vein directly into the vena cava has also been described. Very rarely, a pulmonary vein may enter the portal vein. Finally, there may be a congenital absence of the left branch of the portal vein. In this situation, the right branch courses through the right liver and curves around peripherally to supply the left liver, or the right anterior sectoral vein can arise from the left portal vein.

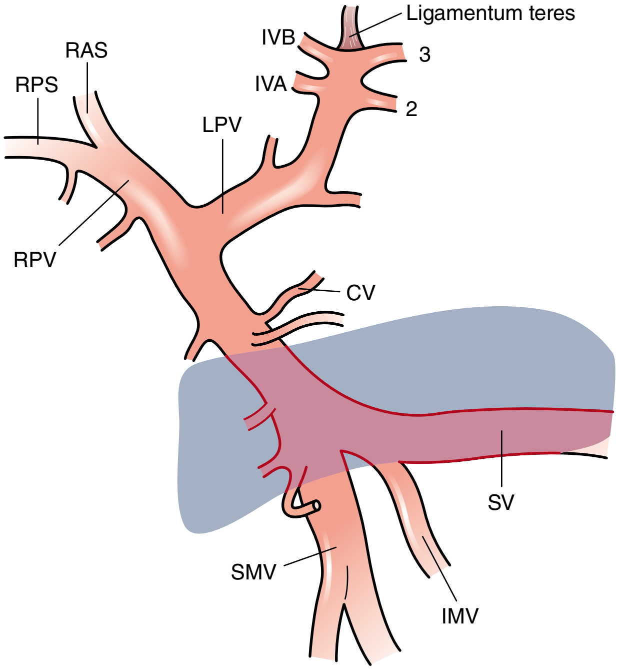

FIGURE 89.9 Anatomy of the portal vein. The superior mesenteric vein *(SMV)* joins the splenic vein *(SV)* posterior to the neck of the pancreas *(shaded area)* to form the portal vein. Note the entrance of the inferior mesenteric vein *(IMV)* into the splenic vein, the most common anatomic arrangement. In its course superiorly in the edge of the lesser omentum posterior to the common bile duct and hepatic artery, the portal vein receives venous effluent from the coronary vein *(CV)*. At the hepatic hilum, the portal vein bifurcates into a larger right portal vein *(RPV)* and a smaller left portal vein *(LPV)*. The LPV runs transversely at the base of segment IV and enters the umbilical fissure to supply the segments of the left liver. Just before the umbilical fissure, the LPV usually gives off a sizable branch to the caudate lobe. The RPV enters the substance of the liver and splits into right anterior sectoral *(RAS)* and right posterior sectoral *(RPS)* branches. It also gives off a posterior branch to the right side of the caudate lobe–caudate process. (From Blumgart LH, Hann LE. Surgical and radiologic anatomy of the liver and biliary tract. In: Blumgart LH, Fong Y, eds. *Surgery of the Liver and Biliary Tract*. London: WB Saunders; 2000:3-34.)

Hepatic artery. The hepatic artery, representing high-volume oxygenated systemic arterial flow, provides approximately 25% of the hepatic blood flow and 30% to 50% oxygenation. The common description of the arterial supply to the liver and biliary tree is present only approximately 60% of the time (Fig. 89.10). The celiac trunk originates directly off the aorta, just below the aortic diaphragmatic hiatus, and branches into the splenic artery, left gastric artery, and common hepatic artery. The common hepatic artery passes forward and to the right along the superior border of the pancreas. It runs along the right side of the lesser omentum, where it ascends toward the hepatic hilum, lying anterior to the portal vein and the left of the bile duct. At the point where the common hepatic artery begins to head superiorly toward the hepatic hilum, it gives off the gastroduodenal artery, followed by the supraduodenal artery and right gastric artery. The common

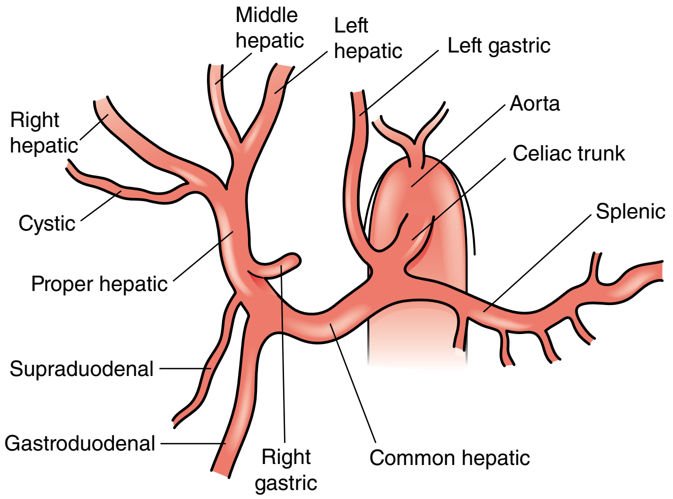

FIGURE 89.10 Most common anatomy of the celiac axis and hepatic arterial system. The celiac axis, just below the diaphragmatic hiatus, trifurcates into the splenic, left gastric, and common hepatic arteries. The common hepatic artery heads to the right and turns superiorly toward the hilum. At the point of this turn, the gastroduodenal artery is given off, and the proper hepatic artery is formed. The common hepatic artery gives off right and left hepatic arteries in the hilum. Note the middle hepatic artery off the proximal left hepatic artery, which goes on to supply segment IV. The cystic artery usually comes off the right hepatic artery within the triangle of Calot. (From Blumgart LH, Hann LE. Surgical and radiologic anatomy of the liver and biliary tract. In: Blumgart LH, Fong Y, eds. *Surgery of the Liver and Biliary Tract*. London: WB Saunders; 2000:3-34.)

hepatic artery beyond the takeoff of the gastroduodenal is called the *proper hepatic artery;* it divides into right and left hepatic arteries at the hilum. The left hepatic artery heads vertically toward the umbilical fissure to supply segments II, III, and IV. The left hepatic artery usually also gives off a middle hepatic artery branch that heads toward the right side of the umbilical fissure and supplies segment IV. The right hepatic artery usually runs posterior to the common hepatic bile duct and enters the Calot triangle, bordered by the cystic duct, common hepatic duct, and liver edge, where it gives off the cystic artery to supply the gallbladder and then continues into the substance of the right liver.

Unlike portal vein anatomy, hepatic arterial anatomy is extraordinarily variable (Fig. 89.11). An accessory vessel is described as an aberrant origin of a branch that is in addition to the normal branching pattern. A replaced vessel is described as an aberrant origin of a branch that substitutes for the lack of the normal branch. The hepatic artery usually originates off the celiac trunk. However, branches or the entire hepatic arterial system can originate off the superior mesenteric artery. The right and left hepatic arteries can also arise separately off the celiac axis. Replaced or accessory right hepatic arteries come off the superior mesenteric artery and are present approximately 11% to 21% of the time. Hepatic vessels replaced to the superior mesenteric artery run behind the head of the pancreas, posterior to the portal vein in the portacaval space. This is evident on cross-sectional imaging as well as during operative exploration by feeling hepatic artery pulsation in the lateral border of the hepatoduodenal ligament behind the portal vein and bile duct. The right hepatic artery, in its usual branching pattern, can also course anterior to the common hepatic duct. A replaced or accessory left hepatic artery is present approximately 3.8% to 10% of the time, originates from the left gastric artery, and courses within the lesser omentum, heading toward the umbilical fissure. Other important variations include the origin of the gastroduodenal artery, which originates from the right hepatic artery and is occasionally duplicated. The anatomy of the cystic artery is also variable; knowledge of these variations is of particular importance in the performance of cholecystectomy (Fig. 89.12). An accessory cystic artery can originate from the proper hepatic artery or gastroduodenal artery, where it runs anterior to the bile duct. A single cystic artery can originate anywhere off the proper hepatic artery or gastroduodenal artery or directly from the celiac axis. These variant cystic arteries can run anterior to the bile duct and are not necessarily present in the triangle of Calot. All these variations in hepatic arterial anatomy are of obvious importance during hepatic resection, hepatic arterial pump placement, cholecystectomy, and hepatic interventional radiologic procedures.

Hepatic veins. The three major hepatic veins drain from the superior-posterior surface of the liver directly into the IVC (see Figs. 89.4–89.6). The right hepatic vein runs in the right scissura between the anterior and posterior sectors of the right liver and drains most of the right liver after a short (1-cm) extrahepatic course into the right side of the IVC. The left and middle hepatic veins usually join intrahepatically and enter the left side of the IVC as a single vessel, although they may drain separately. The left hepatic vein runs in the left scissura between segments II and III and drains segments II and III; the middle hepatic vein runs in the portal scissura between segment IV and the anterior sector of the right liver, composed of segments V and VIII, and drains segment IV and some of the anterior sector of the right liver. The umbilical vein is an additional vein that runs under the falciform ligament, between the left and middle veins, and usually empties into the left hepatic vein. Several small posterior venous branches from the right posterior sector and caudate lobe drain directly into the IVC. A substantial inferiorly located accessory right hepatic vein is commonly encountered. There is also often a venous tributary from the caudate lobe that drains superiorly into the left hepatic vein.

Biliary system. The intrahepatic bile ducts are the terminal branches of the right and left hepatic ductal branches that invaginate the Glisson capsule at the hilum, along with their corresponding portal vein and hepatic artery branches, forming the peritoneal covered portal triads also known as *portal pedicles.* Along these intrahepatic portal pedicles, the bile duct branches are usually superior to the portal vein, whereas the hepatic artery branches run inferiorly. The left hepatic bile duct drains segments II, III, and IV, which constitute the left liver. The intrahepatic ductal branches of the left liver join to form the main left duct at the base of the umbilical fissure, where the left hepatic duct courses transversely across the base of segment IV to join the right hepatic duct at the hilum. In its transverse portion, the left hepatic duct drains one to three small branches from segment IV. The right hepatic duct drains the right liver and is formed by the joining of the anterior sectoral duct (draining segments V and VIII) and the posterior sectoral duct (draining segments VI and VII). The posterior sectoral duct runs in a horizontal and posterior direction; the anterior sectoral duct runs vertically. The main right hepatic duct bifurcates just above the right portal vein. The short right hepatic duct meets the longer left hepatic duct to form the confluence anterior to the right portal vein, constituting the common hepatic duct. The caudate lobe (segment I) has its own

FIGURE 89.11 Variable anatomy of the hepatic artery. The common hepatic artery can originate off the superior mesenteric artery instead of the celiac axis. A replaced or accessory right hepatic artery comes off the superior mesenteric artery and runs posterior to the head of the pancreas, to the right of the portal vein, and behind the common bile duct into the hilum. A replaced or accessory left hepatic artery originates off the left gastric artery and runs through the lesser omentum into the umbilical fissure. (From Netter FH. Netter Anatomy Collection. www.netterimages.com. Copyright Elsevier, Inc. All rights reserved.)

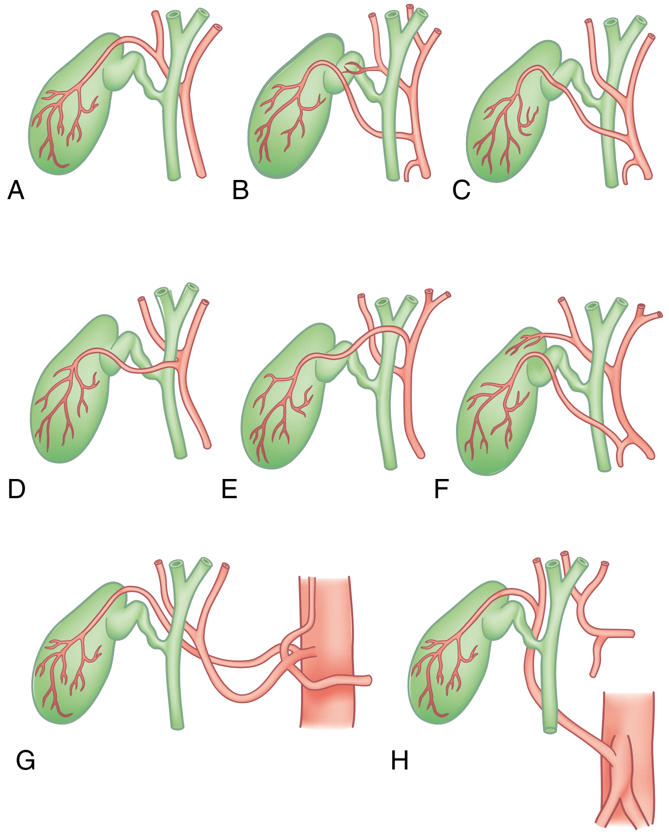

FIGURE 89.12 Variations in the anatomy of the cystic artery. (A) Most common anatomy. (B) Double cystic artery, one off the proper hepatic artery. (C) Origin off the proper hepatic artery and coursing anterior to the bile duct. (D) Originating off the right hepatic artery and coursing anterior to the bile duct. (E) Originating from the left hepatic artery and coursing anterior to the bile duct. (F) Originating off the gastroduodenal artery. (G) Originating off the celiac axis. (H) Originating from a replaced right hepatic artery. (From Blumgart LH, Hann LE. Surgical and radiologic anatomy of the liver and biliary tract. In: Blumgart LH, Fong Y, eds. *Surgery of the Liver and Biliary Tract.* London: WB Saunders; 2000:3-34.)

biliary drainage, which is usually through right and left systems. However, in up to 15% of individuals, drainage is through the left system only, and in 5%, it is through the right system only.

The common hepatic duct drains inferiorly. Below the takeoff of the cystic duct, it is referred to as the *common bile duct.* The common bile duct usually measures 10 to 15 cm in length and is typically 6 mm in diameter. The common hepatic (bile) duct runs along the right side of the hepatoduodenal ligament (free edge of the lesser omentum) to the right of the hepatic artery and anterior to the portal vein. The common bile duct continues inferiorly behind the first portion of the duodenum and into the head of the pancreas in an inferior and slightly rightward direction. The intrapancreatic distal common bile duct then joins with the main pancreatic duct (of Wirsung), with or without a common channel, and enters the second portion of the duodenum through the major papilla of Vater. At the choledochoduodenal junction, a complex muscular complex known as the *sphincter of Oddi* regulates bile flow and prevents reflux of duodenal contents into the biliary tree. There are three major parts to this sphincter: (1) the sphincter choledochus, a circular muscle that regulates bile flow and the filling of the gallbladder; (2) the pancreatic sphincter, present to variable degrees, which surrounds the intraduodenal pancreatic duct; and (3) the sphincter ampullae, made up of longitudinal muscle, which prevents duodenal reflux.

The gallbladder is a biliary reservoir that lies against the inferior surface of segments IV and V of the liver, usually making an impression against the liver. A peritoneal layer covers most of the gallbladder, except for the portion adherent to the liver. Here, the gallbladder adheres to the liver by a layer of fibroconnective tissue known as the *cystic plate,* an extension of the hilar plate (see Fig. 89.7). Variable in size but usually about 10 cm long and 3 to 5 cm wide, the gallbladder is composed of a fundus, body, infundibulum, and neck, which ultimately empty into the cystic duct. The fundus usually projects just slightly beyond the liver edge anteriorly; when it is folded on itself, it is described as a *phrygian cap.* Continuing toward the bile duct, the body of the gallbladder is usually close to the second portion of the duodenum and transverse colon. The infundibulum (or Hartmann pouch) hangs forward along the free edge of the lesser omentum and can fold in front of the cystic duct. The portion of gallbladder between the infundibulum and cystic duct is referred to as the *neck.* The cystic duct is variable in its length, course, and insertion into the main biliary tree. The first portion of the cystic duct is usually tortuous and contains mucosal duplications, referred to as the *folds of Heister,* which regulate the filling and emptying of the gallbladder. The cystic duct usually joins the common hepatic duct to form the common bile duct.

Knowledge of the multiple and frequent variations in the anatomy of the biliary tree is essential for performing hepatobiliary procedures. Anomalies of the hepatic ductal confluence are common and are present approximately one-third of the time. The most common anomalies involve variations in the insertion of the right sectoral ducts. Usually, this is the posterior sectoral duct. The confluence can be a trifurcation of the right anterior sectoral, right posterior sectoral, and left hepatic ducts. Either of the right sectoral ducts can drain into the left hepatic duct, the common hepatic duct, the cystic duct, or, rarely, the gallbladder (Fig. 89.13).

Anomalies of the gallbladder itself are rare. Agenesis of the gallbladder, bilobar gallbladder with two ducts or a single duct, septations, and congenital diverticulum of the gallbladder have been described. Anomalies of the position of the gallbladder are more common; these include an intrahepatic position and, rarely, location on the left side of the liver. The gallbladder can also have a long mesentery, which can predispose it to torsion.

The position and entry of the cystic duct into the main ductal system are also variable. Double cystic ducts draining a unilocular gallbladder and drainage into hepatic duct branches have been reported. The cystic duct usually joins the common hepatic duct at an angle, but it can run parallel and enter it more distally; in this situation, the cystic duct can be fused to the hepatic duct along its parallel course by connective tissue. The cystic duct can also run a spiral course anteriorly or posteriorly and enter the left side of the common hepatic duct. Finally, the cystic duct can be very short or even absent (Fig. 89.14).

The supraduodenal and infrahilar bile ducts are predominantly supplied by two axial vessels that run at 3-o'clock and 9-o'clock positions. These vessels are derived from the superior pancreaticoduodenal, right hepatic, cystic, gastroduodenal, and retroduodenal arteries. It has been estimated that only 2% of the arterial supply to this portion of the bile duct is segmental, arising directly from the proper hepatic artery. The bile duct and its bifurcation in the hilum derive their arterial blood supply from a rich network of multiple small branches from surrounding vessels. Similarly, the retropancreatic bile duct derives its arterial supply

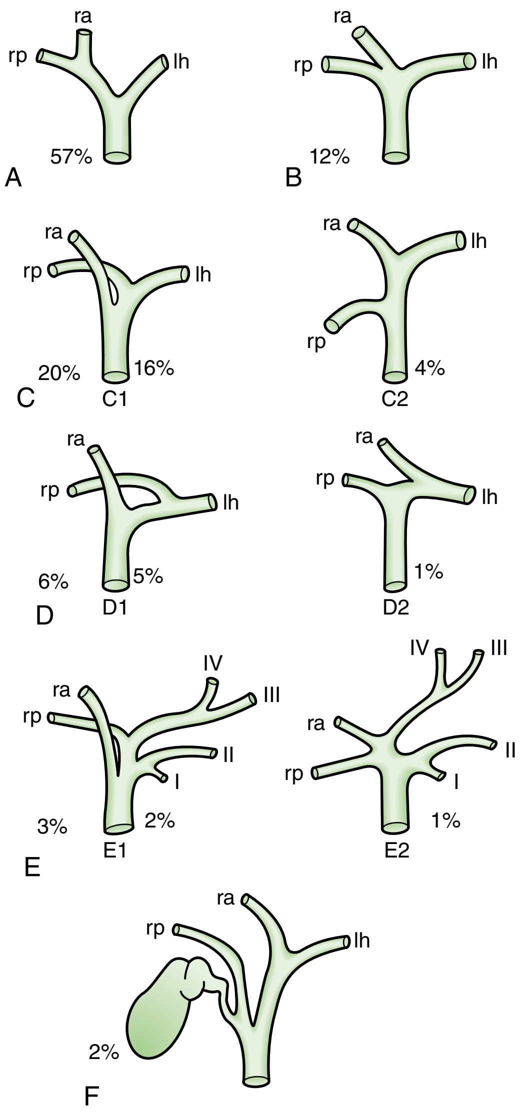

FIGURE 89.13 Variations of the hepatic duct confluence. (A) Most common anatomy. (B) Trifurcation at the confluence. (C) Either of the right sectoral ducts drains into the common hepatic duct. (D) Either of the right sectoral ducts drains into the left hepatic duct. (E) Absence of a hepatic duct confluence. (F) Absence of right hepatic duct and drainage of right posterior sectoral duct into the cystic duct. (From Blumgart LH, Hann LE. Surgical and radiologic anatomy of the liver and biliary tract. In: Blumgart LH, Fong Y, eds. *Surgery of the Liver and Biliary Tract*. London: WB Saunders; 2000:3-34.)

from the retroduodenal artery, which provides a rich network of multiple small branches (Fig. 89.15). Venous drainage of the bile duct parallels the arterial supply and drains into the portal venous system. The venous drainage of the gallbladder empties into the veins that drain the bile duct and does not flow directly into the portal vein.

Nerves. The innervation of the liver and biliary tract is through sympathetic fibers originating from T7–T10 as well as parasympathetic fibers from both vagal nerves. The sympathetic fibers pass through celiac ganglia before giving off postganglionic fibers to the liver and bile ducts. The right-sided celiac ganglia and right vagal nerve form an anterior hepatic plexus of nerves that runs along the hepatic artery. The left-sided celiac ganglia and left vagal nerve form a posterior hepatic plexus that runs posterior to the

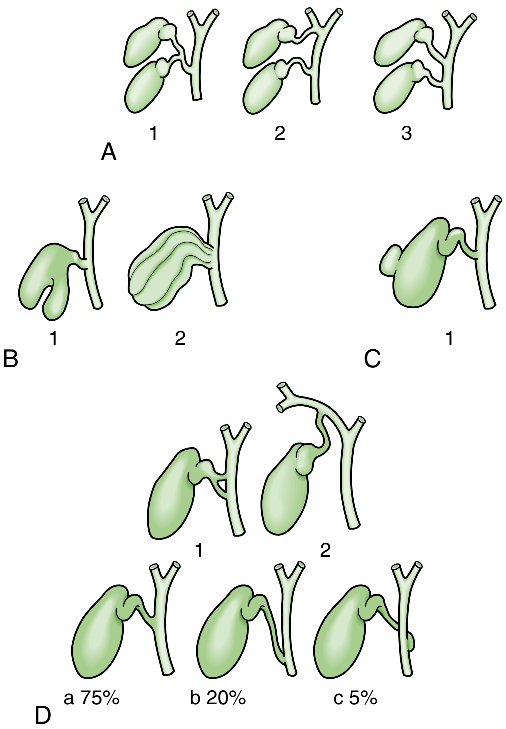

FIGURE 89.14 Variations in the anatomy of the gallbladder and cystic duct. (A) Bilobar gallbladder. (B) Septations of the gallbladder. (C) Diverticulum of the gallbladder. (D) Variations in cystic duct anatomy. The three types of union of the cystic duct and common hepatic duct are illustrated. (From Blumgart LH, Hann LE. Surgical and radiologic anatomy of the liver and biliary tract. In: Blumgart LH, Fong Y, eds. *Surgery of the Liver and Biliary Tract*. London: WB Saunders; 2000:3-34.)

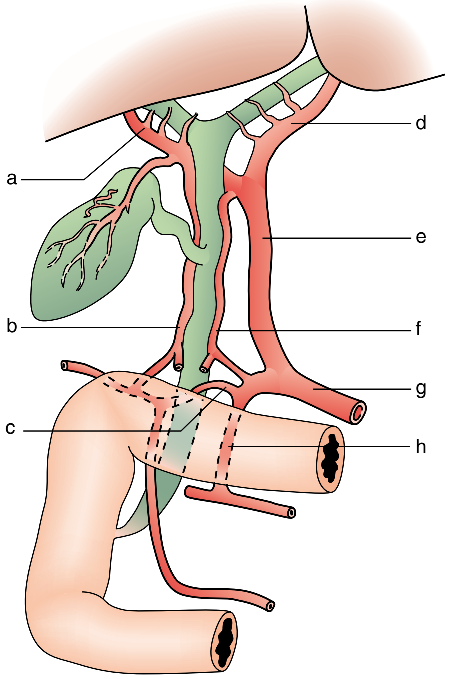

FIGURE 89.15 Blood supply to the common bile duct and common hepatic duct: right hepatic artery *(a)*; 9:00 artery *(b)*; retroduodenal artery *(c)*; left hepatic artery *(d)*; proper hepatic artery *(e)*; 3:00 artery *(f)*; common hepatic artery *(g)*; gastroduodenal artery *(h)*. (From Blumgart LH, Hann LE. Surgical and radiologic anatomy of the liver and biliary tract. In: Blumgart LH, Fong Y, eds. *Surgery of the Liver and Biliary Tract*. London: WB Saunders; 2000:3-34.)

bile duct and portal vein. The hepatic arteries are supplied by sympathetic fibers, whereas the gallbladder and extrahepatic bile ducts receive innervation from sympathetic and parasympathetic fibers. The clinical significance of these nerves is still not well understood. Acute distention of the liver, and thus the liver capsule, can result in right upper quadrant pain, which may be referred to the right shoulder through phrenic nerve innervation of the diaphragmatic peritoneum.

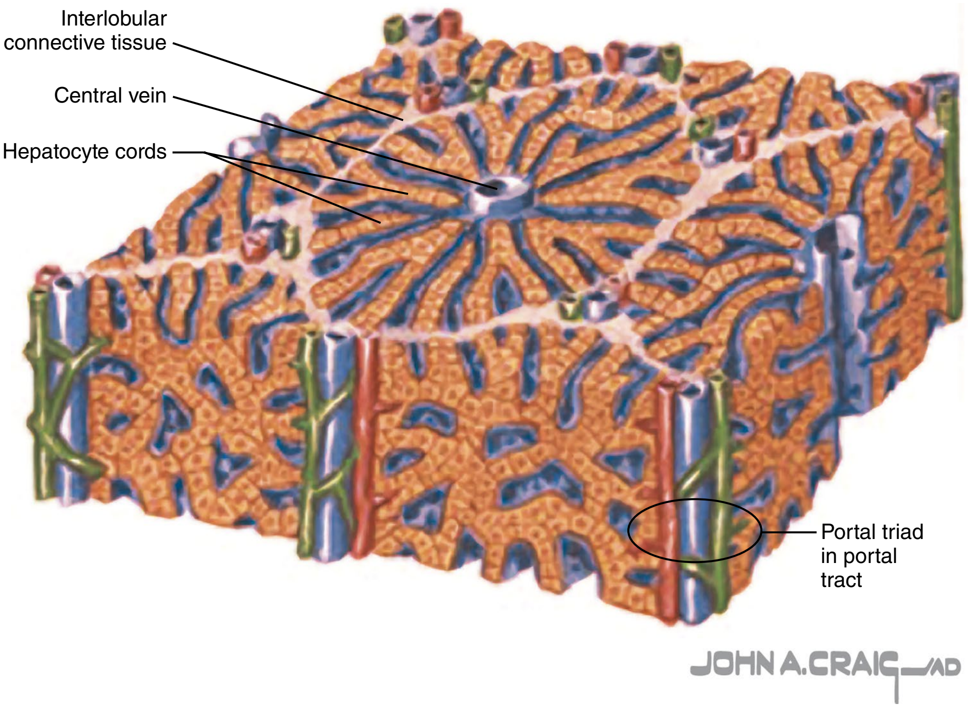
Lymphatics. Most lymph node drainage from the liver is to the hepatoduodenal ligament. From here, lymphatic drainage usually continues along the hepatic artery to the celiac lymph nodes and then to the cisterna chyli. Lymphatic drainage can also follow the hepatic veins to lymph nodes in the area of the suprahepatic IVC and through the diaphragmatic hiatus. The lymphatic drainage of the gallbladder and most of the extrahepatic biliary tract is generally into the lymph nodes of the hepatoduodenal ligament. This drainage may follow along the hepatic artery to the celiac lymph nodes, but it can also flow into lymph nodes behind the head of the pancreas or within the aortocaval groove.

Microscopic Anatomy

Functional unit of the liver. The organization of hepatic parenchyma into microscopic functional units has been described in several ways, referred to as an *acinus* or a *lobule* (Fig. 89.16). This was originally described by Rappaport and then modified by Matsumoto and Kawakami. A lobule is made up of a central terminal hepatic venule surrounded by four to six terminal portal triads that form a polygonal unit. This unit is lined on its periphery between each terminal portal triad by terminal portal triad branches. In between the terminal portal triads and the central hepatic venule, hepatocytes are arranged in one-cell-thick plates, surrounded on each side by endothelium-lined and blood-filled sinusoids. Blood flows from the terminal portal triad through the sinusoids into the terminal hepatic venule. Bile is formed within the hepatocytes and empties into terminal canaliculi, which form on the lateral walls of the intercellular hepatocyte. These ultimately coalesce into bile ducts and flow toward the portal triads. This functional hepatic unit provides a structural basis for the many metabolic and secretory functions of the liver.

Between the terminal portal triad and central hepatic venule are three zones that differ in their enzymatic makeup as well as exposure to nutrients and oxygenated blood. There is debate about the shape of these zones and their relationship to the basic lobular unit, but in general, zones 1 through 3 splay out from the terminal portal triad toward the central hepatic venule. Zone 1 (periportal zone) is rich in nutrients and oxygen. Zone 2 (intermediate zone) and zone 3 (perivenular zone) are exposed to environments that are poorer in oxygen and nutrients. The cells of the different zones differ enzymatically and respond differently to toxin exposure and hypoxia. This anatomic arrangement also explains the phenomenon of centrilobular necrosis from hypotension because zone 3 is the most susceptible to decreases in oxygen delivery.

Hepatic microcirculation. Terminal portal venous and hepatic arterial branches directly supply the hepatic sinusoids with blood. The portal branches provide a constant but minimal flow into this



Hepatic lobule. Liver arranged as series of hexagonal lobules, each composed of series of hepatocyte cords (plates) interspersed with sinusoids. Each lobule surrounds a central vein and is bounded by 6 peripheral portal triads (low magnification).

FIGURE 89.16 Schematic illustration of a hepatic lobule seen as a three-dimensional polyhedral unit. The terminal portal triads (hepatic artery, portal vein, and bile duct) are at each corner and give off branches along the sides of the lobule. Hepatocytes are in single-cell sheets with sinusoids on either end aligned radially toward a central hepatic venule. (From Netter FH. Netter Anatomy Collection. www.netterimages.com. Copyright Elsevier, Inc. All rights reserved.)

low-volume system; the arterial branches provide the sinusoids with pulsatile but low-volume flow that enhances flow in the sinusoids. Hepatic arterial branches terminate in a plexus around the terminal bile ductules and provide nutrients. Arterial and portal vein flow varies inversely in the sinusoids and can be compensatory. Local control of blood flow in the sinusoids likely depends on arteriolar sphincters and contraction of the sinusoidal lining by endothelial cells and hepatic stellate cells or portal myofibroblasts. Blood within the sinusoids empties directly into terminal hepatic venules at the center of a functional lobule. This process results in the unidirectional flow of blood in the liver from zone 1 to zone 3.

The endothelium-lined sinusoids of the hepatic lobule represent the functional unit of the liver, where afferent blood flow is exposed to functional hepatic parenchyma before being drained into hepatic venules (Fig. 89.17). The hepatic sinusoids are 7 to 15 μm wide but can increase in size by up to tenfold. This yields a low-resistance and low-pressure (generally 2–3 mm Hg) system. The sinusoidal endothelial cells account for 15% to 20% of the total hepatic cell mass.

Sinusoidal endothelial cells are separated from hepatocytes by the space of Disse (perisinusoidal space). This is an extravascular fluid compartment into which hepatocytes project microvilli, which allows proteins and other plasma components from the sinusoids to be taken up by the hepatocytes. Within this space, the endothelial cells are specialized in that they lack intercellular junctions and a basement membrane but contain multiple large fenestrations. This arrangement provides for the maximal contact of hepatocyte membranes with this extravascular fluid compartment and blood in the sinusoidal space. Thus, this system permits bidirectional movement of solutes (high- and low-molecular-weight substances) into and out of hepatocytes, providing tremendous filtration potential. On the other hand, the fenestrations of the endothelial cells restrict movement of molecules between the sinusoids and hepatocytes and vary in response to exogenous and endogenous mediators.

Other cell types are found along the sinusoidal lining. Kupffer cells, derived from the macrophage-monocyte system, are irregularly shaped cells that also line the sinusoids insinuating between endothelial cells. Kupffer cells are phagocytic, can migrate along sinusoids to areas of injury, and play a major role in the trapping of foreign substances and initiating inflammatory responses. Major histocompatibility complex II antigens are expressed on Kupffer cells but do not confer efficient antigen presentation compared with macrophages elsewhere in the body. Other lymphoid cells also exist in hepatic parenchyma, such as natural killer, natural killer T, CD4 T, and CD8 T cells. These provide the liver with an innate immune system. Hepatic stellate cells, previously known as *Ito cells,* are cells high in retinoid content (accounting for their phenotypic identification) found in the space of Disse. They have dendritic processes that contact hepatocyte microvilli and wrap around endothelial cells. The major functions of these stellate cells include vitamin A storage and the synthesis of extracellular collagen and other extracellular matrix proteins. In acute and chronic hepatic liver injuries, hepatic stellate cells are activated to a myofibroblastic state associated with morphologic changes, cellular contractility, decreases in intracellular vitamin A, and production of extracellular matrix. Ultimately, stellate cells play a central role in the development and progression of hepatic fibrosis to cirrhosis and are the target for the development of antifibrotic treatments.

Hepatocytes. Hepatocytes are complex multifunctional cells that make up 60% of the hepatic cellular mass and 80% of the

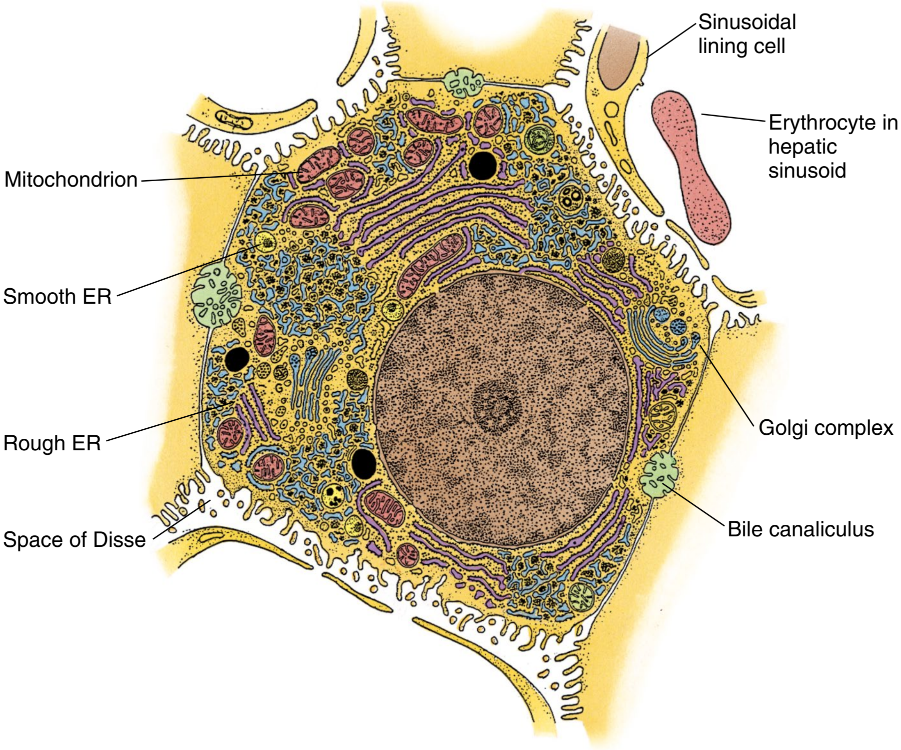


FIGURE 89.17 A hepatocyte and its sinusoidal and lateral domains. *ER*, Endoplasmic reticulum. (From Ross MH, Reith EJ, Romrell LJ. The liver. In: Ross RH, Reith EJ, Romrell LJ, eds. *Histology: A Text and Atlas*. Baltimore: Williams & Wilkins; 1989:471-478.)

cytoplasmic mass of the liver (see Fig. 89.17). The hepatocyte is a polyhedral cell with a central spherical nucleus. As noted, hepatocytes are arranged in single-cell-layer plates lined on either side by blood-filled sinusoids. Every hepatocyte has contact with adjacent hepatocytes, the biliary space (bile canaliculus), and the perisinusoidal space, enabling these cells to perform their broad range of functions. Among the many essential functions of the hepatocyte are uptake, storage, and release of nutrients; synthesis of glucose, fatty acids, lipids, and numerous plasma proteins (including C-reactive protein and albumin); production and secretion of bile for digestion of dietary fats; and degradation and detoxification of toxins.

To carry out these functions, the plasma membrane of the hepatocyte is organized in a specific manner into three specific domains. The sinusoidal membrane is exposed to the space of Disse and has multiple microvilli that provide a surface specializing in the active transport of substances between the blood and hepatocytes. The lateral domain exists between neighboring hepatocytes and contains gap junctions that provide for intercellular communication. The canalicular membrane is a tube containing microvilli formed by two apposed hepatocytes. These bile canaliculi are sealed by zonula occludens (tight junctions), which prevent the escape of bile. The bile canaliculi form a ring around the hepatocyte that drains into small bile ducts known as *canals of Hering,* which empty into a bile duct at a portal triad. The canalicular membrane contains adenosine triphosphate (ATP)-dependent active transport systems that enable solutes to be secreted into the canalicular membrane against large concentration gradients.

The hepatocyte is one of the most diverse and metabolically active cells in the body, as reflected by its abundance of organelles. There are 1000 mitochondria/hepatocytes, occupying approximately 20% of the cell volume. Mitochondria generate energy (ATP) through oxidative phosphorylation and provide the energy for the metabolic demands of the hepatocyte. The hepatocyte mitochondria are also essential for fatty acid oxidation. The monoclonal antibody HepPar1 (hepatocyte paraffin 1) identifies a unique antigen on hepatocyte mitochondria and is widely used to identify hepatocytes or hepatocellular neoplasms on immunohistochemical examination.

An extensive system of interconnected membrane complexes made up of smooth and rough endoplasmic reticulum and the Golgi apparatus compose what is known as the *hepatocyte microsomal fraction.* These complexes have a diverse range of functions, including the following: synthesis of structural and secreted proteins, metabolism of lipids and glucose, production and metabolism of cholesterol, glycosylation of secretory proteins, bile formation and secretion, and drug metabolism. Finally, hepatocytes also contain lysosomes, which are intracellular single-membrane vesicles that contain several enzymes. These vesicles store and degrade exogenous and endogenous substances. Coordination of these numerous organelles in the hepatocyte allows these cells to accomplish a large variety of functions.

Functions

The unique anatomic arrangement of the liver provides a remarkable landscape on which the multiple central and critical functions of this organ can be carried out. The liver is the center of metabolic homeostasis; it serves as the regulatory site for energy metabolism by coordinating the uptake, processing, and distribution of nutrients and their subsequent energy products. The liver also synthesizes many proteins, enzymes, and vitamins that participate in a broad range of body functions. Finally, the liver detoxifies and eliminates many exogenous and endogenous substances, serving as the major filter of the human body. The following sections summarize the functions.

Energy

The liver is the critical intermediary between dietary sources of energy and the extrahepatic tissues that require this energy. The liver receives dietary byproducts through portal circulation and sorts, metabolizes, and distributes them into the systemic circulation. The liver also plays a major role in regulating endogenous sources of energy, such as fatty acids and glycerol from adipose tissues and lactate, pyruvate, and certain amino acids from skeletal muscle. The two major sources of energy that the liver releases into the extrahepatic circulation are glucose and acetoacetate. Glucose is derived from the glycogenolysis of stored glycogen and from gluconeogenesis from lactate, pyruvate, glycerol, propionate, and alanine. Acetoacetate is derived from the β-oxidation of fatty acids. Also, storage lipids such as triacylglycerols and phospholipids are synthesized and stored as lipoproteins by the liver. These can be circulated systemically for uptake by peripheral tissues. These complex and essential functions are regulated by hormones, overall nutritional state of the organism, and requirements of obligate glucose-requiring tissues.

Blood Flow

There is a dual blood supply to the liver that comes from the portal vein and hepatic artery. The portal vein provides approximately 75% of the blood flow to the liver, which is oxygen poor but rich in nutrients. The hepatic artery provides the other 25% of the blood flow, which is oxygen rich and represents systemic arterial blood flow. The large flow rate of the portal vein is still able to provide 50% to 70% of the afferent oxygenation to the liver. Overall, hepatic blood flow represents about 25% of the cardiac output, demonstrating its central role in whole-body metabolism. Hepatic blood flow is decreased during exercise and increased after ingestion of food. Carbohydrates have the most profound effect on hepatic blood flow. Hepatic arterial pressure is representative of systemic arterial pressure. Portal pressure is generally 6 to 10 mm Hg, and sinusoidal pressure is usually 2 to 4 mm Hg.

Hepatic blood flow is regulated by various factors. Differences in afferent and efferent vessel pressures as well as muscular sphincters located at the inlet and outlet of the sinusoids play a major role. Muscular sphincter tone is regulated by the autonomic nervous system, circulating hormones, bile salts, and metabolites. Specific endogenous factors known to affect hepatic blood flow include glucagon, histamine, bradykinin, prostaglandins, nitric oxide, and many gut hormones, including gastrin, secretin, and cholecystokinin. The sinusoids are also the primary regulators of hepatic blood flow through contraction and expansion of their endothelial cells, Kupffer cells, and hepatic stellate cells.

A one-way reciprocal relationship between hepatic artery and portal vein flow has been demonstrated. Increases in hepatic arterial flow accompany decreases in portal vein flow, but the opposite does not occur. Hepatic arterial compensation, however, cannot provide complete compensation to support hepatic parenchyma in total portal vein occlusion, which is likely the cause of ipsilateral atrophy in this case. Experimental evidence has suggested that the buildup of adenosine in the liver plays an important role in this hepatic arterial compensatory response.

Bile Formation

One of the primary functions of the liver is bile production and secretion. The physiologic role of bile is twofold. The first is to

TABLE 89.1 **Solute Concentrations of Hepatic Bile**

SOLUTE	CONCENTRATION
Na^+	132–165 mEq/L
K^+	4.2–5.6 mEq/L
Ca^{2+}	1.2–4.8 mEq/L
Mg^{2+}	1.4–3.0 mEq/L
Cl^-	96–126 mEq/L
HCO_3^-	17–55 mEq/L
Bile acids	3–45 mM
Phospholipid	25–810 mg/dL
Cholesterol	60–320 mg/dL
Protein	300–3000 mg/L

dispose of substances secreted into bile; the second is to provide enteric bile salts to aid in the digestion of fats. Bile is a substance containing organic and inorganic solutes produced by an active process of secretion and subsequent concentration of these solutes. The concentration of inorganic solutes in bile in the main biliary tree resembles that of plasma (Table 89.1). In the case of bile loss (e.g., from an external biliary fistula), the high concentrations of protein and electrolytes must be considered in replacing the losses. The osmolality of bile is approximately 300 mOsmol/kg and is accounted for by the inorganic solutes. The major organic solutes in bile are bile acids, bile pigments, cholesterol, and phospholipids.

The contents of bile are generally absorbed from the bloodstream through sinusoids into the hepatocyte through the sinusoidal membrane. Bile is initially secreted by hepatocytes into the canaliculi through specialized microvilli containing lateral membranes of the hepatocytes that form the canaliculi. Tight junctions along the canalicular membranes prevent leakage of bile in the normal state. This also provides a route for paracellular secretion of solutes and water into bile. The canaliculi coalesce into larger bile ductules containing biliary epithelium, which then form the intrahepatic and extrahepatic biliary tree. Thus, the liver, in part, serves as an epithelial structure that moves solutes from the blood to the bile and provides a route of secretion for bile into the intestines.

Approximately 1500 mL of bile is secreted daily, and about 80% is secreted by hepatocytes into canaliculi. Such canalicular bile flow is largely the result of water flow in response to active solute transport. Bile acids are transported from the sinusoidal blood into the hepatocyte by an ATP-requiring active transport system. Intracellular transport to the canalicular membrane is through bile acid–binding proteins that are transported by a vesicular system derived from the Golgi apparatus. The bile acids are then actively pumped into the canaliculus through an ATP-requiring active transport system. It is well recognized that bile flow has a linear association with bile acid secretion, known as *bile acid–dependent flow.* Because bile acids form micelles in the bile and do not provide osmotic potential, it is likely that flow related to bile acid secretion is secondary to ions that accompany the bile acids (counterions). Bile flow can also occur in the near-absence of bile acid secretion, known as *bile acid–independent flow.* Experimental evidence has suggested that bile acid–independent flow is at least partially the result of biliary glutathione secretion.

Once bile has passed from the canaliculi to the biliary ductules and then to main bile ducts, bile undergoes further reabsorption and secretion. The epithelial cells of the biliary tract actively reabsorb and secrete water and electrolytes. Secretion is generally through a chloride channel activated by secretin, its most powerful activator, and its subsequent activation of cyclic adenosine monophosphate production. There is usually a net secretion of water and electrolytes, accounting for the other 20% of biliary secretion. Ultimately, bile becomes highly enriched in bicarbonate ions. Many organic substances, such as glutathione, are degraded in the biliary tree. Many drugs can be secreted into the biliary tree in a highly concentrated form (e.g., ceftriaxone). The gallbladder acts as the reservoir of the biliary tree; its function is to store bile in the fasting state. The gallbladder reabsorbs water, concentrating stored bile, and secretes mucin. Contraction of the gallbladder is mediated hormonally, largely through cholecystokinin, in response to a meal, with the simultaneous relaxation of the sphincter of Oddi and release of bile into the duodenum.

Enterohepatic Circulation

Bile salts are primarily produced in the liver and secreted to be used in the biliary tree and intestine. The primary bile salts cholic acid and chenodeoxycholic acid are produced in the liver from cholesterol and subsequently conjugated with glycine or taurine in the hepatocyte. Once secreted in the gut, the primary bile acids are modified by intestinal bacteria to form the secondary bile acids deoxycholic acid and lithocholic acid. Bile acids are reabsorbed passively into the jejunum and actively into the ileum. Thus, the bile acids reenter the portal venous system, and up to 90% of the bile acids are extracted by hepatocytes. Only a small fraction spills over into the systemic circulation because of efficient hepatic extraction, which accounts for low levels of plasma bile acids. After hepatic extraction, bile acids are recirculated into the canaliculi and back into the biliary tree, completing the circuit. A small amount of intestinal bile acids is not absorbed by the portal system and is excreted in the stool. Thus, the active secretion of bile salts from hepatocytes into bile and from ileal enterocytes into the portal vein is the engine behind the enterohepatic circulation.

The enterohepatic circulation is more than a unique mechanism for reusing physiologically valuable bile acids. This circulation of bile constitutes the primary mechanism for eliminating excess cholesterol because cholesterol is consumed during the production of bile salts and is excreted in the feces by mixed micelles formed by organic biliary solutes. Bile salts also play a critical role in the absorption of dietary fats, fat-soluble vitamins (i.e., vitamins A, D, E, and K), and lipophilic drugs. Water movement from hepatocytes into bile and water absorption through the small bowel are also regulated by bile salts. The enterohepatic circulation is therefore central to a number of solubilization, transport, and regulatory functions.

Bilirubin Metabolism

Bilirubin is the result of heme breakdown. An early phase of heme breakdown, accounting for 20% of bilirubin, is from hemoproteins (heme-containing enzymes) and occurs within 3 days of labeling with radioactive heme. A late phase of heme breakdown, accounting for 80% of bilirubin, is from senescent red blood cells. This occurs approximately 110 days after administration of radioactively labeled heme and is consistent with the life span of red blood cells. Heme is initially broken down into green biliverdin by heme oxygenase, which is then broken down into the orange bilirubin by biliverdin reductase.

Circulating bilirubin is bound to albumin, which protects many organs from the potentially toxic effects of this compound.

The bilirubin-albumin complex enters hepatic sinusoidal blood, where it enters the space of Disse through the large sinusoidal fenestrations. The bilirubin-albumin complex is disassociated in this space. Free bilirubin is internalized into the hepatocyte, where it is conjugated to glucuronic acid. Conjugated bilirubin is then secreted in an energy-dependent fashion into canalicular bile against a large concentration gradient. Bilirubin is secreted with bile into the gastrointestinal tract. Within the gastrointestinal tract, bilirubin is deconjugated by intestinal bacteria to a group of compounds known as *urobilinogens.* These urobilinogens are further oxidized and reabsorbed into the enterohepatic circulation and secreted into bile. A small percentage of the reabsorbed urobilinogens is excreted into urine. These oxidized urobilinogens account for the colored compounds that contribute to the yellow color of urine and the brown color of stool.

Bilirubin has long been known to be a toxic compound and is the agent responsible for neonatal encephalopathy and cochlear damage secondary to severe unconjugated hyperbilirubinemia (kernicterus). The binding of serum bilirubin to albumin protects the tissues from exposure to bilirubin. However, binding sites can be overwhelmed by increasing amounts of bilirubin or displaced by other binding agents (e.g., various drugs). The mechanism of bilirubin toxicity appears to be related to several of its effects. Free bilirubin can uncouple oxidative phosphorylation, inhibit ATPases, decrease glucose metabolism, and inhibit a broad spectrum of protein kinase activities.

Portosystemic shunts, such as those seen with cirrhosis and portal hypertension, decrease the first-pass hepatic clearance of bilirubin, resulting in a mildly increased serum unconjugated hyperbilirubinemia. Several disorders can result in an unconjugated serum hyperbilirubinemia, including neonatal hyperbilirubinemia, an increased bilirubin load caused by hemolytic syndromes, and inherited enzymatic deficiencies such as Crigler-Najjar and Gilbert syndromes. Disorders presenting with serum conjugated hyperbilirubinemia include cholestasis, Dubin-Johnson, and Rotor syndromes.

Carbohydrate Metabolism

The liver is the center of carbohydrate metabolism because it is the primary regulator of storage and distribution of glucose to the peripheral tissues and, in particular, to glucose-dependent tissues such as the brain and erythrocytes. Both the liver and muscle can store glucose in the form of glycogen, but only the liver can break down glycogen to provide glucose for systemic circulation. Glycogen that is broken down can be used only in muscle and is therefore not a source of systemically circulated glucose.

In the fed state, carbohydrates absorbed through the intestines (mostly glucose) are circulated systemically. Carbohydrates reaching the liver are rapidly converted to glycogen for storage. The liver contains up to 65 g of glycogen per kilogram of liver tissue. Excess carbohydrates are mostly converted to fatty acids and stored in adipose tissue. In the postabsorptive state (between meals, nonfasting), there is no further systemic glucose coming directly from the gut, and the liver becomes the primary source of circulating glucose by the breakdown of glycogen. This is crucial for the brain and erythrocytes, which rely on glucose for their metabolism. In the postabsorptive state, most other tissues begin to rely on fatty acids derived from adipose tissue as their primary fuel. Highly active muscle may deplete its own glycogen and depend on liver-derived glucose for its substrate in the postabsorptive state. After 48 hours of fasting, hepatic glycogen is depleted, and the liver shifts from glycogenolysis to gluconeogenesis. The substrate for hepatic gluconeogenesis is mostly from amino acids (mainly alanine) derived from muscle breakdown, but they also come from glycerol derived from adipose breakdown. During a prolonged fast, fatty acids from adipose breakdown are β-oxidized in the liver, which releases ketone bodies that then become the primary fuel for the brain.

Transitions in and out of these various metabolic states and regulation of carbohydrate metabolism are mostly influenced by glucose concentration in sinusoidal blood and hormonal influences (e.g., insulin, catecholamines, glucagon). In the fasting state, during anaerobic metabolism, lactate is produced largely from muscle. The liver uses this lactate, which is converted to pyruvate that enters the gluconeogenic pathways to produce glucose. This cycle is known as the *Cori cycle.*

Derangements of carbohydrate metabolism are common in liver disease. People with cirrhosis often demonstrate abnormal glucose tolerance. Its mechanism is unclear but is probably related to associated insulin resistance. This phenomenon is not caused by shunting of glucose-containing blood away from the liver. Hypoglycemia is distinctly uncommon in chronic liver disease because of the remarkable resilience of the liver and its metabolic function. Only with massive hepatocyte loss in fulminant hepatic failure does gluconeogenesis fail and hypoglycemia ensue.

Lipid Metabolism

Fatty acids are synthesized in the liver during states of glucose excess when the liver's ability to store glycogen has been exceeded. Adipocytes have a limited ability to synthesize fatty acids. Therefore, the liver is the predominant source of synthesized fatty acids, although they are largely stored in adipose tissue. During lipolysis, free fatty acids are transported to the liver, where they are metabolized. Fatty acids in the liver undergo esterification with glycerol to form triglycerides for storage or transportation, or they undergo β-oxidation, yielding energy in the form of ATP and ketone bodies. In general, this process is regulated by the nutritional state; starvation favors oxidation, and the fed state favors esterification.

There is a constant cycling of fatty acids between the liver and adipose tissue that is under a delicate balance, which can easily be offset, resulting in fatty infiltration of the liver. A few factors influence this balance; for example, hepatic uptake of fatty acids is a function of plasma concentrations. Although there is no limit to the liver's ability to esterify fatty acids, its ability to dispose of or break down fatty acids is limited, as is its ability to secrete triglycerides in the form of lipoproteins. Therefore, conditions of increased circulating fatty acids can easily override the liver's ability to handle them, resulting in fatty accumulation in the liver. This is known as *steatosis* or, when it is associated with chronic inflammation in more advanced cases, *steatohepatitis*. Many conditions have been associated with hepatic steatosis, such as diabetes, steroid use, starvation, obesity, and extensive administration of cytotoxic chemotherapeutic agents. Fatty liver associated with alcohol intake has several causes; it is related to increased lipolysis, reduced oxygenation, and augmented esterification of hepatic fatty acids and may also be related to relative starvation in the chronic alcoholic.

Protein Metabolism

The liver is also a central site for the metabolism of proteins and is involved in synthesis of protein, catabolism of proteins into energy or storage forms, and management of excess amino acids and nitrogen waste. Ingested protein is broken down into amino acids that are circulated throughout the body, where they are used as the building blocks for proteins, enzymes, and hormones. Excess amino acids not used in peripheral tissues are generally handled by the liver, in which they are oxidized for energy—providing 50% of the liver's energy needs—or converted into glucose, ketone bodies, or fats. When amino acids are catabolized for energy production throughout the body, ammonia, glutamine, glutamate, and aspartate are produced. These products are largely processed in the liver, where the waste nitrogen is converted to urea through the urea cycle, and the urea is generally excreted in the urine. Thus, the liver is central and critical to the body's nitrogen balance and amino acid metabolism.

Although the liver can catabolize most amino acids, yielding energy or other storable energy forms such as glucose and fats, notable exceptions are the branched-chain amino acids. Branched-chain amino acids cannot be catabolized in the liver and are mostly dealt with by muscle. It has been postulated that this may act as a so-called safety net that helps spare the liver some of the demands of protein and amino acid metabolism.

The liver is also the main site of synthesis for many proteins involved in such wide-ranging and critical functions as coagulation, transport, copper and iron binding, and protease inhibition. These proteins include ceruloplasmin, iron storage and binding proteins, and α_1-antitrypsin. Albumin is made exclusively in the liver and is the predominant serum binding protein. Hepatic insufficiency or specific genetic abnormalities can result in altered amounts and functions of these proteins, with wide-ranging pathologic effects.

The liver is also responsible for the so-called acute-phase response, a synthetic response by protein to trauma or infection. Its purpose is to restrict organ damage, maintain vital hepatic function, and control defense mechanisms. The response is incited by proinflammatory cytokines such as interleukin-1 (IL-1), IL-6, and tumor necrosis factor, which induce acute-phase protein gene expression in the liver. Some of the well-known hepatic acute-phase proteins are α_1-, α_2-, and β-globulin as well as C-reactive protein and serum amyloid A. An equally important part of this response is its termination. Antiinflammatory cytokines such as IL-1 receptor antagonist, IL-4, and IL-10 appear to play important roles. The acute-phase response is usually completed in 24 to 48 hours but can be prolonged in the context of ongoing injury.

Vitamin Metabolism

Along with the intestine, the liver is responsible for the metabolism of the fat-soluble vitamins A, D, E, and K. These vitamins are obtained exogenously and absorbed in the intestine. Their adequate intestinal absorption is critically dependent on adequate fatty acid micellization, which requires bile acids.

Vitamin A is from the retinoid family and is involved in normal vision, embryonic development, and adult gene regulation. Storage of vitamin A is solely in the liver and occurs in the hepatic stellate cells. Overingestion of vitamin A can result in hepatic toxicity. Vitamin D is involved in calcium and phosphorus homeostasis. One of vitamin D's activation steps (25-hydroxylation) occurs in the liver. Vitamin E is a potent antioxidant and protects membranes from lipid peroxidation and free radical formation. Finally, vitamin K is a critical cofactor in the posttranslational γ-carboxylation of the hepatically synthesized coagulation factors II, VII, IX, and X as well as of protein C and protein S, the so-called vitamin K–dependent cofactors. Cholestasis syndromes can result in the inadequate absorption of these vitamins secondary to poor micellization in the intestine. The associated vitamin deficiency syndromes, such as metabolic bone disease (vitamin D deficiency), neurologic disorders (vitamin E deficiency), and coagulopathy (vitamin K deficiency), can subsequently occur.

The liver is also involved in the uptake, storage, and metabolism of several water-soluble vitamins, including thiamine, riboflavin, vitamin B_6, vitamin B_{12}, folate, biotin, and pantothenic acid. The liver is responsible for converting some of these vitamins to active coenzymes, transforming some to storage metabolites, and using some for enterohepatic circulation (e.g., vitamin B_{12}).

Coagulation

The liver is responsible for synthesizing almost all the identified coagulation factors as well as many of the fibrinolytic system components and several plasma regulatory proteins of coagulation and fibrinolysis. As noted, the liver is critical for the absorption of vitamin K, synthesizes the vitamin K–dependent coagulation factors, and contains the enzyme that activates these factors. Also, the reticuloendothelial system of the liver clears activated clotting factors, activated complexes of the coagulation and fibrinolytic systems, and end products of fibrin degradation. Diseases of the liver are often associated with thrombocytopenia, qualitative platelet abnormalities, vitamin K deficiency with impaired modulation of vitamin K–dependent coagulation factors, and disseminated intravascular coagulation. It is no surprise that liver disease is firmly associated with coagulation disorders that are often challenging to deal with.

Warfarin, one of the most dispensed anticoagulants, acts in the liver by blocking vitamin K–dependent activation of factors II, VII, IX, and X. Factor VII has the shortest half-life of the coagulation factors; its deficiency is manifested clinically as abnormalities of the measured prothrombin time (PT) or international normalized ratio (INR). Patients with hepatic synthetic dysfunction similarly have an abnormal PT.

Metabolism of Drugs and Toxins (Xenobiotics)

The human body is exposed to an inordinate amount of foreign chemicals during a lifetime. This poses a challenge to our ability to detoxify and eliminate these potentially harmful chemicals. Many of these chemicals are not incorporated into cellular metabolism and are referred to as *xenobiotics.* The liver plays a central role in handling them through complex enzymes and reaction pathways, which are increasingly recognized as new chemicals are discovered.

Hepatic-based reactions to xenobiotics are broadly classified into phase I and phase II reactions. Through oxidation, reduction, and hydrolysis, phase I reactions increase the polarity and thus water solubility of compounds. This, in turn, allows easier excretion. Phase I reactions do not necessarily detoxify chemicals and may, in fact, create toxic metabolites. Phase I reactions occur in the cytochrome P450 system. Phase II reactions generally act to create a less toxic or less active byproduct. This is generally accomplished through transferase reactions, in which a compound is usually coupled to a conjugate, rendering the xenobiotic more innocuous.

Regeneration

The liver possesses the unique quality of adjusting its volume to the needs of the body. This is observed clinically in its regeneration after partial hepatectomy or after toxic liver injury. It is also seen in liver transplantation, in that donor liver size mismatches adjust to the new host. This quality is highly conserved evolutionarily because of the critical functions of the liver and the fact that the liver is the first line of exposure to ingested toxic agents.

Liver regeneration is a hyperplastic response of all cell types of the liver, in which the microscopic anatomy of the functional liver is maintained. Much information about the regenerative response of the liver is based on experimental evidence in rodents. Normally quiescent hepatocytes rapidly enter the cell cycle after partial hepatectomy. Maximal hepatocyte DNA synthesis occurs 24 to 36 hours after partial hepatectomy, and maximal DNA synthesis occurs in the other cell types 48 to 72 hours later. Most of the increase in hepatic mass in rodents is seen 3 days after partial hepatectomy, and it is usually almost complete after 7 days.

In the late 1960s, it was recognized that circulating factors were responsible, in part, for the regenerative response, and much research has focused on the humoral and genetic control of hepatic regeneration. The major circulating factors identified, largely from rodent studies, are hepatocyte growth factor, epidermal growth factor, transforming growth factors, insulin, glucagon, and the cytokines tumor necrosis factor-α, IL-1, and IL-6. These factors, when infused into a normal host, do not result in hepatic growth, indicating that hepatocytes must be primed in some way before responding to these growth factors. Remarkable progress in the understanding of liver regeneration has been made because of the development of improved genetic and molecular biology techniques. Hundreds of genes involved at all stages of regeneration have been identified by RNA microarray techniques. Also, numerous cytokine-dependent and growth factor–independent pathways have been further defined. A complete description is beyond the scope of this chapter, however, and many questions remain.

Assessment of Liver Function

A wide variety of tests are available to evaluate hepatic diseases. Screening for hepatic disease, assessing hepatic function, diagnosing specific disorders, and prognosticating are critical in the management of hepatic disease. For the surgeon, assessment of hepatic function and estimation of the ability of a hepatic remnant to be sufficient after liver resection are also of obvious importance. Unfortunately, most measures of hepatic disease are gross indicators and lack sensitivity, specificity, and accuracy. We have divided these hepatic function tests into three categories: routine screening, specific diagnostic, and quantitative tests.

Routine Screening Tests

Screening blood tests are often used to determine whether there is disease in the hepatobiliary system. Standard liver function tests (LFTs) are generally not tests of function and are not always specific to hepatic disease. Nonetheless, they are a valuable screening tool to provide basic indications to recognize the presence of hepatic disease and yield clues about the cause of that disease. Total bilirubin, direct bilirubin (conjugated), and indirect bilirubin (unconjugated) levels can be affected by several processes related to bilirubin metabolism. Unconjugated hyperbilirubinemia can reflect increased bilirubin production (e.g., hemolysis), drug effects, inherited enzymatic disorders, or physiologic jaundice of the newborn. Conjugated hyperbilirubinemia is generally a result of cholestasis or mechanical biliary obstruction but can also be seen in some inherited disorders or hepatocellular disease.

The transaminases alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are the most common serum markers of hepatocellular necrosis, with subsequent leak of these intracellular enzymes into the circulation. AST is found in other organs, such as the heart, muscle, and kidney, but ALT is liver specific. However, the degree of elevation of these enzyme levels has never been shown to be of prognostic value. Alkaline phosphatase (ALP) is expressed in liver, bile ducts, bone, intestine, placenta, kidney, and leukocytes. Isoenzyme determinations can sometimes help distinguish the source of an elevated ALP level. Elevations of ALP levels in hepatobiliary diseases are generally secondary to cholestasis or biliary obstruction. Such elevations are caused by increased production of this enzyme. The ALP level can also be increased in malignant disease of the liver. Gamma-glutamyl transpeptidase (GGT) is an enzyme in many organs in addition to the liver, such as the kidneys, seminal vesicles, spleen, pancreas, heart, and brain. Its level can be elevated in diseases affecting any of these tissues. It is also induced by alcohol intake and is elevated in biliary obstruction. Thus, it is also a nonspecific marker of liver disease but can help determine whether an elevated ALP level is from hepatic disease. 5′-Nucleotidase is found in a wide variety of organs in addition to the liver, but increased levels are specific to hepatic disease. Like GGT, it can help determine whether an elevated ALP level is secondary to hepatic disease.

Albumin is synthesized exclusively in the liver and can be used as a general measure of hepatic synthetic function. Because chronic malnutrition and acute injury, infection, and/or inflammation can decrease albumin synthesis, these factors must be considered in evaluating a low serum albumin level. Because of the remarkable protein synthetic capacity of the liver, hypoalbuminemia is a marker of severe liver disease. However, it lacks sensitivity, and large decreases in hepatic function are required to be reflected in albumin levels. In general, it is most helpful in chronic liver disease.

Clotting factors are largely synthesized in the liver; abnormalities of coagulation can be a marker of hepatic synthetic dysfunction. Measurement of specific clotting factors, such as factors V and VII, has been used to evaluate hepatic function in the transplantation population. PT or INR is the best test to measure the effects of hepatic disease on clotting, and prolonged PT or elevated INR is usually a marker of advanced chronic liver disease. Hepatic disease can also affect clotting through intravascular coagulation and vitamin K malabsorption. Patients with liver disease have thrombocytopenia. Although platelets are not incorporated in any measure of liver function and thrombocytopenia may be multifactorial, platelet levels provide insight into severity of portal hypertension in patients with liver disease.

Specific Diagnostic Tests

Once screening tests, along with clinical findings, have suggested liver disease, specific tests can help elucidate the cause and guide treatment, if necessary. Hepatitis serologies are important to determine the presence of viral hepatitis. Autoimmune antibodies are used to diagnose primary biliary cirrhosis (e.g., antimitochondrial), primary sclerosing cholangitis (e.g., antineutrophil), and autoimmune hepatitis. α_1-Antitrypsin and ceruloplasmin levels assist in the diagnosis of α_1-antitrypsin deficiency and Wilson disease, respectively. Tumor markers such as α-fetoprotein (AFP) and carcinoembryonic antigen (CEA) are helpful in the diagnosis and management of primary and metastatic tumors of the liver.

In general, the LFTs discussed in this section are gross, nonspecific, and of little, if any, prognostic value. Many attempts have been made to formulate dynamic and quantitative tests of hepatic function based on the liver's ability to clear various exogenously administered substances. Despite many years of research, it remains unclear whether these tests of hepatic function are any better than scoring systems derived from simple blood tests and clinical observations. For example, the aminopyrine breath test is based on cytochrome P450 clearance of radiolabeled aminopyrine. A breath test measuring radiolabeled CO_2 as a breakdown product of aminopyrine is performed after administration at a specified time. The results largely depend on the functional hepatic mass, which is generally not depleted until end-stage liver disease has developed. There are varying results of studies comparing the aminopyrine breath test with standard LFTs and scoring systems; its main value appears to be prognosis in chronic liver disease, but it is clearly not an effective test to detect subclinical hepatic dysfunction.

Substances such as antipyrine and caffeine can evaluate liver function in a similar way, with similar results. The lidocaine clearance test yields similar information to the aminopyrine test because it is based on its clearance by the hepatic cytochrome P450 test. Lidocaine clearance depends on blood flow and a complex distribution process, but measurement of one of its metabolites, monoethylglycinexylidide, has greatly simplified the test. It has been shown to have some prognostic value in the transplantation population. The galactose elimination test is based on the liver's role in phosphorylating galactose and converting it to glucose. The rate at which galactose is eliminated from the bloodstream can be used as a measure of hepatic function. Problems related to this test are that the enzymes involved are genetically heterogeneous, and considerable extrahepatic metabolism occurs. Also, multiple blood draws are necessary, which makes the test cumbersome. The value of this test is probably in assessing the prognosis of patients with chronic liver disease rather than in screening. Indocyanine green is a dye removed by the liver by a carrier-mediated process and excreted into bile. This dye is rapidly cleared from the bloodstream and is not metabolized. This is the only test that has been shown to have some prognostic ability in patients with cirrhosis undergoing liver resection, although this is not universally demonstrated in studies, nor is it universally accepted.

Nuclear imaging studies overcome some of the limitations of the lidocaine and indocyanine green tests described earlier and have the advantage of providing simultaneous morphologic (visual) and physiologic (quantitative functional) information about the liver. This not only helps quantitate the liver function but also in determining the distribution of that function. Thus, regional (segmental) differentiation allows specific functional assessment of the future remnant liver. Technetium-99m (99mTc)–galactosyl human serum albumin scintigraphy and 99mTc-mebrofenin hepatobiliary scintigraphy potentially identify patients at risk for postresectional liver failure who might benefit from liver-augmenting techniques.

Quantitative Tests

Many scoring systems based on clinical observation and standard blood tests have been proposed. The most used system is Pugh's modification of the Child score (Table 89.2). Although all these systems are less than perfect and not universally accepted, the Child-Pugh score is commonly used for patients with cirrhosis who require liver surgery. Mortality and survival rates after hepatectomy correlate with this score but are not always related to liver failure. Child-Pugh class B and C patients have higher perioperative mortality after any partial hepatectomy than Child-Pugh class A patients, who can generally withstand a major hepatectomy. The presence of portal hypertension has been shown to predict poor outcome after partial hepatectomy. Portal hypertension in patients with cirrhosis is usually manifested as thrombocytopenia, splenomegaly, and presence of intraabdominal varices on imaging or at endoscopy. The best evidence for portal hypertension is a hepatic vein wedge pressure higher than 10 mm Hg, which has been shown to correlate strongly with postoperative liver failure.

TABLE 89.2 **Child-Pugh Classification**

	NO. OF POINTS		
FACTOR	1	2	3
Bilirubin (mg/dL)	<2	2–3	>3
Albumin (g/dL)	>3.5	2.8–3.5	<2.8
Prothrombin time (increased seconds)	1–3	4–6	>6
Ascites	None	Slight	Moderate
Encephalopathy	None	Minimal	Advanced

Class A, 5–6 points; class B, 7–9 points; class C, 10–15 points.

PORTAL HYPERTENSION

Cirrhosis is the result of a healing response initiated by chronic liver injury. It is characterized by development of fibrous septa surrounding regenerating hepatocellular nodules. Besides development of synthetic deficiencies, cirrhosis is associated with development of portal hypertension. At present, effective treatments for cirrhosis are nonexistent. As a result, its treatment has largely been focused on the treatment of resultant portal hypertension and its complications. The major challenge for the hepatologist or surgeon treating patients with cirrhosis and end-stage liver disease is determining when definitive treatment (e.g., liver transplantation) rather than palliative treatment (e.g., interventions to prevent recurrent variceal hemorrhage) should be applied. Cirrhosis can be classified as compensated or decompensated based on the absence or presence of clinically evident decompensating events (variceal hemorrhage, encephalopathy, ascites). This classification provides important prognostic information, as patients with compensated cirrhosis have a median survival exceeding 12 years, whereas patients with decompensated cirrhosis have a median survival of only 1.8 years.

Definition

Portal hypertension is defined by a portal pressure gradient (the difference in pressure between the portal vein and the hepatic veins) higher than 5 mm Hg. The best method to estimate this gradient is by transfemoral-hepatic vein catheterization with a balloon tip catheter. However, higher pressures (8–10 mm Hg) are typically required to begin stimulating the development of portosystemic collateralization. Collateral vessels usually develop where the portal and systemic venous circulations are in close apposition (Fig. 89.18). The collateral network through the coronary and short gastric veins to the azygos vein is clinically the most important because it results in formation of esophagogastric varices. However, other sites include a recanalized umbilical vein from the left portal vein to the epigastric venous system (caput medusae), retroperitoneal collateral vessels, and hemorrhoidal venous plexus. In addition to extrahepatic collateral vessels, a significant fraction of portal venous flow passes through anatomic and physiologic (e.g., capillarization of hepatic sinusoids) intrahepatic shunts. As hepatic portal perfusion decreases, hepatic arterial flow generally increases (buffer response).

Pathophysiology

Portal hypertension usually occurs because of increased portal venous resistance that is prehepatic, intrahepatic, or posthepatic in location. Several factors may contribute to this, including the

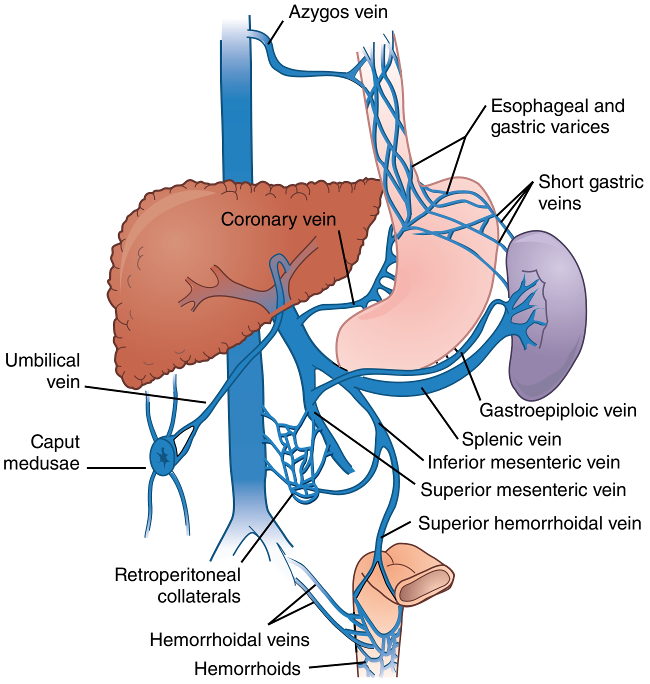

FIGURE 89.18 Portosystemic collateral pathways develop where the portal venous and systemic venous systems are in close apposition. (From Rikkers LF. Portal hypertension. In: Miller TA, ed. *Physiologic Basis of Modern Surgical Care*. St Louis: Mosby; 1988:417-428.)

following: increased passive resistance secondary to fibrosis and regenerative nodules; increased hepatic vascular resistance caused by active vasoconstriction by norepinephrine, endothelin, and other humoral vasoconstrictors; and increased portal venous inflow secondary to a hyperdynamic systemic circulation and splanchnic hyperemia. The last one is a major contributor to the maintenance of portal hypertension as portal systemic collaterals develop. Unfortunately, the exact causes remain unknown, but splanchnic hormones, decreased sensitivity of the splanchnic vasculature to catecholamines, and increased production of nitrous oxide and prostacyclin may be involved. Understanding the pathophysiology of portal hypertension may have therapeutic implications because these factors may represent targets for treatment.

The most common cause of prehepatic portal hypertension is portal vein thrombosis (PVT). This accounts for approximately 50% of cases of portal hypertension in children. When the portal vein is thrombosed in the absence of liver disease, hepatopetal (to the liver) portal collateral vessels develop to restore portal perfusion. This combination is termed *cavernomatous transformation of the portal vein*. Isolated splenic vein thrombosis (left-sided portal hypertension) is usually secondary to pancreatic inflammation or neoplasm. The result is gastrosplenic venous hypertension, with superior mesenteric and portal venous pressures remaining normal. The left gastroepiploic vein becomes a major collateral vessel, and gastric rather than esophageal varices develop. This variant of portal hypertension is important to recognize because it is easily reversed by splenectomy alone.

The site of increased resistance in intrahepatic portal hypertension may be at the presinusoidal, sinusoidal, or postsinusoidal level. Frequently, more than one level may be involved. The most common cause of intrahepatic presinusoidal hypertension is schistosomiasis. In addition, many causes of nonalcoholic cirrhosis result in presinusoidal portal hypertension. In contrast, alcoholic cirrhosis, the most common cause of portal hypertension in the United States, usually causes increased resistance to portal flow at the sinusoidal (secondary to deposition of collagen in the space of Disse) and postsinusoidal (secondary to regenerating nodules distorting small hepatic veins) levels.

Posthepatic or postsinusoidal causes of portal hypertension are rare; they include Budd-Chiari syndrome (hepatic vein thrombosis), constrictive pericarditis, and heart failure. Rarely, increased portal venous flow alone, secondary to massive splenomegaly (e.g., idiopathic portal hypertension) or a splanchnic arteriovenous fistula, causes portal hypertension.

Assessment of Chronic Liver Disease and Portal Hypertension

The key aspects of assessing a patient with suspected chronic liver disease or complications of portal hypertension are the following: diagnosis of the underlying liver disease; estimation of functional hepatic reserve; definition of portal venous anatomy and hepatic hemodynamic evaluation; and identification of the site of upper gastrointestinal hemorrhage, if present. These diagnostic categories take on varying degrees of importance, depending on the clinical situation. For example, estimation of functional hepatic reserve is useful in determining the risk associated with therapeutic intervention and whether definitive (e.g., hepatic transplantation) or palliative (e.g., endoscopic variceal ligation or a shunt procedure) treatment is indicated.

Variceal Hemorrhage

Bleeding from esophagogastric varices is the single most life-threatening complication of portal hypertension. It is responsible for approximately one-third of all deaths in patients with cirrhosis. Approximately 50% of these deaths are caused by uncontrolled bleeding. The risk for death from bleeding is mainly related to the underlying hepatic functional reserve. Patients with extrahepatic portal venous obstruction and normal hepatic function rarely die of bleeding varices, whereas those with decompensated cirrhosis (e.g., Child-Pugh class C) may face a mortality rate of more than 50%. Once bleeding is controlled, the greatest risk for rebleeding from varices is within the first few days after the onset of hemorrhage; the risk declines rapidly between that point and 6 weeks. Subsequently, the risk returns to the prehemorrhage rate.

Treatment

In a patient with upper gastrointestinal bleeding, general measures are instituted; these include securing the airway (especially in an encephalopathic patient), ensuring adequate access (two large-bore intravenous [IV] lines), fluid infusion, type and crossmatch of blood, and judicious blood and products transfusion. A randomized controlled trial comparing liberal transfusion (transfusion when the hemoglobin fell below 9 g/dL) with restrictive transfusion (transfusion when the hemoglobin levels fell below 7 g/dL) demonstrated that the restrictive strategy led to better survival at 6 weeks and reduced risk of rebleeding. Therapy for portal hypertension and variceal bleeding has evolved over time and now encompasses a spectrum of treatment modalities in which sequential therapies are often necessary. For acutely bleeding patients with portal hypertension, nonoperative treatments are generally used as a first-line approach, as these patients are at high operative risk because of decompensated hepatic function. Endoscopic treatment (e.g., sclerosis or ligation) has become the mainstay of nonoperative treatment of acute hemorrhage because bleeding can be controlled in more than 85% of patients. This allows an interval of medical management for improvement of hepatic function, resolution of ascites and encephalopathy, and enhancement of nutrition before definitive treatment for prevention of recurrent bleeding is instituted. Pharmacotherapy can also be initiated, and trials have suggested that it may be as effective as endoscopic treatment. Balloon tamponade, which is infrequently used, can be lifesaving in patients with exsanguinating hemorrhage when other nonoperative methods are not successful. A transjugular intrahepatic portosystemic shunt (TIPS) is another treatment option whereby a percutaneous connection is created within the liver, between the portal and systemic circulations, to reduce portal pressure in patients with complications related to portal hypertension. TIPS has replaced operative shunts for managing acute variceal bleeding when pharmacotherapy and endoscopic treatment fail to control bleeding. As a result, emergency surgical intervention in most centers is reserved for select patients who are not TIPS candidates.

Endoscopy. About 80% to 90% of acute variceal bleeding episodes are successfully controlled by endoscopic measures. Sclerotherapy and band ligation of varices are the two main options available for control of acute variceal bleeding. Data suggest that band ligation is better than sclerotherapy in the initial control of bleeding and is associated with fewer complications. The literature also suggests that sclerotherapy, but not band ligation, may increase portal pressures. Thus, currently, band ligation is the modality of choice for initial control of variceal bleeding. Endoscopic sclerotherapy may be used if technology for band ligation is not available. Early endoscopy, preferably within 12 hours of admission, with an attempt at control of bleeding is recommended. Patients should be started on vasoactive drugs early, and endoscopy with band ligation is performed after initial resuscitation.

Pharmacotherapy. Pharmacotherapy works by reducing variceal blood flow, which in turn reduces variceal pressure. Medical therapy should be initiated at the onset of variceal bleeding. Because infections are common in patients with variceal bleeding, antibiotic prophylaxis should be initiated. This has been shown to decrease the infection rate by more than 50%, to decrease rebleeding, and to improve survival. Randomized trials have also shown that somatostatin and its longer-acting analogue octreotide are as efficacious as endoscopic treatment for control of acute variceal bleeding. Because of the minimal adverse effects and ease of administration, octreotide is now commonly used as an adjunct to endoscopic therapy. In fact, the combination of octreotide and endoscopic therapy is more effective than octreotide alone in controlling bleeding and is the preferred treatment for most patients. In severe cases of hemorrhage, vasopressin can be used to diminish splanchnic blood flow. However, because of the adverse systemic effects of vasopressin, nitroglycerin should be simultaneously infused and then titrated to achieve blood pressure control.

Variceal tamponade. Controlled trials have demonstrated that balloon tamponade is as effective as pharmacotherapy and endoscopic therapy in controlling acute variceal bleeding. The major advantages of variceal tamponade using the Sengstaken-Blakemore tube are immediate cessation of bleeding in more than 85% of patients and the widespread availability of this device (Fig. 89.19). However, there are also significant disadvantages of balloon tamponade, including frequent recurrent hemorrhage in up to 50% of patients after balloon deflation, considerable discomfort for the patient, and a high incidence of serious complications when it is used incorrectly by an inexperienced healthcare provider.

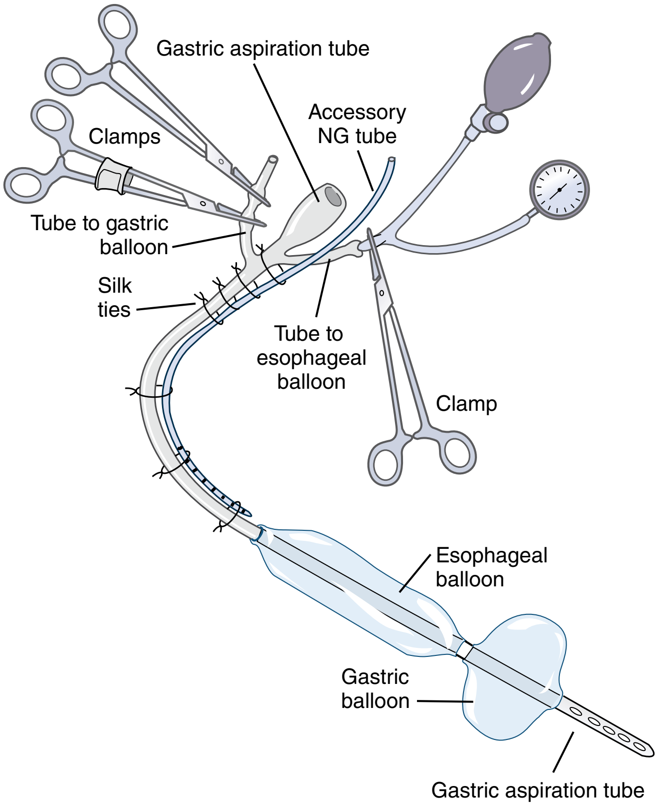

FIGURE 89.19 Modified Sengstaken-Blakemore tube. Note the accessory nasogastric *(NG)* tube for suctioning of secretions above the esophageal balloon and the two clamps, one secured with tape, to prevent inadvertent decompression of the gastric balloon. (From Rikkers LF. Portal hypertension. In: Goldsmith H, ed. *Practice of Surgery*. Philadelphia: Harper & Row; 1981:1-37.)

Interventional approaches. In most institutions, TIPS has become the preferred treatment for acute variceal bleeding when pharmacotherapy and endoscopic treatment fail. With TIPS, a functional portacaval side-to-side shunt is established. TIPS can control bleeding in almost all patients, but it is associated with risk of encephalopathy. Furthermore, in the case of shunt dysfunction, there is risk of recurrent bleeding. Use of polytetrafluoroethylene (PTFE)-covered stents has been a major step forward. PTFE stents have higher patency rates over time and reduced mortality rates.[2] Use of TIPS in patients with multiorgan failure or in patients with decompensated liver disease is associated with high 30-day mortality. In such patients, early use of TIPS, rather than after failure of other therapies, may be associated with better outcomes.

Operative approaches. Operative procedures are typically reserved for those situations in which TIPS is not indicated or is not available. Selection of the appropriate emergency operation should mainly be guided by the experience of the surgeon. Although nonoperative therapies are effective in most patients with acute variceal bleeding, an emergency operation should be promptly carried out when less invasive measures fail to control hemorrhage or are not indicated. The most common situations requiring urgent or emergency surgery are failure of acute endoscopic treatment, failure of long-term endoscopic therapy, hemorrhage from gastric varices or portal hypertensive gastropathy, and failure of TIPS placement.

Esophageal transection with a stapling device is rapid and relatively simple, but rebleeding rates after this procedure are high.

Moreover, there is little evidence that operative mortality rates are lower than after surgical portal decompression.

A commonly performed shunt operation in the emergency setting is the portacaval shunt because it rapidly and effectively decompresses the portal venous circulation. Impressive results have been achieved by Orloff and colleagues,[3] but not by others, when an emergency portacaval shunt is used as routine therapy for acute variceal bleeding. In patients who are not actively bleeding at the time of surgery and in those in whom bleeding is temporarily controlled by pharmacotherapy or balloon tamponade, a more complex operation, such as the distal splenorenal shunt, may be appropriate. The major disadvantage of emergency surgery is that operative mortality rates exceed 25% in most reported series. Early postoperative mortality is usually related to the status of hepatic functional reserve rather than to the type of emergency operation selected.

Prevention of Recurrent Variceal Hemorrhage

After a patient has bled from varices, the likelihood of a repeated episode exceeds 70%. Because most patients with variceal hemorrhage have chronic liver disease, the challenge of long-term management is prevention of recurrent bleeding and maintenance of satisfactory hepatic function. Options available for definitive treatment include pharmacotherapy, chronic endoscopic treatment, TIPS, shunt operations (e.g., nonselective, selective, partial), various nonshunt procedures, and liver transplantation. The most effective treatment regimen usually requires two or more of these therapies in sequence. In most centers, initial treatment consists of pharmacotherapy or endoscopic therapy, with portal decompression by means of TIPS or an operative shunt reserved for failures of first-line treatment. Hepatic transplantation is used for patients with end-stage liver disease.

Pharmacotherapy. A meta-analysis of controlled trials of nonselective β-adrenergic blockade has shown that this treatment significantly decreases the likelihood of recurrent hemorrhage and demonstrates a trend toward decreased mortality. The combination of a β-blocker and long-acting nitrate (e.g., isosorbide 5-mononitrate) has been shown to be more effective than variceal ligation.[4] Combination therapy is also more effective than β-blockade alone. Long-term pharmacotherapy should be used only in compliant patients who are observed closely by their physician.

Endoscopic therapy. Several controlled trials and a meta-analysis comparing endoscopic sclerotherapy with variceal ligation have shown a significant advantage to variceal ligation. Complications are less frequent after variceal ligation, and fewer treatment sessions are required to eradicate varices (Fig. 89.20). Rebleeding and mortality rates also appear to be lower after variceal ligation. The combination of variceal ligation and pharmacotherapy with nonselective β-blockade is more effective than variceal ligation alone. This result has been confirmed in a meta-analysis that included the data from 17 randomized controlled trials.[5] In this trial, a combination of β-blocker and endoscopic treatment significantly reduced rebleeding rates at 6, 12, and 24 months. Furthermore, mortality at 24 months was significantly lower for the combined treatment group. Thus, at this time, combination therapy should be recommended as the first line of treatment for secondary prophylaxis of variceal bleeding.

Several controlled trials comparing chronic endoscopic therapy with conventional medical management have been completed. Although fewer patients receiving endoscopic treatment than medical treatment experienced rebleeding in all the investigations, recurrent bleeding still occurred in approximately 50% of endoscopic therapy patients. Rebleeding is most frequent during the initial year, but the rate decreases by about 15% annually thereafter. Although a single episode of recurrent hemorrhage does not signify failure of therapy, uncontrolled hemorrhage, multiple major episodes of rebleeding, and hemorrhage from gastric varices and hypertensive gastropathy all require that endoscopic therapy be abandoned and another treatment modality substituted. Endoscopic treatment failure secondary to rebleeding occurs in as many as one-third of patients. Thus, chronic endoscopic therapy is a rational initial treatment for many patients who bleed from esophageal varices, but subsequent treatment with TIPS, a shunt procedure, a nonshunt operation, or liver transplantation should be anticipated for a significant percentage of patients. Because of its relatively high failure rate, a course of chronic endoscopic therapy should not be undertaken for noncompliant patients and those living a long distance from advanced medical care.

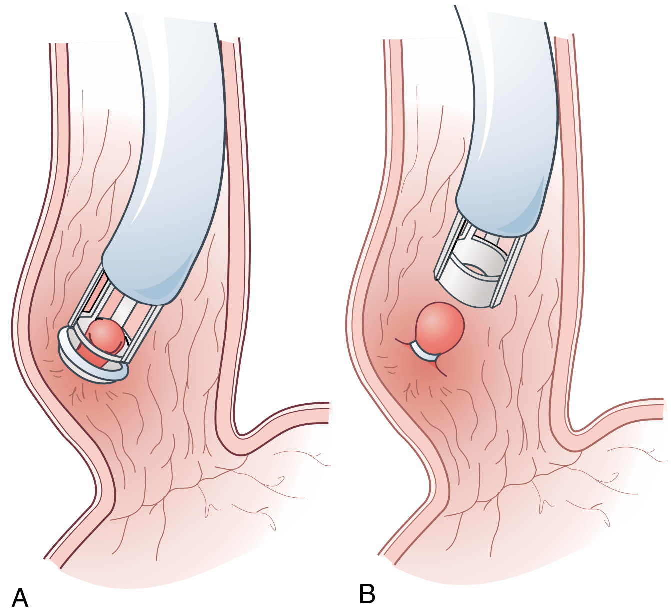

FIGURE 89.20 Endoscopic ligation of esophageal varices. (A) The varix is drawn into the ligator by suction. (B) An O ring is applied. (From Turcotte JG, Roger SE, Eckhauser FE. Portal hypertension. In: Greenfield LJ, Mulholland MW, Oldham KT, eds. *Surgery: Scientific Principles and Practice*. Philadelphia: JB Lippincott; 1993:899.)

Interventional therapy. TIPS is being increasingly used for definitive treatment of patients who bleed from portal hypertension (Fig. 89.21). A major limitation of TIPS, however, is a high incidence (up to 50%) of shunt stenosis or shunt thrombosis within the first year. Shunt stenosis, which is usually secondary to neointimal hyperplasia, is more common than thrombosis and can often be resolved by balloon dilation of the TIPS or, in some cases, by placement of a second shunt. Total shunt occlusion occurs in 10% to 15% of patients. Shunt stenosis and shunt thrombosis are often followed by recurrent portal hypertensive bleeding. TIPS stenosis and occlusion have become less frequent with use of PTFE-covered stents.

TIPS has been compared with chronic endoscopic therapy in 11 randomized controlled trials. Fewer patients rebled after TIPS (19%) than after endoscopic treatment (47%), but encephalopathy was significantly more common in patients undergoing TIPS (34%). TIPS dysfunction developed in 50% of patients. The major advantage of TIPS is that it is a nonoperative approach.

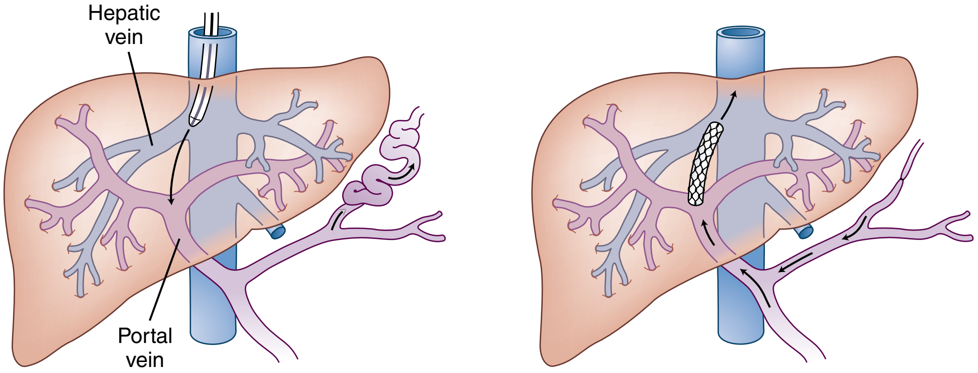

FIGURE 89.21 Transjugular intrahepatic portosystemic shunt placement. The inferior vena cava is accessed through the right internal jugular vein. If the right internal jugular vein is unsuitable, the left internal jugular vein may also be used. Through this access, a 5-Fr catheter is placed into the right hepatic vein and wedged into a peripheral branch. Wedged hepatic venography is then performed with CO_2 gas to opacify the portal venous system. Using the wedged hepatic venogram image as a guide, a needle is advanced through the wall of the right hepatic vein and directed in an anteroinferior direction to access the right portal vein. Once the portal vein is cannulated, CO_2 is injected into the parenchymal tract to exclude transgression of the bile duct or hepatic artery. Once proper placement is confirmed, TIPS endoprosthesis is deployed, which creates a shunt between the portal vein and the hepatic vein, thus decreasing resistance and decompressing varices. *TIPS,* Transjugular intrahepatic portosystemic shunt.

Thus, it would appear to be the ideal therapy when only short-term portal decompression is required. Liver transplantation candidates who fail to respond to endoscopic therapy or pharmacotherapy are therefore well suited for TIPS followed by transplantation when a donor organ becomes available. As a result, the patient is protected from bleeding in the interim, and the transplantation procedure may be facilitated by the lower portal pressure. Another group of patients in whom TIPS may be advantageous includes those with advanced hepatic functional decompensation who are unlikely to survive long enough for the TIPS to malfunction. Because it functions as a side-to-side portosystemic shunt, TIPS is also effective for the treatment of medically intractable ascites.

Surgical therapy. Portosystemic shunts are the most effective at preventing recurrent hemorrhage in patients with portal hypertension. These procedures are effective because they all decompress the portal venous system to varying degrees by shunting portal flow into the lower-pressure systemic venous system. However, diversion of portal blood, which contains hepatotropic hormones, nutrients, and cerebral toxins, is also responsible for the adverse consequences of shunt operations, namely, portosystemic encephalopathy and accelerated hepatic failure. Depending on whether they completely decompress, compartmentalize, or partially decompress the portal venous circulation, portosystemic shunts can be classified as nonselective, selective, or partial. In addition to variceal decompression, selective and partial portosystemic shunts aim to preserve hepatic portal perfusion and therefore to prevent or to minimize the adverse consequences of these procedures.

Nonselective shunts. Commonly used nonselective shunts, all of which completely divert portal flow, include the end-to-side portacaval shunt (Eck fistula), side-to-side portacaval shunt, large-diameter interposition shunts, and conventional splenorenal shunt (Fig. 89.22). The end-to-side portacaval shunt is the prototype of nonselective shunts and is the only shunt procedure that has been compared with conventional medical treatment in randomized controlled trials.

All the other nonselective shunts in Fig. 89.22 maintain continuity of the portal vein, thereby connecting the portal and systemic venous systems in a side-to-side fashion. Therefore, these procedures decompress the splanchnic venous circulation and intrahepatic sinusoidal network. Because the liver and intestines are both important contributors to ascites formation, side-to-side portosystemic shunts are the most effective for relieving ascites and preventing recurrent variceal bleeding. Because they completely divert portal flow, like the end-to-side portacaval shunt, however, side-to-side shunts also accelerate hepatic failure and lead to frequent postshunt encephalopathy.

The conventional splenorenal shunt consists of anastomosis of the proximal splenic vein to the renal vein. Splenectomy is also performed. Because the smaller proximal rather than the larger distal end of the splenic vein is used, shunt thrombosis is more common after this procedure than after the distal splenorenal shunt. Although early series noted that postshunt encephalopathy was less common after the conventional splenorenal shunt than after the portacaval shunt, subsequent analyses have suggested that this low frequency of encephalopathy was probably a result of restoration of hepatic portal perfusion after shunt thrombosis developed in many patients. A conventional splenorenal shunt that is of sufficient caliber to remain patent gradually dilates and eventually causes complete portal decompression and portal flow diversion. A purported advantage of the procedure is that hypersplenism is eliminated by splenectomy. The thrombocytopenia and leukopenia that accompany portal hypertension, however, are rarely of clinical significance, making splenectomy an unnecessary procedure in most patients.

In summary, nonselective shunts effectively decompress varices. Because of complete portal flow diversion, however, they are complicated by frequent postoperative encephalopathy and accelerated hepatic failure. Side-to-side nonselective shunts effectively relieve ascites and prevent variceal hemorrhage. Presently, nonselective shunts are only rarely indicated. TIPS, also a nonselective shunt, is the preferred therapy for most situations in which nonselective shunts were previously used (e.g., patients with both variceal bleeding and medically

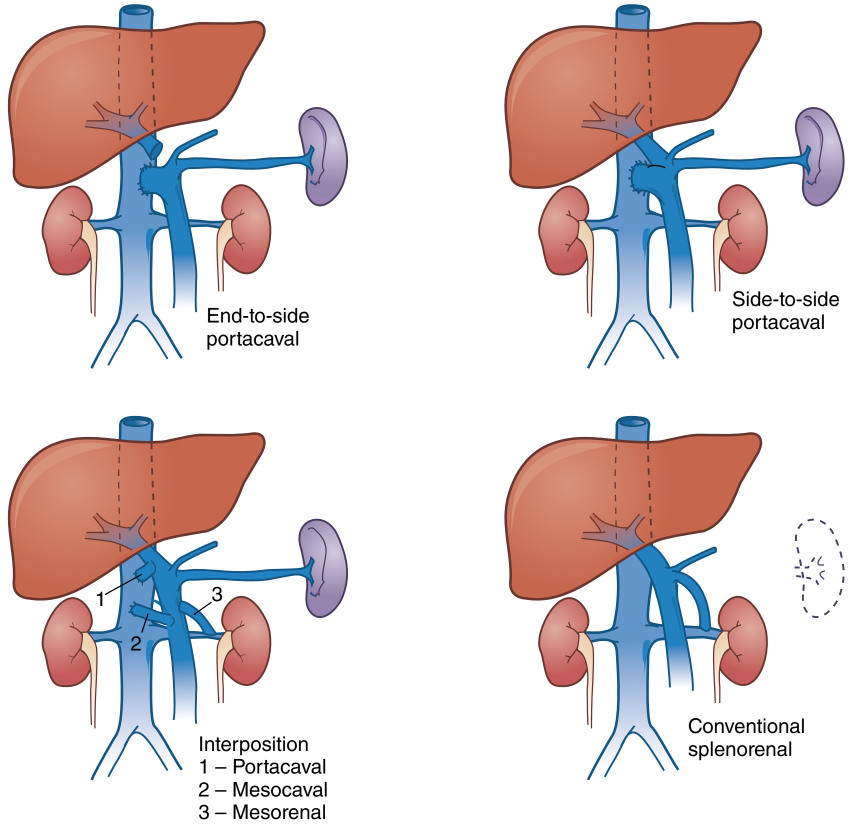

FIGURE 89.22 Nonselective shunts completely divert portal blood flow away from the liver. (From Rikkers LF. Portal hypertension. In: Moody FG, Carey LC, Scott Jones RS, et al., eds. *Surgical Treatment of Digestive Disease*. Chicago: Year Book Medical; 1986:409-424.)

intractable ascites). In general, a nonselective shunt is constructed only when a TIPS cannot be performed or when a TIPS fails.

Selective shunts. The hemodynamic and clinical shortcomings of nonselective shunts stimulated development of the concept of selective variceal decompression. In 1967, Warren and colleagues introduced the distal splenorenal shunt. In the following year, Inokuchi and associates reported their initial results with the left gastric–vena cava shunt, which consists of interposition of a vein graft between the left gastric (coronary) vein and IVC. Therefore, it directly and selectively decompresses esophagogastric varices. However, only a minority of patients with portal hypertension have appropriate anatomy for this operation; experience with it has been limited to Japan, and no controlled trials have been conducted.

The distal splenorenal shunt consists of anastomosis of the distal end of the splenic vein to the left renal vein and interruption of all collateral vessels (e.g., coronary vein and gastroepiploic veins) that connect the superior mesenteric vein and gastrosplenic components of the splanchnic venous circulation (see Fig. 89.23). This results in separation of the portal venous circulation into a decompressed gastrosplenic venous circuit and high-pressure superior mesenteric venous system that continues to perfuse the liver. Although the procedure is technically demanding, it can be mastered by most well-trained surgeons who are knowledgeable in the principles of vascular surgery.

Not all patients are candidates for the distal splenorenal shunt. Because sinusoidal and mesenteric hypertension is maintained and important lymphatic pathways are transected during dissection of the left renal vein, the distal splenorenal shunt tends to aggravate rather than to relieve ascites. Thus, patients with medically intractable ascites should not undergo this procedure. However, the larger population of patients who develop transient ascites after resuscitation from a variceal hemorrhage are candidates for a selective shunt. Another contraindication to a distal splenorenal shunt is prior splenectomy. A splenic vein diameter less than 7 mm is a relative contraindication to the procedure because the incidence of shunt thrombosis is high when a small-diameter vein is used. Although selective variceal decompression is a sound physiologic

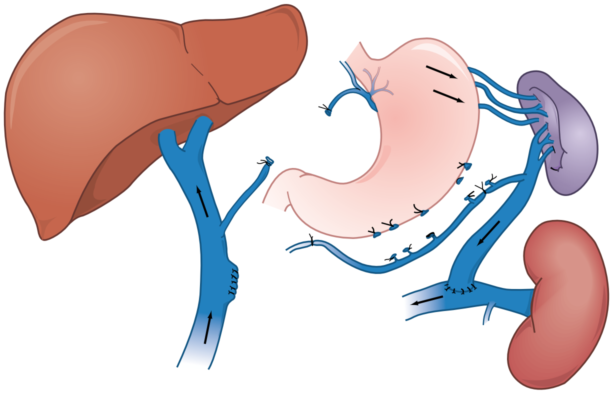

FIGURE 89.23 The distal splenorenal shunt provides selective variceal decompression through the short gastric veins, spleen, and splenic vein to the left renal vein. Hepatic portal perfusion is maintained by interrupting the umbilical vein, coronary vein, gastroepiploic vein, and any other prominent collaterals. (From Salam AA. Distal splenorenal shunts: hemodynamics of total versus selective shunting. In: Baker RJ, Fischer JE, eds. *Mastery of Surgery*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2001:1357-1366.)

concept, the distal splenorenal shunt remains controversial after an extensive clinical experience spanning almost 40 years.

Although the distal splenorenal shunt results in portal flow preservation in more than 85% of patients during the early postoperative interval, the high-pressure mesenteric venous system gradually collateralizes to the low-pressure shunt, resulting in loss of portal flow in approximately 50% of patients by 1 year. The degree and duration of portal flow preservation depend on the cause of portal hypertension and the technical details of the operation (the extent to which mesenteric and gastrosplenic venous circulations are separated). Although portal flow is maintained in most patients with nonalcoholic cirrhosis and noncirrhotic portal hypertension (e.g., PVT), portal flow rapidly collateralizes to the shunt in patients with alcoholic cirrhosis.

Modification of the distal splenorenal shunt by purposeful or inadvertent omission of coronary vein ligation results in early loss of portal flow. Even when all major collateral vessels are interrupted, portal flow may be gradually diverted through a pancreatic collateral network (pancreatic siphon). This pathway can be discouraged by dissecting the full length of the splenic vein from the pancreas, splenopancreatic disconnection, which results in better preservation of hepatic portal perfusion, especially in patients with alcoholic cirrhosis. However, this extension of the procedure makes it technically more challenging and a significant disadvantage in an era when fewer shunts are being placed because of increased use of endoscopic therapy, TIPS, and liver transplantation.

Six of the seven controlled comparisons of the distal splenorenal shunt and nonselective shunts have included predominantly patients with alcoholic cirrhosis. None of these trials has demonstrated an advantage to either procedure with respect to long-term survival. Three of the studies found a lower frequency of encephalopathy after the distal splenorenal shunt, whereas the other trials showed no difference in the incidence of this postoperative complication. In contrast to survival, encephalopathy is a subjective end point that was assessed with various methods in the trials. Another important end point in comparing treatments for variceal hemorrhage was the effectiveness with which recurrent bleeding was prevented. In almost all uncontrolled and controlled series of the distal splenorenal shunt, this procedure was equivalent to nonselective shunts in preventing recurrent hemorrhage. Mainly because of these inconsistent results of the controlled trials, there is no consensus as to which shunting procedure is superior in patients with alcoholic cirrhosis. Because the quality of life (e.g., lower encephalopathy rate) was significantly better in the distal splenorenal shunt group in three of the trials, there appears to be an advantage to selective variceal decompression, even in this population.

Considerably fewer data are available regarding selective shunting in nonalcoholic cirrhosis and noncirrhotic portal hypertension. Because hepatic portal perfusion after the distal splenorenal shunt is better preserved in these disease categories, one might expect improved results. A single controlled trial in patients with schistosomiasis (presinusoidal portal hypertension) has demonstrated a lower frequency of encephalopathy after the distal splenorenal shunt than after a conventional splenorenal shunt (nonselective). Another large series from Emory University has shown that distal splenorenal shunt is associated with better survival in patients with nonalcoholic cirrhosis than in those with alcoholic cirrhosis. However, this has not been a consistent finding in all centers in which the distal splenorenal shunts have been performed.

Several controlled trials have also compared the distal splenorenal shunt with chronic endoscopic therapy. In these investigations, recurrent hemorrhage was more effectively prevented by selective shunting than by sclerotherapy. However, hepatic portal perfusion was maintained in a significantly higher fraction of patients undergoing sclerotherapy. Despite this hemodynamic advantage, encephalopathy rates were similar after both therapies.

The two North American trials were dissimilar with respect to the effect of these treatments on long-term survival. Sclerotherapy with surgical rescue for one-third of sclerotherapy failures resulted in significantly better survival than selective shunt alone, whereas 85% of sclerotherapy failures could be salvaged by surgery. In contrast, a similar investigation conducted in a sparsely populated area (Intermountain West and Great Plains) showed superior survival after the distal splenorenal shunt. Only 31% of sclerotherapy failures could be salvaged by surgery in this trial. The survival results of these two studies suggest that endoscopic therapy is a rational initial treatment for patients who bleed from varices if sclerotherapy failure is recognized, and these patients promptly undergo surgery or TIPS. However, patients living in remote areas are less likely to be salvaged by shunt surgery when endoscopic treatment fails; therefore, a selective shunt may be preferable initial treatment for such patients.

In one nonrandomized comparison to TIPS, the distal splenorenal shunt had lower rates of recurrent bleeding, encephalopathy, and shunt thrombosis. Ascites was less prevalent after TIPS. A multicenter randomized trial comparing TIPS and the distal splenorenal shunt for the elective treatment of variceal bleeding in good-risk patients with cirrhosis has shown generally equivalent results for these two procedures. Rebleeding rates were not significantly different between the distal splenorenal shunt (6%) and TIPS (11%), but this represents the lowest reported rate of rebleeding after TIPS. This was likely secondary to meticulous surveillance of TIPS patency by duplex ultrasound and angiography. Frequent reintervention in TIPS patients (82% compared with 11% for distal splenorenal shunt patients) was necessary to achieve these results. In this trial, postshunt encephalopathy and survival were similar after the two procedures.

Hepatic transplantation. Liver transplantation is not a treatment for variceal bleeding, but rather needs to be considered for all patients who present with end-stage hepatic failure, whether or not it is accompanied by bleeding. Transplantation in patients who have bled secondary to portal hypertension is the only therapy that addresses the underlying liver disease in addition to providing reliable portal decompression. Because of economic factors and a limited supply of donor organs, liver transplantation is not available to all patients. Also, transplantation is not indicated for some of the more common causes of variceal bleeding, such as schistosomiasis (normal liver function) and active alcoholism (noncompliance).

There is accumulating evidence that variceal bleeders with well-compensated hepatic functional reserve (Child-Pugh class A and B+) are initially better served by nontransplantation strategies. The first-line treatment for such patients should be pharmacologic and endoscopic therapy. For those who fail to respond to first-line therapy, an operative shunt or TIPS can be performed. These can also be applied when pharmacologic or endoscopic treatment would be risky, such as patients with gastric varices and those geographically separated from tertiary medical care.

Patients with variceal bleeding who are transplantation candidates include nonalcoholic cirrhotic patients and abstinent alcoholic cirrhotic patients with limited hepatic functional reserve (Child-Pugh class B and C) or a poor quality of life secondary to the disease (e.g., encephalopathy, fatigue, bone pain). In these patients, the acute hemorrhage should be treated with endoscopic therapy and pharmacotherapy and the patient's transplantation candidacy immediately activated. If endoscopic treatment and pharmacotherapy are ineffective, a TIPS should be inserted as a short-term bridge to transplantation.

If a nontransplantation procedure (e.g., operative shunt or TIPS) is performed initially, these patients should be carefully assessed at regular intervals of 6 to 12 months. Hepatic transplantation should be considered when other complications of cirrhosis develop or when hepatic functional decompensation is evident clinically or by careful assessment with quantitative LFTs.

Algorithm for Management of Variceal Hemorrhage

Definitive management of variceal hemorrhage is based on several factors, including cause of portal hypertension, abstinence for patients with alcoholic cirrhosis, presence or absence of other diseases, and physiologic rather than chronologic age. Transplantation candidates with decompensated hepatic function or a poor quality of life secondary to their liver disease should undergo transplantation as soon as possible.

Most future transplantation and nontransplantation candidates should undergo initial endoscopic treatment or pharmacotherapy unless they bleed from gastric varices or portal hypertensive gastropathy or live in a remote geographic location and have limited access to emergency tertiary care. Patients who live in remote locations and those who fail to respond to endoscopic and drug therapy should receive a selective shunt or TIPS. A controlled trial has shown that if careful surveillance of TIPS patency and frequent TIPS reinterventions are done, these procedures are equally efficacious.

Until improvements in TIPS technology are fully realized, the distal splenorenal shunt is likely to remain a more durable long-term solution and a reasonable alternative for TIPS failure. However, a TIPS is more commonly done, and few surgeons who are experienced in shunt surgery remain. Therefore, it is likely that operative shunts will play an even smaller role in the management of variceal bleeding in the future than they do now. Patients with medically intractable ascites in addition to variceal bleeding are best treated with TIPS when less invasive measures fail to control bleeding. If the TIPS eventually fails, an open side-to-side shunt can then be constructed if the patient has reasonable hepatic function and is not a transplantation candidate. On the other hand, TIPS is clearly indicated for patients with endoscopic treatment failure who may require transplantation soon and for nontransplantation candidates with advanced hepatic functional deterioration. Future transplantation candidates should be carefully monitored so that they undergo transplantation at the appropriate time before they become poor operative risks.

The treatment algorithm for variceal bleeding has changed considerably since the 1970s, during which time endoscopic therapy, liver transplantation, and TIPS have become available to these patients. Nontransplantation operations are now less frequently necessary, the survival results are better because patients at high operative risk are managed by other means, and emergency surgery has almost been eliminated.

INFECTIOUS DISEASES

Pyogenic Abscess

Epidemiology

Ochsner and DeBakey, in their classic paper on pyogenic liver abscess in 1938, described 47 cases and reviewed world literature. This was the largest experience at that time and the first serious attempt to study this disease. In that era, pyogenic liver abscess was largely a disease of people in their 20s and 30s, mostly the result of acute appendicitis. With the marked changes in medical care since then, notably effective antibiotics and prompt effective treatments for acute inflammatory disorders, and an aging population, the spectrum of this disease has changed. Pyogenic liver abscess is now mostly seen in patients in their 50s to 60s and is more often related to biliary tract disease or is cryptogenic in nature (Table 89.3). There are no significant sex, ethnic, or geographic differences in disease frequency; the male-to-female ratio is approximately 1.5:1. Comorbid conditions associated with pyogenic abscess are cirrhosis, diabetes, chronic renal failure, and a history of malignant disease.

Pathogenesis

The liver is probably exposed to portal venous bacterial loads on a regular basis and usually clears this bacterial load without problems. The development of a hepatic abscess occurs when an inoculum of bacteria, regardless of the route of exposure, exceeds the liver's ability to clear it. This results in tissue invasion, neutrophil infiltration, and formation of an organized abscess. The potential routes of hepatic exposure to bacteria are the biliary tree, portal vein, hepatic artery, direct extension of a nearby nidus of infection, and trauma. The relative contribution of these routes to the formation of hepatic abscess is summarized in Table 89.3.

Along with cryptogenic infections, infections from the biliary tree are the most common identifiable cause of hepatic abscess. Biliary obstruction results in bile stasis with the potential for subsequent bacterial colonization, infection, and ascension into the liver. This process is known as *ascending suppurative cholangitis.* The nature of biliary obstruction is mostly related to stone disease or malignant disease. In Asia, intrahepatic stones and cholangitis (recurrent pyogenic cholangitis [RPC]; see later) are common causes, whereas in the West, malignant obstruction has become a more predominant cause. Other factors associated with increased risk include Caroli disease, biliary ascariasis, and biliary tract surgery. The common link between all causes of hepatic abscesses from the biliary tree is obstruction and bacteria in the biliary

tract. Prior biliary-enteric anastomosis has also been associated with hepatic abscess formation, likely because of unimpeded exposure of the biliary tree to enteric organisms.

The portal venous system drains the gastrointestinal tract; therefore, any infectious disorder of the gastrointestinal tract can result in an ascending portal vein infection (pylephlebitis), with exposure of the liver to large amounts of bacteria. Historically, untreated appendicitis was considered the most common cause of hepatic abscess, but with the advent of antibiotics and the development of prompt and effective treatment of acute intraabdominal infections, portal venous infections of the liver have become less frequent. The most common causes of pylephlebitis are diverticulitis, appendicitis, pancreatitis, inflammatory bowel disease, pelvic inflammatory disease, perforated viscus, and omphalitis in the newborn. Hepatic abscess has also been associated with colorectal malignant disease. In a case-control study from Taiwan, the incidence of gastrointestinal cancers was increased fourfold among patients with pyogenic liver abscess compared with controls.[6]

Any systemic infection (e.g., endocarditis, pneumonia, osteomyelitis) can result in bacteremia and infection of the liver through the hepatic artery. Microabscess formation is a relatively common finding at autopsy in patients dying of sepsis, but these patients are generally not included in analyses of pyogenic liver abscess. Hepatic abscess from systemic infections may also reflect an altered immune response, such as in patients with malignant disease, AIDS, or disorders of granulocyte function. Children with chronic granulomatous disease are particularly susceptible.

Hepatic abscess can be the result of direct extension of an infectious process. Common examples include suppurative cholecystitis, subphrenic abscess, perinephric abscess, and even perforation of the bowel directly into the liver.

Penetrating and blunt trauma can also result in an intrahepatic hematoma or an area of necrotic liver, which can subsequently develop into an abscess. Bacteria may have been introduced from the trauma, or the affected area may have been seeded from systemic bacteremia. Hepatic abscesses associated with trauma can be manifested in a delayed fashion up to several weeks after injury. Other mechanisms of iatrogenic hepatic necrosis, such as hepatic artery embolization or, more recently, thermal ablative procedures, can be complicated by abscess. This is an uncommon complication of these procedures but is seen more often when there has been a previous biliary-enteric anastomosis.

Usually, no cause for a hepatic abscess is found. Cryptogenic abscesses predominate in many series and are more common in some case reports. Possible explanations for cryptogenic hepatic abscess are undiagnosed abdominal disease, resolved infectious process at the time of presentation, and host factors such as diabetes or malignant disease rendering the liver more susceptible to transient hepatic artery or portal vein bacteremia. In patients with cryptogenic hepatic abscess who have undergone computed tomography (CT) and ultrasonography, it has been argued whether a diligent search for a cause should ensue. In a series evaluating colonoscopy and endoscopic retrograde cholangiopancreatography (ERCP) in patients with cryptogenic abscess, the yield has been low and often is only fruitful in patients with some objective finding that might have suggested a subclinical abnormality (e.g., mildly elevated bilirubin level). In general, these patients should undergo a thorough history, physical examination, and laboratory workup in search of abnormalities in the intestinal tract or biliary tree. Further invasive procedures or imaging studies should be based on clinical suspicions raised by this workup.

Pathology and Microbiology

Most hepatic abscesses involve the right hemiliver, accounting for about 75% of cases. The explanation for this is not known, but preferential laminar blood flow to the right side has been postulated. The left liver is involved in approximately 20% of the cases; the caudate lobe is rarely involved (5%). Bilobar involvement with multiple abscesses is uncommon. Approximately 50% of hepatic abscesses are solitary. Hepatic abscesses can vary in size from less than 1 mm to 3 or 4 cm in diameter and can be multiloculated or a single cavity. At abdominal exploration, hepatic abscesses appear tan and are fluctuant to palpation, although deeper abscesses may not be visible and can be difficult to palpate. Surrounding inflammation can cause adhesions to local structures.

Studies of the microbiology of hepatic abscesses have had variable results, for several reasons. In early series, sterile abscesses were commonly reported but probably reflected inadequate culture techniques, whereas in modern series, few abscesses are sampled before the administration of antibiotics. Also, the heterogeneity of the routes of infection makes the microbiology variable. Abscesses from pylephlebitis or cholangitis tend to be polymicrobial, with a high preponderance of gram-negative bacilli. Systemic infections, on the other hand, usually cause infection with a single organism.

Although the rate of sterility reported by Ochsner's review in 1938 was approximately 50%, series in the 1990s reported sterile abscess rates in approximately 10% to 20% of cases. Many hepatic abscesses are polymicrobial in nature and account for approximately 40% of cases. Some have suggested that solitary abscesses are more likely to be polymicrobial. Anaerobic organisms are involved approximately 40% to 60% of the time. The most common organisms cultured are *Escherichia coli* and *Klebsiella pneumoniae*. Other commonly encountered organisms are *Staphylococcus aureus, Enterococcus* spp., viridans streptococci, and *Bacteroides* spp. *Klebsiella* is frequently associated with gas-forming abscesses. Enterococci and viridans streptococci are generally found in polymicrobial abscesses, whereas staphylococcal infections are typically caused by a single organism. Uncommonly encountered organisms (<10% of cultures) include species of *Pseudomonas, Proteus, Enterobacter, Citrobacter, Serratia,* β-hemolytic streptococci, microaerophilic streptococci, *Fusobacterium, Clostridium,* and other rare anaerobes. Blood cultures are positive in approximately 50% to 60% of cases. Of note, highly resistant organisms in patients with indwelling biliary catheters, multiple episodes of cholangitis, and repeated use of antibiotics are being encountered as the use of these catheters becomes more common. Fungal and mycobacterial hepatic abscesses are rare and are almost always associated with immunosuppression, usually from chemotherapy.

Clinical Features

The classic description of the presenting symptoms of hepatic abscess is fever, jaundice, and right upper quadrant pain, with tenderness to palpation. Unfortunately, this presentation is seen in only 10% of cases. Fever, chills, and abdominal pain are the most common presenting symptoms, but a broad array of nonspecific symptoms can be present (Table 89.4). A study from Taiwan of 133 patients found fever in 96% of patients, chills in 80%, abdominal pain in 53%, and jaundice in 20%. Many of the symptoms, such as malaise and vomiting, were constitutional in nature. Involvement of the diaphragm may result in symptoms of cough or dyspnea. Rarely, patients can present with peritonitis secondary to rupture. Cases of rupture into the pleural space or

[a] From Ochsner A, DeBakey M, Murray S. Pyogenic abscess of the liver. *Am J Surg.* 1938;40:292-319. This is the classic study of Ochsner and DeBakey that reviewed 286 previously reported cases and 47 new cases.

pericardium have been reported but are distinctly uncommon. The duration of symptoms is variable, ranging from an acute presentation to a chronic illness lasting months. It has been suggested that acute presentation is associated with identifiable abdominal disease, whereas chronic presentation is often associated with a cryptogenic abscess. A rare complication specific to *Klebsiella* hepatic abscesses is endogenous endophthalmitis, occurring in approximately 3% of cases. This serious complication is more common in patients with diabetes. The best chance to preserve visual function is with early diagnosis and treatment.

On physical examination, fever and right upper quadrant tenderness are the most common findings. Tenderness is present in 40% to 70% of patients. Jaundice is also found in approximately 25% of cases and is often secondary to underlying biliary disease. Chest findings are often found in approximately 25% of patients, and hepatomegaly is also commonly noted in approximately 50%. Ascites, splenomegaly, and severe sepsis are uncommon signs of hepatic abscesses.

Nonspecific abnormalities of blood tests are common in pyogenic abscesses. Leukocytosis is present in 70% to 90% of patients, and anemia is commonly encountered. Abnormalities of LFT results are generally present. The ALP level is mildly elevated in 80% of patients, whereas total bilirubin concentration is elevated 20% to 50% of the time. Transaminases are mildly elevated in approximately 60% of patients. Severe abnormalities of liver function are almost always associated with underlying biliary disease. Hypoalbuminemia or mild elevations of the PT and INR can be present and reflect a degree of chronicity. None of these blood tests specifically help diagnose a hepatic abscess. However, together, they may suggest a liver abnormality that often leads to imaging studies.

The most essential element to establishing the diagnosis of hepatic abscess is radiographic imaging. Chest radiographs are abnormal approximately 50% of the time, and findings generally reflect subdiaphragmatic disease, such as an elevated right hemidiaphragm, right pleural effusion, or atelectasis. On occasion, these can be left-sided findings in the case of an abscess involving the left liver. Plain abdominal radiographs, in rare cases, can be helpful. They can show air-fluid levels or portal venous gas (Fig. 89.24).

Ultrasound and CT are the mainstays of diagnostic modalities for hepatic abscess. Ultrasound usually demonstrates a round or oval area less echogenic than the surrounding liver. Ultrasound can reliably distinguish solid from cystic lesions. The limitations of ultrasound are in its ability to visualize lesions high up in the dome of the liver and that it is a user-dependent modality. The sensitivity of ultrasound in diagnosing hepatic abscess is 80% to 95%. CT demonstrates similar findings to ultrasound, and lesions are of lower attenuation than surrounding hepatic parenchyma. High-quality CT scans can demonstrate very small abscesses and can more easily identify multiple small abscesses. The abscess wall usually has an intense enhancement on contrast-enhanced CT. The sensitivity of CT in diagnosing hepatic abscess is 95% to 100%. Both CT and ultrasound are useful in diagnosing other intraabdominal pathologic processes, such as biliary disease (ultrasound) and inflammatory disorders such as appendicitis and diverticulitis (CT). Magnetic resonance imaging (MRI) can help distinguish the cause of many hepatic masses and in evaluating the biliary tree for pathologic changes, but it does not appear to have any distinct advantage over CT in diagnosing hepatic abscess.

Differential Diagnosis

Differentiating pyogenic abscess from other cystic infective diseases of the liver, such as amebic abscess or echinococcal cyst, is important because of differences in treatment. Pyogenic abscess (see later) is largely treated by antibiotics and drainage. Amebic abscess is mainly treated by antibiotics, whereas echinococcal cysts

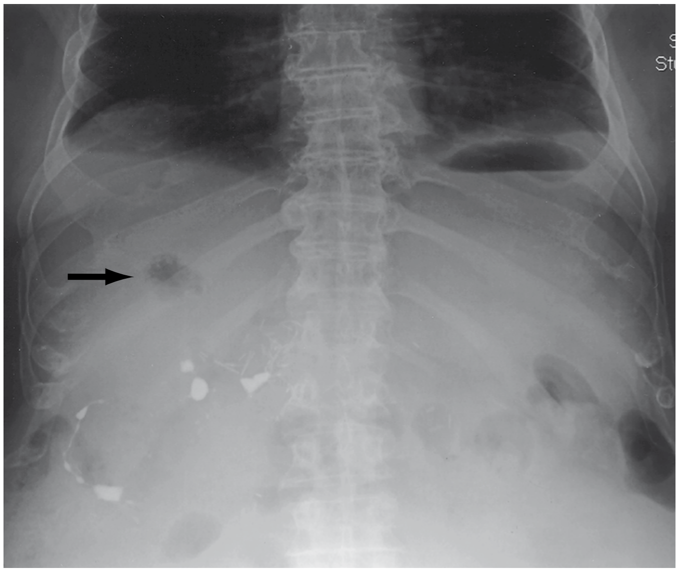

FIGURE 89.24 Plain abdominal radiograph demonstrating an abnormal collection of air in the right upper quadrant consistent with a pyogenic hepatic abscess *(arrow)*.

TABLE 89.5 Features of Amebic Versus Pyogenic Liver Abscess

CLINICAL FEATURES	AMEBIC ABSCESS	PYOGENIC ABSCESS
Age	20–40 years	>50 years
Male-to-female ratio	≥10:1	1.5:1
Solitary versus multiple	Solitary 80%[a]	Solitary 50%
Location	Usually right liver	Usually right liver
Travel in endemic area	Yes	No
Diabetes	Uncommon (~2%)	More common (~27%)
Alcohol use	Common	Common
Jaundice	Uncommon	Common
Elevated bilirubin	Uncommon	Common
Elevated alkaline phosphatase	Common	Common
Positive blood culture	No	Common
Positive amebic serology	Yes	No

[a] In acute amebic abscess, 50% are solitary.

often require surgical management. Fortunately, echinococcal cysts can usually be diagnosed by history and characteristic radiologic findings (see later). The presentations of amebic and pyogenic abscess, however, are more similar, with some notable exceptions that are critical in distinguishing the two (Table 89.5). Amebic abscesses generally occur in young Hispanic males, whereas pyogenic abscess tends to occur in patients 50 to 60 years of age, with no predominant sex or race. Fever is common in both, but chills and symptoms of severe acute bacteremia are more common in pyogenic abscess. On serologic testing, *Entamoeba histolytica* antibodies are almost always present in amebic abscesses but are uncommon in patients with pyogenic abscess. A study comparing 471 patients with amebic abscess with 106 patients with pyogenic abscess found age older than 50 years, pulmonary findings on physical examination, multiple abscesses, and low amebic serology titers to be independently predictive of pyogenic abscess. On occasion, differentiating the two is not possible, and diagnostic aspiration or a trial of antiamebic antibiotics may be necessary. Unfortunately, aspiration is diagnostic in amebic abscess only approximately 10% to 20% of the time.[7]

Treatment

Before the availability of antibiotics and the routine use of drainage procedures, untreated hepatic pyogenic abscess was almost uniformly fatal. It was not until the classic review by Ochsner and DeBakey in 1938 (see earlier) that routine surgical drainage was used and dramatic reductions in mortality were noted. Open surgical drainage of pyogenic abscesses was the sole treatment (with the addition of antibiotics eventually) for hepatic abscess until the 1980s. Since then, less invasive percutaneous drainage techniques and IV antibiotics have been used. Laparotomy is generally reserved for failures of percutaneous drainage.

Once the diagnosis of pyogenic hepatic abscess is suspected, broad-spectrum IV antibiotics should be started immediately to control ongoing bacteremia and its associated complications. Blood samples and specimens of abscess from aspiration should be sent for aerobic and anaerobic cultures. In immunosuppressed patients, mycobacterial and fungal cultures of the aspirate should be considered. Patients who are at risk for amebic infections should have blood samples drawn for amebic serology. Until cultures have specifically identified the offending organisms, broad-spectrum antibiotics covering gram-negative, gram-positive, and anaerobic organisms should be used. Combinations such as ampicillin, an aminoglycoside, and metronidazole or a third-generation cephalosporin with metronidazole are appropriate. The optimal duration of antibiotic treatment is not well defined and must be individualized, depending on the success of the drainage procedure. Antibiotics should certainly be continued while there is evidence of ongoing infection, such as fever, chills, or leukocytosis. Beyond this, it is unclear how long to continue antibiotics, but recommendations are usually for 2 weeks or more.

Percutaneous drainage for pyogenic hepatic abscesses was first reported in 1953 but did not gain widespread acceptance until the 1980s with the development of high-quality imaging and expertise in interventional radiologic techniques. During the past 25 years, percutaneous catheter drainage has become the treatment of choice for most patients (Fig. 89.25). Success rates range from 66% to 90%. The obvious advantages are the simplicity of treatment (usually at the time of radiologic diagnosis) and avoidance of general anesthesia and a laparotomy. Relative contraindications to percutaneous catheter drainage include the presence of ascites, coagulopathy, and proximity to vital structures. Percutaneous drainage of multiple abscesses is usually met with a higher failure rate, but reports have demonstrated a high enough success rate that percutaneous approaches should be made first, reserving surgery for failures. A retrospective study comparing surgical with percutaneous drainage for large abscesses (>5 cm) has shown a better success rate with surgical drainage. Despite this, two-thirds of percutaneous treatments were successful, and the overall morbidity and mortality rates were similar. There has never been a randomized prospective comparison between percutaneous and surgical therapy for hepatic abscess. However, case series have suggested that for most cases, there are similar success and mortality rates. Modern series attempting to compare these two techniques retrospectively must be read with caution because most patients treated surgically have failed to respond to other, less invasive techniques. In general, surgery should be reserved for patients who require surgical treatment of the primary pathologic process (e.g., appendicitis) or for those who have failed to respond to percutaneous techniques. Laparoscopic drainage procedures have been reported with some success, and this can be considered a reasonable option to pursue in select cases.

Percutaneous aspiration without the placement of an indwelling drain has been investigated by several groups. Success rates are generally 60% to 90% and somewhat similar to percutaneous catheter drainage.[8] Most patients, however, require more than one aspiration, and 25% of patients require three or more aspirations. One randomized trial has evaluated percutaneous aspiration versus percutaneous catheter drainage. Success rates were 60% in the aspiration group and 100% in the catheter group. All but one patient in the aspiration group had a single aspiration. Another randomized trial of 64 patients has compared aspiration alone with catheter drainage. There were similar outcomes in terms of treatment success rate, hospital stay, antibiotic duration, and mortality. In the aspiration-only group, 40% required two aspirations and 20% required three aspirations. In general, catheter drainage remains the treatment of choice, although a trial of a single aspiration is reasonable to consider.

Some investigators have reported success with antibiotics alone. Most of these patients, however, have had a diagnostic aspiration and thus at least a partial drainage. Also, other series have reported that antibiotic treatment without drainage carries a prohibitively high mortality (59%–100%). In patients who are not

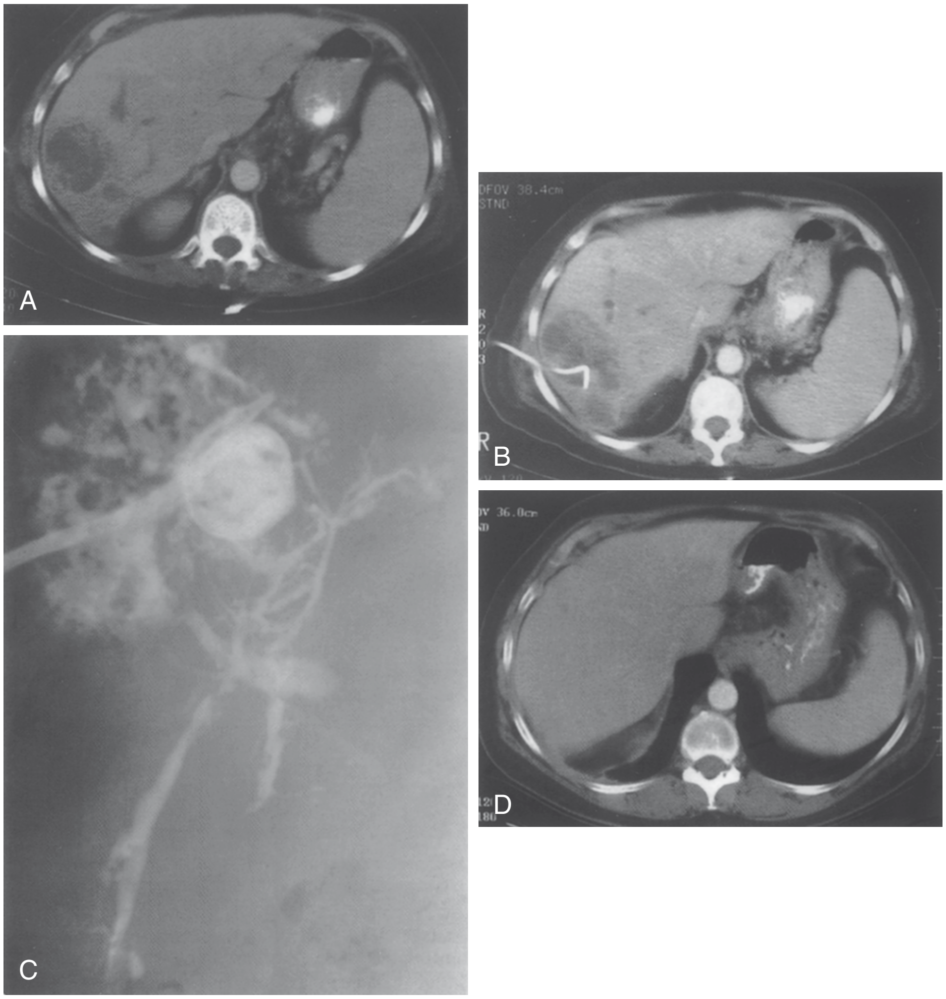

FIGURE 89.25 (A) Computed tomography (CT) scan demonstrating multiloculated hepatic abscess in the right liver. (B) CT scan at the time of percutaneous drainage. (C) Contrast study through the drainage catheter demonstrating typical irregular loculated appearance as well as communication with biliary tree. (D) Follow-up CT scan 3 months after treatment demonstrating complete resolution of abscess. (From Brown KT, Getrajdman GI. Interventional radiologic techniques in the liver and biliary tract. In: Blumgart LH, Fong Y, eds. *Surgery of the Liver and Biliary Tract*. London: WB Saunders; 2000:575-594.)

surgical candidates or who refuse any invasive procedure, an attempt at antibiotic treatment is reasonable. However, this is not recommended in other situations.

Liver resection is occasionally required for hepatic abscess. This may be required for an infected hepatic malignant neoplasm, hepatolithiasis, or intrahepatic biliary stricture. If hepatic destruction from infection is severe, some patients may benefit from resection.

Outcomes

Mortality from pyogenic hepatic abscess has dramatically improved during the past 70 years. Before the routine use of surgical drainage, pyogenic abscess was uniformly fatal. With the routine use of surgical drainage and the use of IV antibiotics, mortality was reduced to approximately 50%, a figure that stayed relatively constant from 1945 until the early 1980s. Since then, the mortality has been reported from 10% to 20%, and series from the 1990s have demonstrated a mortality rate below 10%.[8] The most recent series from Memorial Sloan Kettering Cancer Center (MSKCC) has reported a 3% mortality. Several studies have analyzed factors predictive of a poor outcome in patients with hepatic pyogenic abscess. The presence of malignant disease, factors associated with malignant disease (e.g., jaundice, markedly elevated LFT results), and signs of sepsis appear to be consistent markers of poor prognosis. Signs of chronic disease, such as hypoalbuminemia, are also often associated with a poor outcome. Finally, signs of severe infection, such as marked leukocytosis, APACHE II (Acute Physiology and Chronic Health Evaluation II) scores, abscess rupture, bacteremia, and shock, are also associated with mortality.

Amebic Abscess

Epidemiology

Amebiasis is largely a disease of tropical and developing countries but is also a significant problem in developed countries because of immigration and travel between countries. *E. histolytica* is endemic in Mexico, India, Africa, and parts of Central and South America. In 1995, the World Health Organization estimated that 40 to 50 million people suffer from amebic colitis or amebic liver abscess worldwide, resulting in 40,000 to 100,000 deaths each year.[7] Before this, estimates of amebiasis were unreliable because *E. histolytica* (the pathogenic form) was not differentiated from

Entamoeba dispar (the nonpathogenic form). Male homosexuals with diarrhea, previously thought to harbor *E. histolytica,* were found to be infected with *E. dispar,* which requires no treatment. Epidemiologic studies specifically addressing *E. histolytica* infections have estimated that 55% of those in endemic regions are infected, although less than 50% are symptomatic.

In contrast to pyogenic hepatic abscesses, patients with amebic liver abscesses tend to be Hispanic males 20 to 40 years of age with a history of travel to (or origination from) an endemic area. Poverty and cramped living conditions are associated with higher rates of infection. A male preponderance of more than 10:1 has been reported in almost all studies. For unclear reasons, menstruating females have a low incidence of invasive amebiasis, and pregnancy appears to abrogate this resistance. Heavy alcohol consumption is commonly reported and may render the liver more susceptible to amebic infection. Patients with impaired host immunity also appear to be at higher risk of infection and have higher mortality rates. Patients with amebic liver abscess without a history of travel to an endemic area often have associated immunosuppression, such as human immunodeficiency virus (HIV) infection, malnutrition, chronic infection, or chronic steroid use.

Pathogenesis

E. histolytica is a protozoan and exists as a trophozoite or a cyst. All other species in the genus *Entamoeba* are considered nonpathogenic, and not all strains of *E. histolytica* are considered virulent. Ingestion of *E. histolytica* cysts through a fecal-oral route is the cause of amebiasis. Humans are the principal host, and the main source of infection is human contact with a cyst-passing carrier. Contaminated water and vegetables are also sources of human infection. Once ingested, the cysts are not degraded in the stomach and pass to the intestines, where the trophozoite is released and passed on to the colon. In the colon, the trophozoite can invade mucosa, resulting in disease.

It is thought that the trophozoites reach the liver through the portal venous system. There is no evidence for trophozoites passing through lymphatics. As implied by its name, *E. histolytica* trophozoites can lyse tissues through complex events, including cell adherence, cell activation, and subsequent release of enzymes, resulting in necrosis. The principal mechanism is probably enzymatic cellular hydrolysis. Amebic liver abscesses are formed by progressing, localized hepatic necrosis producing a cavity containing acellular proteinaceous debris surrounded by a rim of invasive amebic trophozoites. Early development of an amebic liver abscess is associated with an accumulation of polymorphonuclear leukocytes, which are then lysed by the trophozoites.

Antiamebic antibodies develop rapidly in patients with invasive disease or an amebic hepatic abscess. Secretory immunoglobulin A (IgA) antibodies have been shown to inhibit adherence to colonic epithelium in vitro. However, the development of these antibodies does not halt the progression of disease. Interestingly, children who lack antiamebic IgG have innate resistance to invasive infection, suggesting an alternative immune-mediated response. There is now evidence that a cell-mediated helper T-cell response is probably the major mechanism of resistance.

Pathology

Hepatic amebic abscess is essentially the result of liquefaction necrosis of the liver, producing a cavity full of blood and liquefied liver tissue. The appearance of this fluid is typically described as resembling anchovy sauce; the fluid is odorless unless secondary bacterial infection has taken place. The progressive hepatic necrosis continues until the Glisson capsule is reached because the capsule is resistant to hydrolysis by the amebae. Thus, amebic abscesses tend to abut the liver capsule. Because of the resistance of the Glisson capsule, the cavity is typically crisscrossed by portal triads protected by this peritoneal sheath. Early on, the formed cavity is ill-defined, with no real fibrous response around the edges. However, a chronic abscess can ultimately develop a fibrous capsule and may even calcify. Like pyogenic abscesses, amebic abscesses tend to occur mainly in the right liver.

Clinical Features

Approximately 80% of patients with amebic liver abscess present with symptoms lasting from a few days to 4 weeks. The duration of symptoms has been found to be typically less than 10 days. The presenting clinical signs and symptoms are summarized in Table 89.6. The typical clinical picture is a patient 20 to 40 years of age who has recently traveled to an endemic area, with fever, chills, anorexia, right upper quadrant pain and tenderness, and hepatomegaly. The abdominal pain is typically constant, dull, and localized to the right upper quadrant. Although some studies report higher numbers, approximately 25% of patients have diarrhea despite an obligatory colonic infection. Synchronous hepatic abscess is found in one-third of patients with active amebic colitis. Jaundice, as a result of a large abscess compressing the biliary tree, is not as rare as was once thought, with an average 22% of patients presenting with this feature worldwide. Weight loss and myalgias may occur when symptoms have been present for weeks. Pleuritic or right shoulder pain can occur if there is irritation of the right hemidiaphragm. Symptoms and tenderness may be epigastric or left sided if the abscess is in the left liver. Rupture into the peritoneum with peritonitis occurs infrequently; when it does occur, it is more often with left-sided

TABLE 89.6 Signs, Symptoms, and Laboratory Findings in Amebic Liver Abscess[a]

PARAMETER	AVERAGE	RANGE	NO. OF CASES REVIEWED
Symptoms and Signs			
Abdominal pain (%)	92	73–100	1701
Fever (%)	90	72–100	2192
Abdominal tenderness (%)	78	40–100	1424
Hepatomegaly (%)	62	20–100	1539
Anorexia (%)	47	28–89	499
Weight loss (%)	39	11–83	871
Diarrhea (%)	23	12–40	1426
Jaundice (%)	22	5–50	1630
Laboratory Tests			
Stool cysts, trophozoites (%)	12	4–30	4908
Amebae in cyst aspirate (%)	42	30–76	1402
Hemoglobin (g/dL)	12.1	10.2–12.8	229
Alkaline phosphatase (% >120 U/L)	76	65–91	589
Total bilirubin (g/dL)	1.4	0.8–2.4	509
Albumin (g/dL)	2.8	2.3–3.4	404
AST (× upper limit normal)	1.7	1.0–2.5	459

[a] In an extensive literature review.

abscesses. Rare cases of rupture into the pleural space, pericardium, and other intraabdominal organs have also been reported.

Patients presenting acutely (symptoms <10 days) versus those with a chronic presentation (>2 weeks) differ clinically. Acute presentations are typically more dramatic, with high fevers, chills, and significant abdominal tenderness. In the acute presentation, 50% of patients have multiple lesions, whereas with the chronic presentation, more than 80% of patients have a single right-sided lesion. A more complicated course tends to ensue in the acute presentation, but response to therapy is similar in both groups.

Laboratory abnormalities are common in amebic abscess (see Table 89.6). Patients typically have mild to moderate leukocytosis, without eosinophilia. Anemia is common. Mild abnormalities of LFT results, including albumin, PT-INR, ALP, AST, and bilirubin levels, are typical. The most common LFT abnormality is an elevated PT-INR. Because more than 70% of patients with amebic liver abscess do not have detectable amebae in their stool, the most useful laboratory evaluation is the measurement of circulating antiamebic antibodies, which are present in 90% to 95% of patients. Many serologic tests have been devised over the years. An indirect hemagglutinin test was used extensively in the past and has a sensitivity of 90%. This test has largely been replaced by enzyme immunoassays, which detect presence of antibodies against the parasite and are simple, rapidly performed, and inexpensive. An enzyme immunoassay has a reported sensitivity of 99% and specificity higher than 90% in patients with hepatic abscess. Unfortunately, the presence of antibodies may reflect prior infection, and interpretation can be difficult in endemic areas. Ongoing studies are focusing on identifying specific *E. histolytica* antigens to identify acute infection. The antigen detection kits have been evaluated in endemic areas. These kits can detect the *E. histolytica* lectin antigen in the serum and liver abscess pus and in small studies have been shown to have high sensitivity. However, the sensitivity may decrease if the test is performed after treatment with metronidazole.

Radiologic studies are a critical element in the diagnosis of amebic liver abscess. Plain chest radiographs are abnormal in approximately 50% of cases, usually demonstrating an elevated right diaphragm, pleural effusion, or atelectasis. Abdominal ultrasound has a reported accuracy of approximately 90% when combined with a typical history and clinical presentation. Typical findings on abdominal ultrasound are a rounded lesion abutting the liver capsule (see earlier) without significant rim echoes, interpreted as an abscess wall. The contents of the cavity are usually hypoechoic and nonhomogeneous (Fig. 89.26). These findings on ultrasound are found in 40% to 70% of cases. Abdominal CT scanning is probably more sensitive than ultrasound and is helpful in differentiating amebic from pyogenic abscess, with rim enhancement noted in the pyogenic abscess (Fig. 89.27). CT can also help identify simple cysts and necrotic tumors. MRI of the liver has no distinct advantages over CT or ultrasound in typical cases but may be helpful in differentiating atypical lesions. Nuclear medicine studies, such as gallium scanning or technetium-99m liver scans, can be helpful in differentiating pyogenic from amebic abscesses because the amebic abscesses typically do not contain leukocytes and therefore do not light up on these scans.[9]

When this workup is still not definitive and diagnostic uncertainty persists, two options should be considered. First, a therapeutic trial of antiamebic drugs can be used. If a rapid improvement occurs, this supports the diagnosis. In situations in which amebic serology is inconclusive and a therapeutic trial of antibiotics is deemed inappropriate or has failed to improve symptoms, the second option, a diagnostic aspiration, should be considered. A pyogenic abscess would have bacteria and leukocytes, whereas an amebic abscess would contain the typical so-called anchovy sauce. Cultures of amebic abscess are usually negative and do not contain leukocytes. In patients for whom neoplasm or hydatid disease is in the differential diagnosis, aspiration should not be performed.

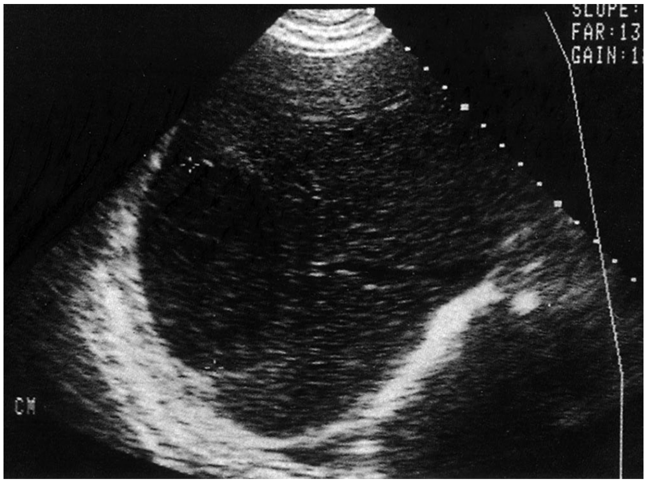

FIGURE 89.26 Typical ultrasound image of an amebic hepatic abscess. Note the peripheral location, rounded shape with poor rim, and internal echoes. (From Thomas PG, Ravindra KV. Amebiasis and biliary infection. In: Blumgart LH, Fong Y, eds. *Surgery of the Liver and Biliary Tract*. London: WB Saunders; 2000:1147-1166.)

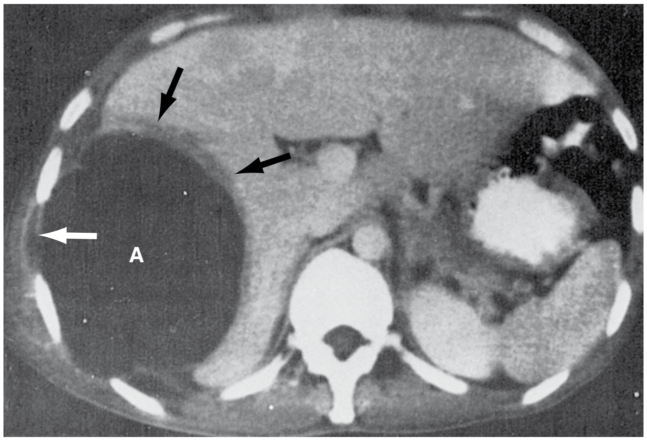

FIGURE 89.27 Computed tomography scan of amebic abscess *(A)*. The lesion is peripherally located and round. The rim is nonenhancing but shows peripheral edema *(black arrows)*. Note the extension into the intercostal space *(white arrow)*.

Differential Diagnosis

The differential diagnosis of an amebic liver abscess can be broad and include diseases such as viral hepatitis, echinococcal disease, cholangitis, cholecystitis, and even other inflammatory abdominal disorders, such as appendicitis. Malignant lesions of the liver can also have similar presentations in atypical situations. On occasion, primary pulmonary disorders must be considered. Usually, the most important distinction to be made is between pyogenic and amebic abscess. The essential elements of this distinction are summarized in Table 89.5 and in the earlier section on pyogenic abscess.

Treatment

The mainstay of treatment for amebic abscesses is metronidazole (750 mg orally, three times daily for 10 days), which is curative in more than 90% of patients. Clinical improvement is usually seen within 3 days. Other nitroimidazoles (e.g., secnidazole, tinidazole) are also as effective and are commonly used outside the United States. If response to metronidazole is poor or the drug is not tolerated, other agents can be used. Emetine hydrochloride is effective against invasive amebiasis, particularly in the liver, but requires intramuscular injections and has serious cardiac side effects. A more attractive option is chloroquine, but this is a less effective agent. After treatment of the liver abscess, it is recommended that luminal agents such as iodoquinol, paromomycin, and diloxanide furoate be administered to treat the carrier state.

Therapeutic needle aspiration of amebic abscesses has been proposed. However, a Cochrane systematic review did not support any benefit of therapeutic aspiration in addition to metronidazole treatment over metronidazole treatment alone to hasten clinical or radiologic resolution of amebic liver abscesses.[10] In general, aspiration is recommended for diagnostic uncertainty (see earlier), with failure to respond to metronidazole therapy in 3 to 5 days, or in abscesses thought to be at high risk for rupture. Abscesses larger than 5 cm in diameter and in the left liver are thought to carry a higher risk of rupture, and aspiration should be considered.

Outcomes

Although amebic liver abscesses usually respond rapidly to treatment, there are uncommon complications of which one must be aware. The most frequent complication of amebic abscess is rupture into the peritoneum, pleural cavity, or pericardium. The size of the abscess appears to be the most important risk factor for rupture, and the overall incidence of rupture ranges from 3% to 17%. Most peritoneal ruptures tend to be contained by the diaphragm, abdominal wall, or omentum, but rupture can fistulize into a hollow viscus. A peritoneal rupture usually is manifested as abdominal pain, peritonitis, and a mass or generalized distention. Laparotomy was advocated in the past for this complication, but now many patients are treated successfully with percutaneous drainage. Laparotomy is indicated in cases of doubtful diagnosis, hollow viscus perforation, fistulization resulting in hemorrhage or sepsis, and failure of conservative therapy. Rupture into the pleural space usually results in a large and rapidly accumulating effusion that collapses the involved lung. Treatment consists of thoracentesis, but if secondary bacterial infection ensues, more aggressive surgical approaches may be necessary. Rupture can occur into the bronchi and is usually self-limited with postural drainage and bronchodilators. Rarely, a left-sided abscess may rupture into the pericardium and can be manifested as an asymptomatic pericardial effusion or even tamponade. This must be treated with aspiration or drainage through a pericardial window. Other complications include compression of the biliary tree or IVC from a very large abscess and the development of a brain abscess.

The mortality for all patients with amebic liver abscess is approximately 5% and does not appear to be affected by the addition of aspiration to metronidazole therapy or by chronicity of symptoms. When an abscess ruptures, mortality ranges from 6% to as high as 50%. Factors independently associated with poor outcome are elevated serum bilirubin level (>3.5 mg/dL), encephalopathy, hypoalbuminemia (<2.0 g/dL), multiple abscess cavities, abscess volume larger than 500 mL, anemia, and diabetes. Although clinical improvement after adequate treatment with antiamebic agents is the rule, radiologic resolution of the abscess cavity is usually delayed. The average time to radiologic resolution is 3 to 9 months, and in some patients, it can take years. Studies have shown that more than 90% of the visible lesions disappear radiologically, but a small percentage of patients are left with a clinically irrelevant residual lesion.

Hydatid Cyst

Hydatid disease, or echinococcosis, is a zoonosis that occurs primarily in sheep-grazing areas of the world but is common worldwide because the dog is a definitive host. Echinococcosis is endemic in Mediterranean countries, the Middle East, Far East, South America, Australia, New Zealand, and east Africa.[11] Humans contract the disease from dogs, but there is no human-to-human transmission.

Three species cause hydatid disease. *Echinococcus granulosus* is the most common, and *Echinococcus multilocularis* and *Echinococcus ligartus* account for a small number of cases.[11] Dogs are the definitive host of *E. granulosus;* the adult tapeworm is attached to the villi of the ileum. Up to thousands of ova are passed daily and deposited in the dog's feces. Sheep are the usual intermediate host, but humans are an accidental intermediate host. Humans are an end stage to the parasite. In the human duodenum, the parasitic embryo releases an oncosphere containing hooklets that penetrate the mucosa, allowing access to the bloodstream. In the blood, the oncosphere reaches the liver (most commonly) or lungs, where the parasite develops its larval stage—the hydatid cyst.

Three weeks after infection, a visible hydatid cyst develops, which then slowly grows in a spherical manner. A pericyst, or fibrous capsule derived from host tissues, develops around the hydatid cyst. The cyst wall itself has two layers: an outer gelatinous membrane (ectocyst) and an inner germinal membrane (endocyst). Brood capsules are small, intracystic cellular masses in which future worm heads develop into scoleces. In a definitive host, the scoleces develop into an adult tapeworm; in the intermediate host, they can differentiate only into a new hydatid cyst. Freed brood capsules and scoleces are found in the hydatid fluid and form the so-called hydatid sand. Daughter cysts are true replicas of the mother cyst. Hydatid cysts can die with degeneration of the membranes, development of cystic vacuoles, and calcification of the wall. Calcification of a hydatid cyst, however, does not always imply that the cyst is dead.

Hydatid cysts are diagnosed in equal numbers of males and females at an average age of about 45 years. Approximately 75% of hydatid cysts are located in the right liver and are solitary. The clinical presentation of a hydatid cyst is largely asymptomatic until complications occur. The most common presenting symptoms are abdominal pain, dyspepsia, and vomiting. The most frequent sign is hepatomegaly. Jaundice and fever are each present in approximately 8% of patients. Bacterial superinfection of a hydatid cyst can occur and manifest like a pyogenic abscess. Rupture of the cyst into the biliary tree or bronchial tree or free rupture into the peritoneal, pleural, or pericardial cavities can occur. Free ruptures can result in disseminated echinococcosis or a potentially fatal anaphylactic reaction. In cases of diagnostic uncertainty, a battery of serologic tests are available to evaluate antibody response, but all are plagued by low sensitivity and specificity.

Ultrasound is most commonly used worldwide for the diagnosis of echinococcosis because of its availability, affordability, and accuracy. Several findings on ultrasound can be diagnostic but depend on the stage of the cyst at the time of the examination. A simple hydatid cyst is well circumscribed with budding signs on the cyst membrane and may contain free-floating hyperechogenic hydatid sand. A rosette appearance is seen when daughter cysts are present. The cyst can be filled with an amorphous mass, which can be diagnostically misleading. Calcifications in the wall of the cyst are highly suggestive of hydatid disease and can be helpful in the diagnosis (Fig. 89.28). Similar findings are seen on CT or MRI scans. These cross-sectional imaging studies can also evaluate extrahepatic disease and demonstrate detailed hepatic anatomic relationships to the cyst. In patients with suspected biliary involvement, ERCP or percutaneous transhepatic cholangiography may be necessary.

Although the treatment of hepatic hydatid cysts is primarily surgical, alternative options are in evolution.[12] In general, most cysts should be treated, but in older patients with small, asymptomatic, densely calcified cysts, conservative management is appropriate. In preparation for an operation, preoperative steroids have been recommended but are not universally used. The anesthesiologist should have epinephrine and steroids available in case of an anaphylactic reaction. Many operations have been used, but in general, the abdomen is completely explored, the liver mobilized, and the cyst exposed. Packing off the abdomen is important because rupture can result in anaphylaxis and diffuse seeding. The cyst is usually then aspirated through a closed suction system and flushed with a scolicidal agent, such as hypertonic saline. It is then unroofed, which can be followed by several possibilities, including excision (or pericystectomy), marsupialization procedures, leaving the cyst open, drainage of the cyst, omentoplasty, and partial hepatectomy to encompass the cyst. Total pericystectomy or formal partial hepatectomy can also be performed without entering the cyst (Fig. 89.29). Both radical (resection) and conservative (drainage and evacuation) surgical approaches appear to be equally effective at controlling disease, although a prospective comparison has never been performed. When bile duct communication is diagnosed preoperatively or at operation, it must be meticulously sought after. Simple suture repair is often sufficient, but major biliary repairs, approaches through the common bile duct, or postoperative ERCP may be necessary. Laparoscopic techniques for drainage and unroofing of cysts have been reported in many series, with encouraging results.[13] Recurrence rates after surgical treatment range from 1% to 20% but are generally 5% or less in experienced centers.

In the past, percutaneous aspiration of hydatid cysts was contraindicated because of the risk of rupture and uncontrolled spillage. However, percutaneous aspiration with injection of scolicidal agents has been reported with high success rates in highly selected patients.[14] This technique, known as *PAIR* (puncture, aspiration, injection, and reaspiration), has become more accepted in some centers. Two randomized trials, one comparing PAIR with surgery ($N = 50$) and one comparing PAIR with medical therapy, have shown similar success rates. These trials were small and had significant methodologic problems, limiting the ability to draw firm conclusions. Although surgery remains the treatment of choice, further prospective trials are clearly indicated to address this interesting and potentially useful technique. Treatment of echinococcosis with albendazole or mebendazole is effective at shrinking cysts in many patients with *E. granulosus* infection, but cyst disappearance occurs in well below 50% of patients. Preoperative treatment may decrease the risk of spillage and is a reasonable and safe practice. Medical therapy without definitive resection or drainage should be considered only for widely disseminated disease or poor surgical candidates.

Recurrent Pyogenic Cholangitis

Recurrent pyogenic cholangitis (RPC) is a syndrome of repeated attacks of cholangitis secondary to biliary stones and strictures that involve the extrahepatic and intrahepatic ducts. The condition has many names but is often referred to as Oriental cholangiohepatitis or hepatolithiasis. The disease is almost exclusively found in Asians and Asian medical centers. However, it is also seen in Asian immigrants throughout the world. Males and females are equally affected, and historically, the disease strikes at an early age (20–40 years) in patients from lower socioeconomic classes.

The cause of RPC is unknown but is related to recurrent infection of biliary radicals with gut bacteria. Ultimately, stones and strictures develop in the biliary tree, but it is not known which occurs first. The stones are bilirubinate stones; in some patients, no stones are found and only biliary sludge is demonstrated. An association between RPC and *Clonorchis sinensis* and *Ascaris lumbricoides* infection has been noted, but a true causal relationship has never been proven.[15]

Strictures can be found anywhere in the biliary tree but usually involve the intrahepatic main hepatic ducts, most often the left hepatic duct. The gallbladder is involved in approximately 20% of cases. Cirrhosis and liver failure are seen only in longstanding disease, usually after multiple operations. Other complications include choledochoduodenal fistulas and acute pancreatitis from common bile duct stones. An increased incidence of cholangiocarcinoma has been noted, but a causal relationship is difficult to prove.

The typical patient with RPC is a young Asian of a lower socioeconomic background who presents with repeated bouts of cholangitis. The symptoms and presentation are those of cholangitis. These include fever, right upper quadrant abdominal pain, and jaundice. Biliary obstruction is usually incomplete; therefore, marked jaundice and pruritus are not common. There is usually leukocytosis and abnormal LFT results consistent with biliary obstruction. Evaluation of the anatomic distribution of disease is critical to formulation of a sound therapeutic plan. A combination of ultrasound, CT, and direct cholangiography is often necessary to evaluate these patients. Direct cholangiography is performed endoscopically or transhepatically and is considered an important study complementing the cross-sectional imaging. Magnetic resonance cholangiopancreatography can combine cross-sectional imaging and cholangiography in one noninvasive test and may ultimately replace direct cholangiography.

In an acute presentation, most patients improve with conservative management, allowing time for radiologic studies and planning of a definitive operation, which is the treatment of choice. If intervention is necessary during the acute phase, it must focus on adequate decompression of the biliary tree through open common bile duct exploration or endoscopic papillotomy with stenting. Although nonoperative approaches, such as percutaneous transhepatic cholangioscopic lithotomy, have been developed, surgical treatment remains the treatment of choice. Percutaneous transhepatic cholangioscopic lithotomy is generally used for poor-risk surgical patients and those who have failed to respond to surgical treatment. Stone clearance rates are high (>80%) and necessary for a successful long-term outcome. Unfortunately, stone recurrence is common and is mostly related to the presence of biliary strictures.

The goal of operative approaches is to clear the biliary tree of stones and to bypass, resect, or enlarge strictures.[16] Many cases require only exploration of the common bile duct, with or without hepaticojejunostomy. In complicated cases, providing permanent access to the biliary tree for interventional radiologic procedures by extending the end of the Roux-en-Y hepaticojejunostomy to the skin or subcutaneous space has been a successful approach (Fig. 89.30). Other potentially necessary procedures include strictureoplasty and partial hepatectomy. Partial hepatectomy is advocated for patients with intrahepatic strictures, hepatic atrophy, liver abscess, or suspicion of cholangiocarcinoma.

In a large series from Asia, where surgery and hepatectomy are liberally applied, surgical mortality rates are 1%. Moreover, with aggressive treatment, there is almost a 100% stone clearance rate. Long-term outcome is excellent, with a less than 5% stone recurrence rate. Long-term survival is mostly related to the presence of cholangiocarcinoma, which is found in approximately 10% of patients. Particularly complicated cases can have a higher rate of recurrent symptoms. In some cases, liver transplantation may be necessary.[17]

NEOPLASMS

Solid Benign Neoplasms

It is estimated that benign focal liver masses are present in approximately 10% to 20% of the population in developed countries. With the increasing use of rapidly improving radiologic examinations, these entities have been encountered more frequently. Familiarity with the clinical characteristics, natural history, imaging

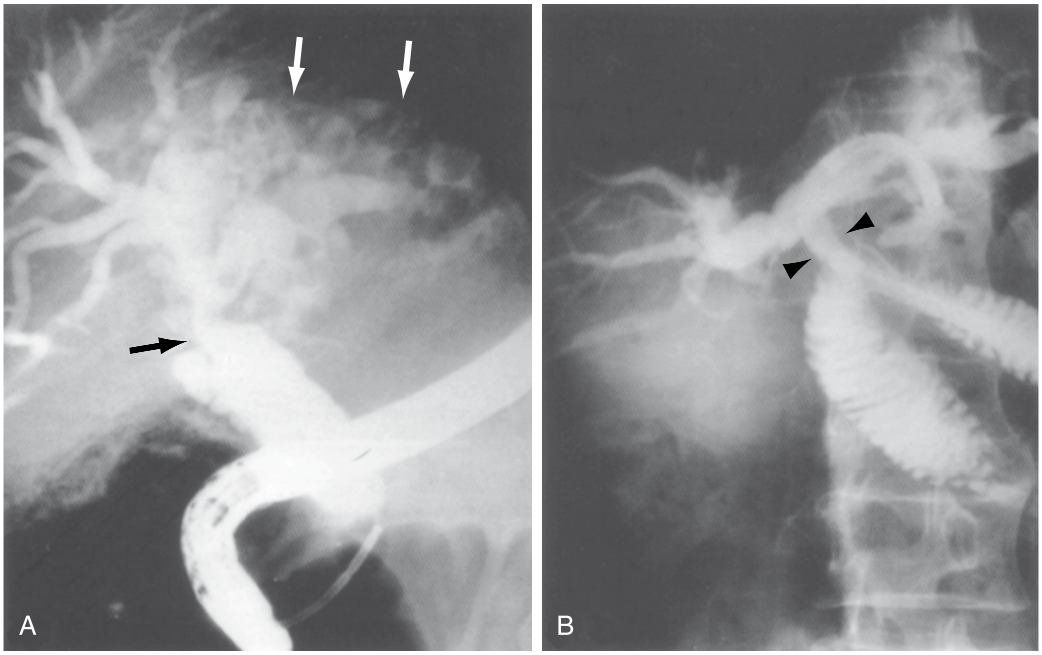

FIGURE 89.30 (A) Cholangiogram of a patient with recurrent pyogenic cholangitis and a common hepatic duct stricture *(black arrow)*. There are numerous stones inside dilated left ducts *(white arrows)*. (B) A hepaticojejunostomy to the segment III duct *(arrowheads)* has been performed, and a flexible choledochoscope is shown passing through the anastomosis into the peripheral left ducts. All stones have been cleared. (From Fan ST, Wong J. Recurrent pyogenic cholangitis. In: Blumgart LH, Fong Y, eds. *Surgery of the Liver and Biliary Tract*. London: WB Saunders; 2000:1205-1225.)

characteristics, and indications for surgery in these tumors is essential. Many benign lesions can be adequately characterized by modern imaging studies, such as CT, ultrasound, and MRI. In unclear cases, serum tumor markers (e.g., AFP, CEA) and a search for a primary tumor in the case of suspected metastases should be carried out. A resection might be necessary to make a definitive diagnosis. Laparoscopy for assessment, biopsy, or resection has become an important diagnostic technique as well.[18,19]

Liver Cell Adenoma

Liver cell adenoma (LCA) is a relatively rare benign proliferation of hepatocytes in the context of a normal liver. It is predominantly found in young females (aged 20–40 years) and is often associated with steroid hormone use, such as long-term oral contraceptive pill (OCP) use. Increased prevalence of LCA was observed in the 1970s, after the introduction of oral contraceptives. Male anabolic hormone use can also predispose to development of LCA. The female-to-male ratio is approximately 11:1. Other risk factors for LCA include vascular liver diseases, glycogenosis type 1A, and familial adenomatous polyposis. LCAs are usually singular, but multiple lesions have been reported in 12% to 30% of cases. Liver adenomatosis is defined by the presence of more than 10 LCAs in the liver. Interestingly, cases with multiple adenomas are not associated with OCP use and do not have as dramatic a female preponderance. On histologic evaluation, LCAs are composed of cords of benign hepatocytes containing increased glycogen and fat. Bile ductules are not observed histologically, and the normal architecture of the liver is absent in these lesions. Hemorrhage and necrosis are commonly seen.[20] On the basis of detailed molecular pathology correlation studies, a French collaborative group has recently proposed a molecular-pathologic classification whereby the adenomas are classified as β-catenin mutated adenoma, *HNF1A* mutated adenoma, inflammatory adenoma, and not otherwise specified adenoma. Molecular studies have also identified genetic signatures associated with a higher risk of malignant transformation. Specifically, the highest risk of malignant transformation is observed in LCA with β-catenin activation.[21,22] With further research, new pathways driving the formation of adenomas are being identified and the "not otherwise specified adenoma" group is becoming smaller. For example, recently sonic hedgehog activation has been observed in 5% of LCAs.[23] Interestingly, these LCAs with sonic hedgehog activation are associated with obesity and bleeding. Furthermore, LCA with β-catenin mutations can be classified by the nature of the mutation. For example, those with exon-3 mutation have increased risk of hepatocellular carcinoma (HCC) degeneration, whereas mutation in exon 7/8 leads to only weak activation of β-catenin and no risk of malignant transformation.

Patients with LCA present with symptoms approximately 50% to 75% of the time. Upper abdominal pain is common and may be related to hemorrhage into the tumor or local compressive symptoms. The physical examination is usually unrevealing, and tumor markers are normal. Dramatic presentations with free intraperitoneal rupture and bleeding can occur. Imaging tends to be characteristic and obviates the need for tissue diagnosis most of the time. Because of intratumoral hemorrhage, the necrosis and fat component of LCA tends to be heterogeneous on CT. On contrast-enhanced CT, LCA tends to have peripheral enhancement with centripetal progression. MRI scans of LCA also have specific imaging characteristics, including a well-demarcated heterogeneous mass containing fat or hemorrhage. Despite high-quality imaging, resection may sometimes be necessary to secure a diagnosis in difficult cases. Intriguingly, studies are elucidating a correlation between the molecular subtypes described and imaging characteristics.[24]

The two major risks of LCA are rupture, with potentially life-threatening intraperitoneal hemorrhage, and malignant transformation. Quantifying the risk of rupture is difficult, but it has been estimated to be as high as 30% to 50%, with all instances of spontaneous rupture occurring in lesions 5 cm and larger.[25] Although there are numerous reports of transformation of LCA into HCC, the true risk of transformation is probably low. Hepatic adenomas with β-catenin activation should be considered for early surgical intervention, as malignant transformation most commonly occurs in this subtype.[22,26]

Patients who present with acute hemorrhage need emergent attention. If possible, hepatic artery embolization is a helpful and usually effective temporizing maneuver. Once the patient is stabilized and appropriately resuscitated, a laparotomy and resection of the mass are required. Symptomatic masses should be similarly resected. Patients with asymptomatic LCAs taking OCPs can be watched for regression after stopping of the OCPs, although progression and rupture have been observed in this setting. Behavior of LCAs during pregnancy has been unpredictable, and resection before a planned pregnancy is usually recommended. Overall, the surgeon must compare the risks of expectant management with serial imaging studies and AFP measurements against those of resection. Resection is usually recommended because of low mortality in experienced hands and the risks of observation. Margin status is not important in these resections, and limited resections can be performed. The management of adenomatosis is controversial, but large lesions should probably be resected because of the risk of rupture, whereas the risk of malignancy is low in lesions smaller than 5 cm. On occasion, liver transplantation is necessary for aggressive forms of adenomatosis.[27,28]

Focal Nodular Hyperplasia

Focal nodular hyperplasia (FNH) is the second most common benign tumor of the liver after hemangioma and is predominantly discovered in young females.[25] FNH is characterized by a central fibrous scar with radiating septa, although no central scar is seen in approximately 15% of cases (Fig. 89.31). On microscopic examination, FNH contains cords of benign-appearing hepatocytes divided by multiple fibrous septa originating from a central scar. Typical hepatic vascularity is not seen, but atypical biliary epithelium is found scattered throughout the lesion. The central scar often contains a large artery that branches out into multiple smaller arteries in a spoke wheel pattern. The cause of FNH is not known, but the most common theory is that FNH is related to a developmental vascular malformation. Female hormones and OCPs have been implicated in the development and growth of FNH, but the association is weak and difficult to prove.

In most patients, FNH is an incidental finding at laparotomy or, more commonly, on imaging studies. If symptoms are noted, vague abdominal pain is most often present, but various nonspecific symptoms have been described. It is often difficult to ascribe these reported symptoms to the presence of FNH; therefore, other possible causes must be sought. Physical examination is usually unrevealing, and mild abnormalities of liver function may be found. Serum AFP levels are normal.

With advances in hepatobiliary imaging, most cases of FNH can be diagnosed radiologically with reasonable certainty. Contrast-enhanced CT and MRI have become accurate methods of diagnosing FNH. FNH typically shows strong hypervascularity in the arterial phase of CT or MRI with a central nonenhancing scar. The enhancement fades over time, and the lesion becomes isointense to the liver parenchyma in the portal and delayed phases. When no central scar is seen, however, radiologic diagnosis is difficult, and differentiation from LCA or a malignant mass, especially fibrolamellar HCC, can sometimes be impossible. On occasion, histologic confirmation is necessary, and resection is recommended for definitive diagnosis. Fine-needle aspiration for the diagnosis of FNH has been recommended but is often unrevealing.

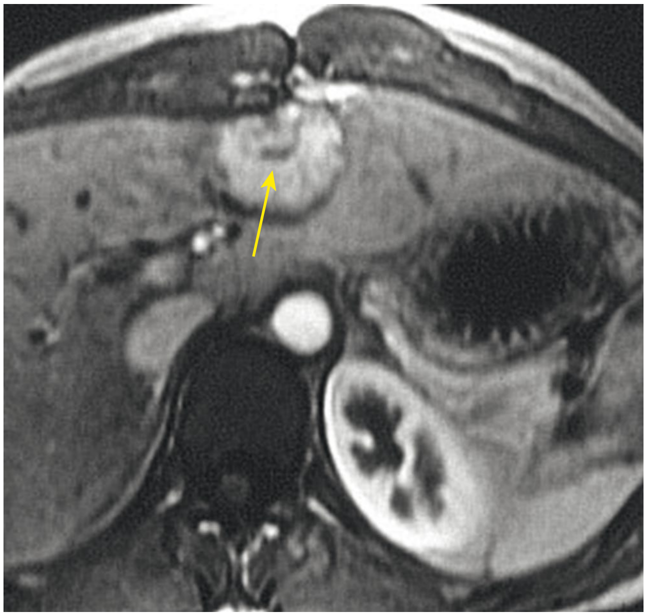

FIGURE 89.31 CT scan of a focal nodular hyperplasia. Note homogenous arterial enhancement with central scar *(arrow).*

Most FNH tumors are benign and indolent. Rupture, bleeding, and infarction are exceedingly rare, and malignant degeneration of FNH has never been reported. The treatment of FNH therefore depends on diagnostic certainty and symptoms. Asymptomatic patients with typical radiologic features do not require treatment.[25] If diagnostic uncertainty exists, resection may be necessary for histologic confirmation. Symptomatic patients should be thoroughly investigated to look for other pathologic processes to explain the symptoms. Careful observation of symptomatic FNH with serial imaging is reasonable because symptoms may resolve in a significant number of cases. Patients with persistent symptomatic FNH or an enlarging mass should be considered for resection. Because FNH is a benign diagnosis, resection must be performed, with minimal morbidity and mortality.

Hemangioma

Hemangioma is the most common benign tumor of the liver.[25] It occurs in females more than in males (3:1 ratio) and at a mean age of approximately 45 years. Small capillary hemangiomas are of no clinical significance, whereas larger cavernous hemangiomas more often come to the attention of the liver surgeon (Fig. 89.32). Cavernous hemangiomas have been associated with FNH and are also theorized to be congenital vascular malformations. The enlargement of hemangiomas is by ectasia rather than by neoplasia. They are usually solitary and less than 5 cm in diameter, and they occur with equal incidence in the right and left hemilivers. Lesions larger than 5 cm are arbitrarily called *giant hemangiomas.* Involution or thrombosis of hemangiomas can result in dense fibrotic masses that may be difficult to differentiate from malignant tumors. On microscopic examination, they are endothelium-lined, blood-filled spaces separated by thin fibrous septa.

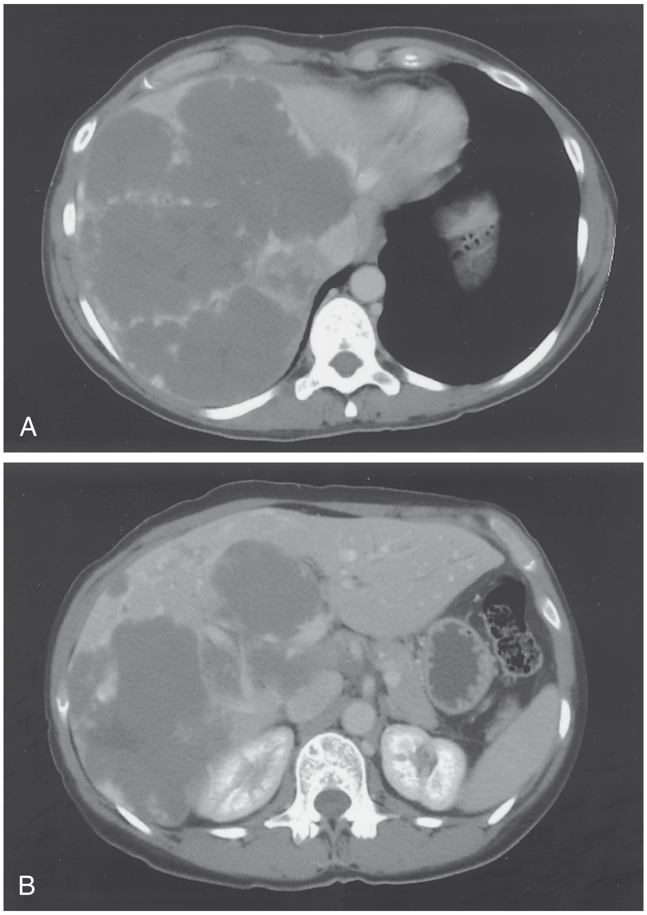

FIGURE 89.32 (A–B) Computed tomography scans of a large cavernous hemangioma showing displacement of left and middle hepatic veins and abutment of the left portal vein. The mass was symptomatic and required an extended right hepatectomy for removal.

Hemangiomas are usually asymptomatic and found incidentally on imaging studies. Large compressive masses may cause vague upper abdominal symptoms. Symptoms ascribed to liver hemangioma, however, mandate a search for other disease because an alternative cause of symptoms will be found in approximately 50% of cases. Rapid expansion or acute thrombosis can occasionally cause symptoms. Spontaneous rupture of liver hemangiomas is exceedingly rare. An associated syndrome of thrombocytopenia and consumptive coagulopathy known as *Kasabach-Merritt syndrome* is rare but well described.

LFT results and tumor markers are usually normal in liver hemangiomas. Radiologic investigation can reliably make the diagnosis in most cases. CT and MRI are usually sufficient if a typical peripheral nodular enhancement pattern is seen. Isotope-labeled red blood cell scans are an accurate test but are rarely necessary if high-quality CT and MRI are available. Percutaneous biopsy of a suspected hemangioma is potentially dangerous and inaccurate. Therefore, biopsy is not recommended.

The natural history of liver hemangioma is generally benign; it appears that most remain stable for a long time, with a low risk of rupture or hemorrhage.[25] Growth and development of symptoms do occur, however, occasionally requiring resection. There has never been a report of malignant degeneration of a liver hemangioma. An asymptomatic patient with a secure diagnosis can therefore be simply observed.[25] Symptomatic patients should undergo a thorough evaluation looking for alternative explanations for the symptoms but are candidates for resection if no other cause is found. Rupture, significant change in size, and development of the Kasabach-Merritt syndrome are indications for resection. In rare cases of diagnostic uncertainty, resection may be necessary for a definitive diagnosis. Resection of liver hemangiomas should be performed, with minimal morbidity and mortality. The preferred approach to resection is enucleation with arterial inflow control, but anatomic resections may be necessary in some cases. Surgery on large central hemangiomas can be associated with significant morbidity.

Liver hemangiomas in children are common, accounting for approximately 12% of all childhood hepatic tumors. They are usually multifocal and can involve other organs. Large hemangiomas in children can result in congestive heart failure secondary to arteriovenous shunting. Untreated symptomatic childhood hemangiomas are associated with high mortality. On the other hand, almost all small capillary hemangiomas resolve. Symptomatic childhood hemangiomas may be treated with therapeutic embolization; medical therapy should be initiated for congestive heart failure. Radiation and chemotherapeutic agents have been used, but experience has been limited. Resection may be necessary for symptomatic lesions or rupture.

Other Benign Tumors

Most benign solid liver tumors are LCAs, FNHs, or hemangiomas, but there are other benign hepatic tumors. However, these are rare and can be difficult to differentiate from malignant neoplasms. Macroregenerative nodules, previously known as adenomatous hyperplasia, are single or multiple well-circumscribed, bile-stained, bulging surface nodules that occur primarily in people with cirrhosis and result from the hyperplastic response to chronic liver injury. These lesions have malignant potential and can be difficult to distinguish from HCC. Nodular regenerative hyperplasia is a benign, diffuse, micronodular (usually <2 cm) process associated with lymphoproliferative disorders, collagen vascular diseases, and the use of steroids or chemotherapy. Nodular regenerative hyperplasia has no malignant potential and is not associated with cirrhosis. Biopsy may be necessary to distinguish these focal nodules from malignant neoplasms.

Mesenchymal hamartomas are rare solitary tumors of childhood that account for 5% of pediatric liver tumors. They are usually large cystic masses found in the right liver that present as progressive, painless abdominal distention. Resection of mesenchymal hamartomas may be necessary in the case of large lesions causing a mass effect.

Fatty tumors of the liver are rarely encountered but can usually be distinguished by typical characteristics on CT or MRI scans. Fatty tumors of the liver include primary lipomas, myelolipomas (which contain hematopoietic tissue), angiolipomas (which contain blood vessels), and angiomyolipomas (which contain smooth muscle). Focal fatty change in the liver can be confused with a neoplastic process and is becoming more common with improved imaging and the increasing incidence of hepatic steatosis.

Benign fibrous tumors of the liver can become large and symptomatic, requiring resection. Inflammatory pseudotumors of the liver are localized masses of inflammatory cells that can mimic a neoplasm. The cause of these inflammatory lesions is unknown but may be related to thrombosed vessels or old abscesses. Other extremely rare benign hepatic tumors include leiomyomas, myxomas, schwannomas, lymphangiomas, and teratomas.

Intrahepatic biliary cystadenomas or bile duct adenomas are rare but can cause biliary symptoms. Biliary hamartomas and biliary hyperplasia are common and are often seen as small white surface lesions that can mimic small metastatic tumors at abdominal exploration. Adrenal and pancreatic rests have also been found in the liver.

Primary Solid Malignant Neoplasms

Hepatocellular Carcinoma

Epidemiology. Liver cancer is the fifth most common cancer and the second most frequent cause of cancer-related death globally.[29] HCC is the most common primary malignant neoplasm of the liver and one of the most common malignant neoplasms worldwide. The epidemiology of HCC varies around the world, being affected by the varying etiologies in different parts. Hepatitis B is the most common cause of HCC. Thus, the highest incidence of HCC occurs in geographic areas where hepatitis B is rampant, namely sub-Saharan Africa and Southeast Asia (>10–20 cases/100,000). The lowest incidence (1–3 cases/100,000) is found in Australia, North America, and Europe. Epidemiologic evidence strongly suggests that HCC is largely related to environmental factors; the incidence of HCC in immigrants eventually approaches that of the local population after several generations. An exception to this is that Whites living in high-prevalence areas tend to have a low incidence of HCC. This is likely related to the continuation of the lifestyle and environment of their home country. It is probable that the variation in incidence rates among immigrants is related to hepatitis B virus (HBV) carrier rates.

A significant rise in the incidence of HCC in the United States and other Western countries has been noted during the past 35 years. However, recent data suggest that at least in the United States, the epidemic may have peaked, as the incidence rates have stabilized in the last few years.[30,31] The explanation for the observed increase during the past few decades is not understood, but the emergence of hepatitis C virus (HCV) infection and immigration patterns have been suggested, as has the increase in obesity and nonalcoholic steatohepatitis (NASH).[32] Given that obesity and its ensuing complications are increasing at epidemic proportions in the Western world, obesity as the cause of HCC is becoming more important. Recent data also suggest that addressing the environmental factors can lead to reduction in incidence of HCC. In Taiwan, treatment of chronic hepatitis B and C under the auspices of a national viral hepatitis therapy program has met with a reduction in incidence and mortality related to HCC.[33]

HCC is two to eight times more common in males than in females in low- and high-incidence areas. Although sex hormones may play a minor role in the development of HCC, the higher incidence in males is probably related to higher rates of associated risk factors, such as HBV infection, cirrhosis, smoking, alcohol abuse, and higher hepatic DNA synthesis in cirrhosis. In general, the incidence of HCC increases with age, but a tendency to develop HCC earlier in high-incidence areas has been noted. For example, in Mozambique, 50% of patients with HCC were found to be younger than 30 years. This may be related to differing ages at infection and the natural histories of hepatitis B and C.

Causative factors. A large number of associations between hepatic viral infections, environmental exposure, alcohol use, smoking, genetic metabolic diseases, cirrhosis, and OCP use and the development of HCC have been recognized. Overall, 75% to 80% of HCC cases are related to HBV (50%–55%) or HCV (25%–30%) infections. Research also shows that the development of HCC is a complex and multistep process that involves any number of these risk factors.

Hepatitis C has been discovered to be a major cause of chronic liver disease in Japan, Europe, and the United States, where there is a relatively low rate of HBV infection. Two percent of the world's population is infected with HCV. Antibodies to HCV are found in 76% of patients with HCC in Japan and Europe and 36% of patients in the United States. HBV and HCV infections are both independent risk factors for the development of HCC but probably act synergistically when an individual is infected with both viruses. Although the natural history of HCV infection is not completely understood, it appears to be one of chronic infection, with a benign early course. However, the ultimate development of cirrhosis with increased risk of HCC may ensue. The rate of HCC among HCV-infected persons ranges from 1% to 3% over 30 years, and in individuals with HCV-related cirrhosis, HCC develops at an annual rate of 1% to 4%. Studies on the rates of progression to cirrhosis estimate a median time of 30 years, but differing progression rates yield a range of less than 20 years to more than 50 years. Factors associated with a more rapid progression include male sex, chronic alcohol use, and older age at the time of infection. HCV is an RNA virus that does not integrate into the host genome; therefore, the pathogenesis of HCV-related HCC may be connected more to chronic inflammation and cirrhosis than to direct carcinogenesis.[34,35] Data from era of interferon-based therapy suggest that the patients who achieved a sustained viral response had up to 75% reduction in their risk of HCC. This is exciting and has immense global health significance, especially now, as many effective HCV treatments are available. However, future studies will determine if these new treatments will change the incidence and course of HCC.

The true relationship between cirrhosis and HCC is difficult to ascertain, and suggestions of causation remain speculative. Cirrhosis is not required for the development of HCC, and hepatocarcinogenesis is not an inevitable result of cirrhosis. The relationship between cirrhosis and HCC is further complicated by the fact that they share common associations. Furthermore, some associations (e.g., HBV infection, hemochromatosis) are associated with higher risk of HCC, whereas others (e.g., alcohol, primary biliary cirrhosis) are associated with a lower risk of HCC. Research has demonstrated that cirrhotic livers with higher DNA replication rates are associated with the development of HCC.

Chronic alcohol abuse has been associated with an increased risk of HCC, and there may be a synergistic effect with HBV and HCV infection. Alcohol causes cirrhosis but has never been shown to be directly carcinogenic in hepatocytes. Thus, alcohol likely acts as a cocarcinogen. Cigarette smoking has been linked to the development of HCC, but the evidence is not consistent, and the contributing risk independent of viral hepatitis is likely to be small. Aflatoxin, produced by *Aspergillus* spp., is a powerful hepatotoxin. With chronic exposure, aflatoxin acts as a carcinogen and increases the risk of HCC. The offending fungi grow on grains, peanuts, and food products in tropical and subtropical regions. Ingestion of contaminated foods results in aflatoxin exposure. Levels of aflatoxin in these implicated foods are regulated in the United States.

Other chemicals have also been implicated as carcinogens related to HCC. These include nitrites, hydrocarbons, solvents, pesticides, and vinyl chloride. Thorotrast (colloidal thorium dioxide) is an angiographic medium that was used in the 1930s. It emits high levels of long-lasting radiation and has been associated with hepatic fibrosis, angiosarcoma, cholangiosarcoma, and HCC. Associations with inherited metabolic liver diseases, such as hereditary hemochromatosis, α_1-antitrypsin deficiency, and Wilson disease, have also been implicated as risk factors for HCC. Associations with hormonal manipulations, such as the use of OCPs and anabolic steroids, have been suggested but are weak and are probably better linked specifically to adenoma and well-differentiated HCC. Research has been focusing on relationships of HCC with diabetes, obesity, and metabolic syndrome.[32,36-38]

Clinical presentation. Most commonly, patients presenting with HCC are males 50 to 60 years of age who complain of right upper quadrant abdominal pain and weight loss and have a palpable mass. In countries endemic for HBV, presentation at a younger age is common and probably related to childhood infection. Unfortunately, in unscreened populations, HCC tends to be manifested at a later stage because of the lack of symptoms in early stages. Presentation at an advanced stage is often with vague right upper quadrant abdominal pain that sometimes radiates to the right shoulder. Nonspecific symptoms of advanced malignant disease, such as anorexia, nausea, lethargy, and weight loss, are also common. Another common presentation of HCC is hepatic decompensation in a patient with known mild cirrhosis or even in patients with unrecognized cirrhosis.

HCC can rarely be manifested as a rupture, with the sudden onset of abdominal pain followed by hypovolemic shock secondary to intraperitoneal bleeding. Other rare presentations include hepatic vein occlusion (Budd-Chiari syndrome), obstructive jaundice, hemobilia, and fever of unknown origin. Less than 1% of cases of HCC are manifested with a paraneoplastic syndrome, usually hypercalcemia, hypoglycemia, and erythrocytosis. Small, incidentally noted tumors have become a more common presentation because of the knowledge of specific risk factors, screening programs for diagnosed HBV or HCV infection, and increasing use of high-quality abdominal imaging.

Diagnosis. Radiologic investigation is a critical part of the diagnosis of HCC. In the past, liver radioisotope scans and angiography were common methods of diagnosis, but ultrasound, CT, and MRI have replaced these studies. Ultrasound plays a significant role in screening and early detection of HCC, but definitive diagnosis and treatment planning rely on CT or MRI. Contrast-enhanced CT and MRI protocols aimed at diagnosing HCC take advantage of the hypervascularity of these tumors, and arterial-phase images are critical to assess the extent of disease adequately. Unlike many other cancers, the diagnosis of HCC can be established based on imaging findings alone. Typical imaging criteria for HCC include rapid arterial enhancement followed by washout in the delayed phase. An enhancing capsule supports the diagnosis of HCC. CT and MRI also evaluate the extent of disease in terms of peritoneal metastases, nodal metastases, and extent of vascular and biliary involvement. Detection of bland or tumor thrombus in the portal or hepatic venous system is also important and can be diagnosed with any of these modalities (Fig. 89.33).

AFP measurements can be helpful in the diagnosis of HCC. However, AFP measurement is associated with multiple problems. First, AFP measurements have low sensitivity and specificity. The specificity and positive predictive values of AFP improve with higher cutoff levels (e.g., 400 ng/mL) but at the cost of sensitivity. False-positive elevations of serum AFP levels can be seen in inflammatory disorders of the liver, such as chronic active viral hepatitis. Furthermore, AFP is not specific to HCC and can be elevated with intrahepatic cholangiocarcinoma (IHC) and colorectal metastases. With improvements in imaging technology and the ability to detect smaller tumors, AFP is largely used as an adjunctive test in patients with liver masses. AFP levels are particularly useful in monitoring treated patients for recurrence after normalization of levels.

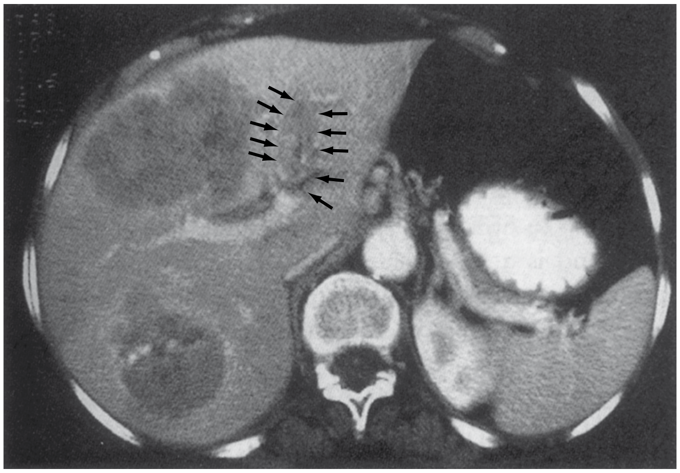

FIGURE 89.33 Contrast-enhanced computed tomography scan demonstrating multifocal hepatocellular carcinoma. The left portal vein is invaded and expanded by tumor *(arrows)*. (From Roddie ME, Adam A. Computed tomography of the liver and biliary tree. In: Blumgart LH, Fong Y, eds. *Surgery of the Liver and Biliary Tract.* London: WB Saunders; 2000:309-340.)

Since the proposal of guidelines for the diagnosis of HCC by the Barcelona-2000 European Association for the Study of the Liver conference and the American Association for the Study of Liver Disease,[39] new data have accumulated and the recommendations have evolved. AFP used to play a major role in the diagnosis of HCC larger than 2 cm.[39] However, given the excellent performance of contrast-enhanced imaging modalities, AFP does not play a critical role in the diagnosis of HCC anymore.[40,41] For hepatic nodules 1 to 2 cm in size on a background of cirrhosis, a contrast-enhanced triple-phase CT and MRI scan is now recommended.[40,41] If typical features of HCC on imaging (arterially enhancing mass with washout of contrast material in delayed phases) are observed, diagnosis of HCC is presumed. For lesions larger than 2 cm, a single study may suffice. However, for lesions 1 to 2 cm in size, contrast-enhanced CT and MRI have a sensitivity of 53% to 62%, specificity of approximately 100%, positive predictive value of 95% to 100%, and negative predictive value of 80% to 84%.[42] Performance of both MRI and CT in a sequential fashion can increase the sensitivity and may be required for difficult cases.[42]

Patients with appropriate risk factors and suggestive radiologic features, with or without an elevated AFP level, who are candidates for potentially curative surgical therapy do not require preoperative biopsy unless the diagnosis is in question. Percutaneous fine-needle aspiration of HCC does run a small risk of tumor cell spillage (estimated to be ~1%) and rupture or bleeding, especially in cirrhotic livers and subcapsular tumors. Once the diagnosis of HCC has been made, the disease must be staged to develop an appropriate treatment plan. Most patients with HCC have two diseases, and survival is as much related to the tumor as it is to cirrhosis. Staging includes extent of disease and extent of cirrhosis workup.

In assessing the extent of disease, the common sites of metastases must be considered. HCC largely metastasizes to the lung, bone, and peritoneum. Preoperative history should focus on symptoms referable to these areas. Extent of disease in the liver, including macrovascular invasion and the presence of multiple liver masses, must also be considered. Cross-sectional abdominal imaging, including arterial-phase images (see earlier), yields information on the extent of disease in the liver as well as peritoneal disease. Preoperative chest CT is mandatory because lung metastases are usually asymptomatic. Routine bone scans are not performed unless there are suggestive symptoms or signs.

Assessment of liver function is absolutely critical when considering treatment options for a patient with HCC. Liver resection is considered the treatment of choice for HCC, and the risk of postoperative liver failure and death must be considered. This risk is related to the degree of cirrhosis, portal hypertension, amount of liver resected (functional liver reserve), and regenerative potential response. Other successful treatments are available for HCC, such as ablative techniques, embolization techniques, and liver transplantation. Therefore, a complete assessment of tumor and liver function must be carried out. Several LFTs are available, generally divided into clinical assessment and functional tests, and there are many clinical assessment schemes (see earlier). However, Child-Pugh status is used most often. Child-Pugh class C patients are not candidates for resectional therapy, whereas Child-Pugh class A patients can usually tolerate some extent of liver resection. Many consider Child-Pugh class B patients to be candidates for operation, but they are generally borderline, and therapy must be individualized. Major resections are not well tolerated by a patient with class B cirrhosis.

Outside of scoring systems, it has been demonstrated that significant portal hypertension, regardless of biochemical assessments, is highly predictive of postoperative liver failure and death. Portal hypertension can be assessed directly through hepatic vein wedge pressures, but it is usually obvious on high-quality imaging in the form of splenomegaly, a cirrhotic-appearing liver, and intraabdominal varices. Blood work usually demonstrates marked cytopenias. Most typically, patients have thrombocytopenia. Functional tests of liver function have been well described but are not routinely used in most Western centers because the results of studies evaluating their predictive value have been mixed.

Laparoscopy has been used as a staging tool in HCC and spares about one in five patients a nontherapeutic laparotomy. Laparoscopy yields additional information about the extent of disease in the liver, extrahepatic disease, and cirrhosis. The yield of laparoscopy is dictated by the extent of disease and is only selectively used. The presence of clinically apparent cirrhosis, radiologic evidence of vascular invasion, or bilobar tumors increases the yield to 30%, whereas without these factors, the yield is 5%.[43]

There are a number of staging systems for HCC, but none are particularly superior; they probably depend on the specific population in which the disease is being staged as well as the cause of HCC in that particular population of patients. The tumor-node-metastasis (TNM) staging system is not routinely used for HCC because it does not accurately predict survival; it does not take liver function into account. Moreover, the TNM staging system relies on pathology that is frequently unavailable preoperatively. The Okuda staging system is an older but simple and effective system that takes liver function and tumor-related factors into account. It adds up a single point for the presence of tumor involving more than 50% of the liver, presence of ascites, albumin level less than 3 g/dL, and bilirubin level higher than 3 mg/dL. The Okuda staging system reliably distinguishes patients with a prohibitively poor prognosis from those with potential for long-term survival. The most well-validated staging system is the Cancer of the Liver Italian Program (CLIP), which was rigorously developed and prospectively validated (Table 89.7). An example of a scoring system that is probably population specific is the Chinese University Prognostic Index (CUPI), which takes into account TNM stage, symptoms, and ascites and the levels of AFP, bilirubin, and ALP; it appears to apply mainly to HBV-related HCC in China.

TABLE 89.7 **Cancer of the Liver Italian Program Score**[a]

CLINICAL PARAMETERS	CUTOFF VALUES	POINTS
Child-Pugh class	A	0
	B	1
	C	2
Tumor morphology	Uninodular, <50% extension	0
	Multinodular, <50% extension	1
	Massive or extension >50%	2
AFP level	<400 ng/dL	0
	>400 ng/dL	1
Portal vein thrombosis	No	0
	Yes	1

[a]Score ranges from 0 to 6; a score of 4 to 6 is generally considered advanced disease, whereas a score of 0 to 3 has the potential for long-term survival.
AFP, α-Fetoprotein.

Pathology. On histologic evaluation, HCC is graded as well, moderately, or poorly differentiated. The grade of HCC, however, has never been shown to predict outcome accurately. In gross appearance, the growth patterns of HCC have been classified in a number of ways. The most useful scheme divides HCC into three distinct growth patterns that have specific relationships to outcome. The hanging type of HCC is connected to the liver by a small vascular stalk and is easily resected without sacrificing a significant amount of adjacent nonneoplastic liver tissue and can grow to substantial size. The pushing type of HCC is well demarcated and often contains a fibrous capsule. It is characterized by growth that displaces vascular structures rather than invading them and is usually resectable. The last type is called the infiltrative type of HCC, which tends to invade vascular structures, even at a small size. Resection of the infiltrative type is often possible, but positive histologic margins are common. Small tumors (<5 cm) usually do not fall into any of these groups and are often discussed as a separate entity.

Finally, HCC can manifest in a multifocal manner. Most HCC probably starts as a single tumor, but ultimately multiple satellite lesions can develop secondary to portal vein invasion and metastases. Multifocal tumors throughout the liver probably represent the end stage of HCC, with multiple metastases and multiple primary tumors.

Treatment. There are a large number of treatment options for patients with HCC, reflecting the heterogeneity of this disease and the lack of a proven superior treatment, except complete resection (Box 89.1). Deciding on a treatment regimen for any one patient must take into consideration the stage of malignancy, condition of the patient and of the liver, and experience of the treating physician.

Surgical Management

Resection. Complete excision of HCC by partial hepatectomy or by total hepatectomy and liver transplantation is the treatment of choice, when possible, because it has the highest chance of long-term

survival. In general, however, only 10% to 20% of patients are considered to have resectable disease. Historically, mortality rates for partial hepatectomy have ranged from 1% to 20%, but if it is performed in healthy patients without advanced cirrhosis, most series have a mortality rate of less than 5%. Advances in surgical technique have also allowed the development of limited segmental resections when appropriate, which preserves liver function and improves early postoperative recovery. Selection of the appropriate patient for resection is critical and must take into account the condition of the liver and extent of disease. Hepatic resection is indicated as a potentially curative option in patients with adequate liver function (Child-Pugh class A without portal hypertension) and solitary HCC without major vascular invasion. Patients with Child-Pugh class B or C cirrhosis or portal hypertension do not tolerate resection. The volume of the FLR is also an important consideration and is associated with postoperative complications and mortality. Preoperative PVT is an effective strategy to increase the volume and function of the FLR and should be used liberally in patients with Child-Pugh class A cirrhosis with a small FLR (i.e., <30%–40% of the total liver volume) who are being considered for a major resection. The overall postresection survival rates for HCC are 58% to 100% at 1 year, 28% to 88% at 3 years, 11% to 75% at 5 years, and 19% to 26% at 10 years. These results obviously depend on the tumor stage and degree of cirrhosis in each series. Together, they give a sense of the possibilities.

Various prognostic factors predictive of survival after resection have been identified, but none are universally agreed on. The most cited negative prognostic factors are tumor size, cirrhosis, infiltrative growth pattern, vascular invasion, intrahepatic metastases, multifocal tumors, lymph node metastases, margin less than 1 cm, and lack of a capsule. The best outcomes are found in patients with single small tumors, but size alone should not contraindicate resection. Especially for patients with large tumors that are outside the criteria for transplantation, not many therapeutic options are available. In such patients with adequate liver function, adequate functional liver remnant, and resectable tumors, surgical resection may offer the best possible outcomes. Multifocal tumors and major vascular invasion are generally associated with a poor outcome, but some groups advocate resection in highly select patients. A randomized controlled trial corroborated these findings. In this study, patients with multifocal HCC outside Milan criteria were randomized to resection or transarterial chemoembolization.[44] In this study, resection provided better overall survival for patients with multifocal HCC compared with transarterial chemoembolization, suggesting that resection may be an option for these patients. For potentially resectable tumors that have high-risk features, various neoadjuvant strategies may help select patients for resection. For instance, a period of observation and tumor control with intraarterial therapies (e.g., transarterial chemoembolization/radioembolization) may help select patients that will benefit most from resection.

Transplantation. Theoretically, orthotopic liver transplantation is the ideal treatment for HCC because it addresses the liver dysfunction and cirrhosis and the HCC. The limitations of transplantation are the need for chronic immunosuppression and the lack of organ donors. There has been growing interest in the use of partial hepatectomy from live donors, which addresses the lack of organ donors but remains a somewhat controversial approach. Early series of transplantation for HCC had high recurrence rates and relatively poor long-term survival, largely attributed to the fact that most of these patients were undergoing transplantation for advanced disease. Refinements in patient selection—namely, patients with single tumors smaller than 5 cm or no more than three tumors 3 cm in size—have resulted in improved outcomes. Long-term survival rates with more stringent selection criteria have ranged from 50% to 85%. Studies have begun to expand the indications for orthotopic liver transplantation without a major effect on long-term survival but likely an increase in overall recurrence rates. While the enlisted patient with HCC and cirrhosis awaits organ availability, the progression of HCC is typically controlled with locoregional therapy, including ablation and transarterial therapies. Comparison of results of resection with transplantation is difficult, as the patients considered for transplantation have a period of observation during which the patients with aggressive disease progress and drop out from the transplant list. As such, these two strategies should be viewed as complementary rather than competitive. Patients with advanced cirrhosis (Child-Pugh class B and C) and early-stage HCC should be considered for transplantation, whereas those with Child-Pugh class A cirrhosis have similar results with transplantation and resection and should probably be resected.

Locoregional Therapies

Ablation. A number of other nonsurgical local ablative therapies are available for the treatment of small tumors. Percutaneous ethanol injection (PEI) is a useful technique for ablating small tumors. The tumor is killed by a combination of cellular dehydration, coagulative necrosis, and vascular thrombosis. Most tumors smaller than 2 cm can be ablated with a single application of PEI, but larger tumors may require multiple injections. Long-term survival after PEI for tumors smaller than 5 cm has been reported to range from 24% to 40%. Percutaneous injection of acetic acid is a technique similar to PEI but has stronger necrotizing abilities, making it more useful in septated tumors.

Thermal ablative techniques that freeze or heat tumors to destroy them have become popular. Cryotherapy uses a specialized cryoprobe to freeze and thaw tumor and surrounding liver tissue, with resulting necrosis. Cryotherapy is usually performed at laparotomy or laparoscopically, but it has been performed with percutaneous techniques. One advantage is that the ice ball formed is easily monitored with ultrasound. Disadvantages include a heat sink effect limiting the usefulness of freezing near major blood vessels and a relatively high complication rate of 8% to 41%. Reported 2-year survival rates for cryoablation of HCC range from 30% to 60%, but no comparative studies to resection have been carried out. Radiofrequency ablation (RFA) uses high-frequency alternating current to create heat around an inserted probe, resulting in temperatures higher than 60°C (140°F) and immediate cell death. Although initially limited to smaller tumors, technologic improvements have created RFA probes reportedly able to ablate tumors as large as 7 cm. Nonetheless, the efficacy of RFA for HCCs larger than 3 cm is limited because of increased local recurrence rates. RFA is also limited by the protective effect of blood vessels and does not ablate well in these areas. The procedure can easily be performed percutaneously, with low complication rates, and optimal guidance systems are being developed. Recent data suggest that resection may be superior to RFA for small HCCs in terms of both disease-free and overall survival.[45] Microwave ablation has emerged as a commonly used thermoablative procedure with durable disease control for small tumors.[46]

Arterially directed therapies. Transarterial therapy for HCC is based on the fact that most of the tumor's blood supply is from the hepatic artery. Today, transarterial therapy is applied in a percutaneous fashion, thus avoiding morbidity and mortality of laparotomy. Percutaneous transarterial embolization can induce ischemic necrosis in HCC, resulting in response rates as high as 50% (Fig. 89.34). Attempts to improve the efficacy of arterial embolization have included adding chemotherapeutic agents (chemoembolization) to the bland embolization particles and oils, such as ethiodized oil (Ethiodol), that are selectively taken up by HCCs. Seven randomized trials have compared embolization or chemoembolization with conservative management. Two of these trials and a meta-analysis have confirmed an overall survival advantage from the embolization strategies.[47] The selection of appropriate candidates for embolization is important, and treatment should generally be limited to patients with preserved liver function and asymptomatic multinodular tumors without vascular invasion. Poor selection will result in a higher incidence of treatment-induced liver failure, offsetting the potential benefits. Intraarterial injections of iodine-131 with Ethiodol or yttrium-90 in glass microspheres have also been used to deliver localized radiation to HCCs, with reports of dramatic response rates. Transarterial radiotherapy is a potentially promising therapy for HCC as a primary or adjuvant therapy.

Radiation. External beam radiation therapy (EBRT) has a limited role in the treatment of HCC, although occasional dramatic responses are seen. EBRT is limited by damage to normal liver parenchyma and to surrounding organs, but newer methods of conformal radiotherapy and breath-gated techniques are improving the usefulness of this treatment modality.

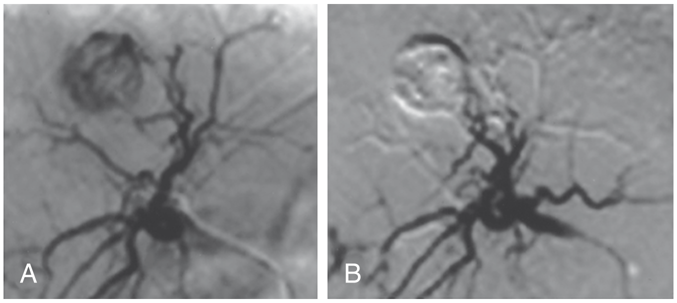

FIGURE 89.34 Angiograms demonstrating hypervascular hepatocellular carcinoma before (A) and after (B) embolization.

Systemic Therapies

Chemotherapy. Systemic chemotherapy with a variety of agents (e.g., cisplatin, doxorubicin, etoposide, 5-fluorouracil [5-FU], mitomycin C, amsacrine, mitoxantrone, picibanil, tamoxifen, uracil, VM-26) has been ineffective and has had a minimal role in the treatment of HCC. Response rates are generally below 20% and of short duration. Hormonal therapy has been used in small numbers of patients with HCC, with some early promising results, but have not yet demonstrated superiority to standard regimens.

Most recently, sorafenib, a molecular targeted therapy that inhibits the serine-threonine kinases Raf-1 and B-Raf and the receptor tyrosine kinase activity of vascular endothelial growth factor (VEGF) receptors 1, 2, and 3 and platelet-derived growth factor β, was evaluated. Llovet and colleagues[48] randomized 599 patients with advanced-stage HCC and Child-Pugh level A cirrhosis to oral sorafenib or placebo. The median overall survival was 10.7 months in the sorafenib group and 7.9 months in the placebo group ($P < 0.001$), a difference of 2.8 months. The median time to radiologic progression was 5.5 months in the sorafenib group and 2.8 months in the placebo group ($P < 0.001$), a difference of 2.7 months. Neither group demonstrated any complete responses by radiologic criteria. Although the adverse event profile of sorafenib was similar to the placebo group, this and earlier studies have shown that sorafenib is best tolerated in patients with Child-Pugh class A cirrhosis. With better understanding of the molecular pathogenesis, there is hope that novel therapeutics will be increasingly evaluated in this disease.[48]

Immunotherapy for primary liver cancers. The liver hosts a complex immune microenvironment that is naturally immunosuppressive and tolerogenic. Physiologically, this immunotolerant environment is essential for normal hepatic function as the primary metabolic organ for digested, non–self-material from the gastrointestinal tract. The environment is maintained by a host of immune cells including resident tissue macrophages (Kupffer cells), myeloid-derived suppressor cells, and regulatory T cells. Dysregulation of these cells contributes to suppression of antitumor immune cells, such as CD8+ T cells, creating a milieu that is predisposed to hepatocarcinogenesis and metastasis. Reactivation of these antitumor immune cells is the primary goal of immunotherapy.[49]

Immunotherapy plays a major role in the treatment of advanced primary liver cancers. Although vaccine and cellular-based therapies are in clinical development, immune checkpoint inhibitors (ICIs) targeting programmed cell death 1 (PD-1), programmed cell death ligand 1 (PD-L1), and cytotoxic T-lymphocyte–associated protein 4 (CTLA-4) are mainstays of treatment for HCC and biliary tract cancers (BTCs). Used in combination with antiangiogenic agents (anti-VEGF), tyrosine kinase inhibitors, and traditional cytotoxic chemotherapies such as gemcitabine and cisplatin, ICI therapy is now used in the first-line setting for HCC and BTC. The approved PD-1, PD-L1, and CTLA-4 inhibitors for HCC and BTCs are listed in Table 89.8.

As described elsewhere in this chapter, HCC most commonly develops in the setting of chronic hepatic inflammation. This chronic inflammation leads to dysregulation of the immunologic network through sustained hepatocellular DNA damage and cell death, compensatory hepatic regeneration, and liver fibrosis. Persistent viral infection and nonviral chronic liver diseases such as nonalcoholic fatty liver disease (NAFLD)/NASH and alcoholic

TABLE 89.8 Immunotherapy Options for HCC and Cholangiocarcinoma

DRUG	TARGET	HCC	BILIARY TRACT CANCERS	REFERENCE TRIAL
Atezolizumab	PD-L1	1L for advanced/unresectable disease (combined with bevacizumab)	n/a	HCC - IMbrave150
Dostarlimab	PD-1	2L for advanced/unresectable disease (monotherapy)	2L for metastatic/unresectable disease (MSI-H tumors)	HCC - GARNET Study
Durvalumab	PD-L1	1L for advanced/unresectable disease (monotherapy or combined with tremelimumab)	1L for metastatic/unresectable disease (combined with gemcitabine, cisplatin)	HCC - HIMALAYA Cholangiocarcinoma - TOPAZ
Ipilimumab	CTLA-4	2L for advanced/unresectable disease (combined with nivolumab)	2L for metastatic/unresectable disease (combined with nivolumab in MSI-H tumors)	HCC - Checkmate 040 trial
Nivolumab	PD-1	2L for advanced/unresectable disease (monotherapy or combined with ipilimumab)	2L for metastatic/unresectable disease (monotherapy, combined with ipilimumab in MSI-H tumors)	HCC - Checkmate 040 trial Cholangiocarcinoma
Pembrolizumab	PD-1	2L for advanced/unresectable disease secondary to HBV (monotherapy)	1L for metastatic/unresectable disease (combined with gemcitabine, cisplatin)	HCC - KEYNOTE-224, KEYNOTE-240, KEYNOTE-394 Cholangiocarcinoma – KEYNOTE-966
Tremelimumab	CTLA-4	1L for advanced/unresectable disease (combined with durvalumab)	n/a	HCC – HIMALAYA

1L, First-line; *2L,* second/subsequent-line; *CTLA-4,* cytotoxic T-lymphocyte–associated protein 4; *HCC,* hepatocellular carcinoma; *MSI-H,* microsatellite instability, high; *PD-1,* programmed cell death 1; *PD-L1,* programmed cell death ligand 1.

steatohepatitis (ASH) induce liver inflammation and uniquely affect the liver immune microenvironment, which significantly influences the efficacy of immunotherapy. Indeed, nonviral-induced HCC is associated with worse responses to ICI. In a meta-analysis of the three large studies evaluating ICI in treatment of HCC, patients with NAFLD/NASH did not respond to ICI; therefore, ICI treatment selection based on etiology of HCC has been advocated.[50]

BTC arises in a desmoplastic tumor microenvironment with a heterogeneous, immunosuppressive cellular milieu. Cancer-associated fibroblasts, tumor-associated macrophages, and myeloid-derived suppressor cells are abundant in the tumor microenvironment and function to exclude and exhaust antitumor T cells. Pharmacologic modification of this microenvironment with ICI has proven efficacious in a subset of patients with BTC in combination with gemcitabine and cisplatin. Along with identification of targetable mutations in BTC (i.e., IDH1, FGFR), the systemic therapeutic options for treatment of BTC are rapidly evolving.

Postoperative adjuvant treatment. Currently, there is no definitive recommendation for adjuvant treatment after HCC resection. This is largely because of a lack of effective chemotherapy for HCC. In a phase III double-blind placebo-controlled study evaluating the efficacy of sorafenib in decreasing recurrence of HCC in patients who underwent complete radiologic response after resection or ablation, sorafenib treatment was not able to decrease recurrence.[51] However, antiviral treatment in patients with HBV infection has been shown to decrease the risk of HCC recurrence and HCC-related deaths.[52,53] With availability of newer and effective antivirals for treatment of HCV, similar results are hoped for in patients infected with this virus. Although a lower level of evidence does suggest that sustained viral response is associated with improved overall survival and better recurrence-free survival after resection or locoregional therapy for HCV-related HCC, this needs to be confirmed in better-designed trials. A recent trial (IMbrave 050 trial) demonstrated adjuvant atezolizumab plus bevacizumab provided a benefit in recurrence-free survival but not overall survival in patients with a high risk of relapse after resection or local ablation.[54] Combinations of immunotherapy, small molecule therapies, and chemotherapies continue to be tested in this setting.

Distinct variants of hepatocellular carcinoma. Fibrolamellar HCC[55] is a variant of HCC with remarkably different clinical features, summarized in Table 89.9. This tumor generally occurs in younger patients without a history of cirrhosis. The tumor is usually well demarcated and encapsulated and may have a central fibrotic area. The central scar can make distinguishing this tumor from FNH difficult. On histologic evaluation, fibrolamellar HCC is composed of large polygonal tumor cells embedded in a fibrous stroma, forming lamellar structures (Fig. 89.35). Fibrolamellar HCC does not produce AFP but is associated with elevated neurotensin levels. In general, fibrolamellar HCC has a better prognosis than HCC, probably related to high resectability rates, lack of chronic liver disease, and a more indolent course (see Table 89.9). Long-term survival can be expected in approximately 50% to 75% of patients after complete resection, but recurrence is common and occurs in at least 80% of patients. The presence of lymph node metastases predicts a worse outcome. Resection of lymph node metastases and recurrent disease has been advocated because of a lack of alternative therapy and the possibility

TABLE 89.9 Comparison of Standard Hepatocellular Carcinoma and Fibrolamellar Hepatocellular Carcinoma

PARAMETER	HCC	FIBROLAMELLAR HCC
Male-to-female ratio	2:1–8:1	1:1
Median age	55 years	25 years
Tumor	Invasive	Well circumscribed
Resectability	<25%	50%–75%
Cirrhosis	90%	5%
AFP positive	80%	5%
Hepatitis B positive	65%	5%

AFP, α-Fetoprotein; *HCC,* hepatocellular carcinoma.

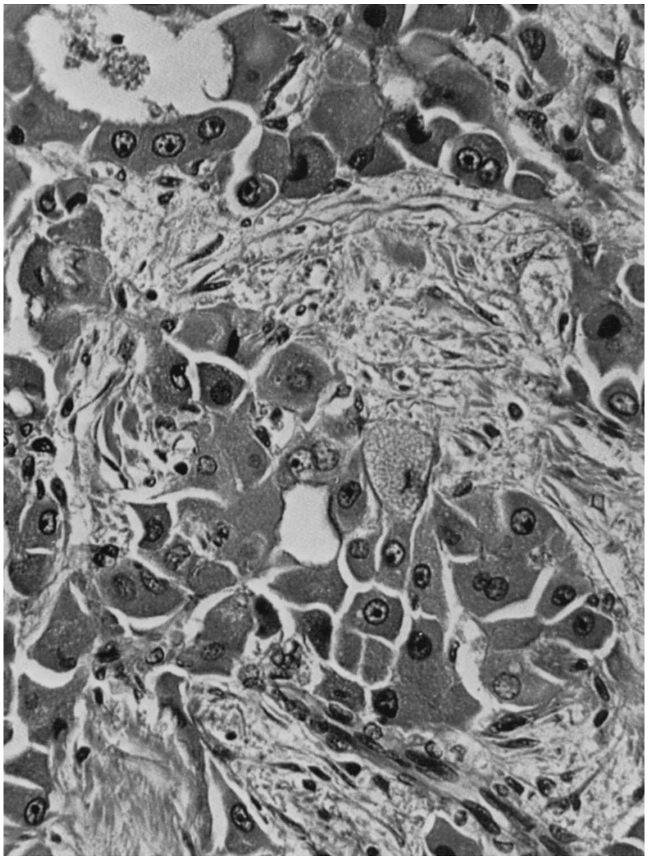

FIGURE 89.35 Fibrolamellar hepatocellular carcinoma. Abundant collagen is evident interconnecting clusters of cells. The cells are often in single-layer sheets. An acinus is present in the left upper field.

of long-term survival. A study identified a chimeric transcript that is expressed in fibrolamellar HCC but not in the adjacent normal liver.[56] The study also suggested that this transcript codes for a chimeric protein containing the catalytic domain of protein kinase A, thus suggesting that this gain of kinase activity may have a role in the pathogenesis of fibrolamellar HCC. Elucidation of such novel processes can lead to development of novel targeted therapies against this disease, which typically strikes young, healthy people.

Rarely, HCC can manifest as a mixed hepatocellular-cholangiocellular tumor, with cellular differentiation of both types present. Whether this is two separate tumors growing into each other or mixed differentiation of the same tumor is not known. These mixed tumors tend to have a prognosis that is worse than for standard HCC but better than expected for IHC.

A clear cell variant of HCC also exists, in which the cells contain a clear cytoplasm. These tumors can resemble renal cell neoplasms. The clear cell variant may have a better prognosis than standard HCC, but this is debatable. A pleomorphic or giant cell variant of HCC has also been reported. Cells of this type are multinucleated, pleomorphic, and large and likely to originate from primary hepatic cells. Some HCCs show evidence of sarcomatoid differentiation and are referred to as a *sarcomatoid variant* or *carcinosarcoma*. These tumors tend not to produce AFP and have a higher incidence of metastases at presentation.

Childhood HCC is a distinct entity that represents almost 25% of pediatric liver tumors but rarely occurs in infancy. Viral hepatitis is associated with childhood HCC in Asia but less so in the United States. Other inherited metabolic liver diseases (see earlier) are often associated with childhood HCC. As in adult HCC, complete resection is the only potentially curative treatment. There is a high incidence of multifocality, vascular invasion, and extrahepatic metastases, resulting in relatively poor long-term survival rates of 10% to 20%.

Intrahepatic Cholangiocarcinoma

Cholangiocarcinoma is an uncommon neoplasm, with an incidence of 1 to 2/100,000 in the United States, and can develop anywhere along the biliary tree, from the ampulla of Vater to the peripheral intrahepatic bile ducts. Most of these tumors (40%–60%) involve the biliary confluence (Klatskin tumor), but approximately 10% emanate from intrahepatic ducts and are known as IHC. IHC is the second most common primary hepatic neoplasm. Studies on the incidence and natural history of IHC have been confused by the fact that in the past, many of these tumors were mistaken for metastatic adenocarcinoma because biopsy is unable to differentiate the two.

IHC is associated with diseases that cause biliary inflammation and fibrosis. Historically, the most common risk factors for the development of cholangiocarcinoma (all types) were primary sclerosing cholangitis, choledochal cyst disease, hepatolithiasis,[57] and RPC. Recent epidemiologic evidence has now linked IHC to HBV infection,[58] HCV infection, cirrhosis, NASH, and diabetes.[59] Increases in the diagnosis of IHC in the United States are likely related to better recognition of the disease, changed classification, and perhaps the rise in HCV infections in the 1960s and 1970s.

The clinical presentation of IHC is similar to that of HCC. These tumors are asymptomatic in early stages. When present, the most common symptoms are right upper abdominal pain and weight loss. Jaundice occurs less commonly, as these tumors tend to arise in the periphery of the liver. More commonly, patients present with incidentally found liver masses on cross-sectional imaging. Unlike in HCC, the AFP levels are normal, although CEA or carbohydrate antigen 19-9 (CA 19-9) levels can be elevated in some cases. Because metastatic adenocarcinoma to liver is more common, IHC is a diagnosis of exclusion, and a search for a primary tumor with upper and lower gastrointestinal endoscopy and cross-sectional imaging of the chest, abdomen, and pelvis should be carried out. If a biopsy has been performed, it is often read as adenocarcinoma. Although special stains may suggest diagnosis of IHC, they are not conclusive. On CT and MRI, IHC is seen as a focal hepatic mass that may be associated with peripheral biliary dilation. The mass typically has peripheral or central enhancement on contrast-enhanced scans. Furthermore, unlike HCC, there is persistent enhancement on delayed phases because of the fibrotic nature of cholangiocarcinoma, in contrast with the vascular nature of HCC. Hepatic capsular retraction is also frequently observed. Intrahepatic metastases, lymph node metastases, and growth along the biliary tree are often encountered.

Complete resection is the treatment of choice for IHC. The concept of optimal surgical margins in the treatment of IHC is evolving. However, surgeons should strive for R0 margins. Because of large tumor size and invasion into the surrounding structures, major hepatectomies with or without resection of surrounding organs may be required for achieving a margin-negative resection. Resectability rates generally range up to 60%, and long-term survival in unresected patients is rare. If it is completely resected, 3-year survival rates range from 16% to 61%, and 5-year survival rates range from 24% to 44%. Factors associated with a poor outcome include multifocality, lymph node metastases, vascular invasion, and positive margins. These factors have now been included in the American Joint Committee on Cancer (AJCC) staging system. A review of prospectively evaluated patients with IHC who underwent resection suggested that although patients with R0 resection did better when compared with R1 resection, width of margin did not influence outcomes. Because of the rarity of IHC, little is known about the effectiveness of radiation therapy and chemotherapy in the adjuvant setting. Thus, their application is not routine.

Use of chemotherapy as an adjuvant strategy is controversial. Because of the overall low incidence of biliary cancers, studies of adjuvant therapy have typically grouped various disease sites to include both intrahepatic and extrahepatic cholangiocarcinoma as well as gallbladder cancer. In a recently reported clinical trial from the United Kingdom (phase III BILCAP study), patients with completely resected gallbladder and cholangiocarcinoma were randomized to receive adjuvant capecitabine or observation. Although on intention-to-treat analysis, adjuvant capecitabine did not improve survival, when comparing patients who received adjuvant therapy per protocol, adjuvant capecitabine was associated with 25% reduced risk of death. Retrospective studies have provided conflicting evidence regarding the benefits of adjuvant therapy. Regional hepatic artery chemotherapy is currently under study and may be a promising approach.

For nonresectable disease, combination chemotherapy of gemcitabine and cisplatin and the anti–PD-L1 agent durvalumab has been considered the most effective first-line regimen (see Table 89.8).[60]

This regimen is often used in the adjuvant setting for patients at high risk for recurrence or in attempts to downstage patients with initially unresectable disease to resectable.

Other Primary Malignant Neoplasms

Hepatoblastoma is the most common primary hepatic tumor of childhood. There are approximately 50 to 70 new cases per year in the United States. Rare cases of adult hepatoblastoma have been reported, but overall, the median age at presentation is 18 months, and almost all cases occur before the age of 3 years. Hepatoblastoma has been associated with familial polyposis syndrome. There are several histologic subtypes, but in general, the tumor is derived from fetal or embryonic hepatocytic progenitors, and mesenchymal elements are often present. This tumor generally is manifested as an asymptomatic mass. Mild anemia and thrombocytosis are commonly found at presentation. Serum AFP levels are elevated in 85% to 90% of patients and can serve as a useful marker for therapeutic response. Most studies have supported the use of chemotherapy followed by resection, and survival appears to be dependent on complete resection. Chemotherapy can serve to downstage tumors, which facilitates resection. In patients without metastatic disease or the anaplastic variant, long-term survival rates of 60% to 70% can be expected with complete resection. Interestingly, 50% of patients with pulmonary metastases can be cured with resection of the hepatic tumor and chemotherapy or resection of the pulmonary metastases.

A variety of sarcomas can rarely be manifested as primary liver tumors, but they must always be considered metastatic lesions until proven otherwise. Angiosarcoma is probably the best-described primary hepatic sarcoma because of its well-known association with vinyl chloride or Thorotrast exposure. Angiosarcoma typically manifests as multiple hepatic masses and can appear in childhood. Long-term survival is uncommon with primary hepatic angiosarcoma. Other sarcomas, including leiomyosarcoma, malignant fibrous histiocytoma, embryonic sarcoma, and primary hepatic rhabdoid tumors, have been described but are rare. The last two lesions are typically seen in the pediatric population.

Non-Hodgkin lymphoma can manifest primarily in the liver, with or without extrahepatic disease. Primary hepatic lymphoma should be treated in the same manner as lymphoma elsewhere in the body if the diagnosis can be made before a liver resection.

Primary hepatic neuroendocrine tumors or carcinoid tumors have been described but are probably extremely rare. Distinguishing the rare primary hepatic neuroendocrine tumor from a metastatic lesion can be difficult because the extrahepatic primary tumor can be radiologically occult for many years, and the liver is the most common site of metastases.

Malignant germ cell tumors of the liver, including teratomas, choriocarcinomas, and yolk sac tumors, are very rare and are principally described in the pediatric population.

Epithelioid hemangioendothelioma of the liver is a rare malignant vascular tumor that manifests with multiple bilateral hepatic masses. Extrahepatic metastases occur in approximately 25% of patients, and clinical behavior is unpredictable, with some patients having a prolonged indolent course. Most patients ultimately die of liver failure, but cases of successful transplantation have been reported.

Cystic Neoplasms

Simple Cyst

Simple cysts of the liver contain serous fluid, do not communicate with the biliary tree, and do not have septations. They are generally spherical or ovoid and can be as large as 20 cm. Large cysts can compress normal liver, inducing regional atrophy and sometimes compensatory contralateral hypertrophy. In 50% of cases, the cysts are singular. On histologic evaluation, a single layer of cuboidal or columnar cells without atypia lines these cysts. Simple cysts are generally regarded as congenital malformations.

Simple cysts are a relatively common finding in adults and are mostly asymptomatic incidental radiologic findings. On occasion, a large cyst will cause symptoms. Although CT demonstrates anatomic relationships, ultrasound is a helpful test of choice to confirm a single thin-walled simple cyst. Hydatid disease, cystadenoma, and metastatic neuroendocrine tumor are the most important differential diagnoses to consider. A thick or nodular wall raises the suspicion of a cystadenoma but can also represent hemorrhage within the cyst. The most common complication is intracystic bleeding, but overall, complications are rare. The treatment of simple hepatic cysts is indicated only if they are symptomatic or there is diagnostic uncertainty. Because most cysts are asymptomatic, a thorough evaluation of the cause of the symptoms must be carried out before attributing them to the cyst. Nonsurgical treatment consists of aspiration and injection of a sclerosing agent. Few studies have documented long-term follow-up of sclerotherapy for hepatic cysts. Surgical therapy is achieved by fenestration or unroofing of the portion of the cyst that is extrahepatic. This can be performed at laparotomy with good long-term results or through laparoscopic approaches. The laparoscopic approach is favored, but long-term efficacy has not been well documented. A meta-analysis including nine retrospective case-control studies involving 657 patients comparing laparoscopic fenestration with the open approach demonstrated that the laparoscopic approach was associated with shorter operative time, shorter hospital stay, and less operative blood loss with no difference in cyst recurrence rates.[61]

Cystadenoma and Cystadenocarcinoma

Cystadenoma of the liver is a rare neoplasm that generally is manifested as a large cystic mass, usually 10 to 20 cm. The cyst has a globular external surface with multiple protruding cysts and locules of various sizes. The fluid contained in these cysts is usually mucinous. On microscopic examination, atypical cuboidal or columnar cells resting on a basement membrane, with ovarian-like stroma, line the cysts. The epithelium often forms polypoid or papillary projections.

Cystadenoma of the liver mainly affects females older than 40 years. Although many cystadenomas are asymptomatic, symptoms can include abdominal pain, anorexia, nausea, and abdominal distention. The diagnosis is usually suspected by a combination of cross-sectional imaging (CT or MRI) and ultrasound. Ultrasound usually demonstrates a cystic structure with varying wall thickness, nodularity, septations, and fluid-filled locules. Importantly, contrast-enhanced CT demonstrates enhancement of the cyst wall and septa. Hydatid disease must always be considered in the differential diagnosis. Cystadenomas tend to grow slowly but can eventually progress to their malignant counterpart, cystadenocarcinomas.

Cystadenocarcinoma is an extremely rare malignant neoplasm with little documentation of its natural history and outcome after resection. Malignant degeneration is typically suggested on imaging, with large projections and a markedly thickened wall. The treatment of cystadenoma or cystadenocarcinoma is complete excision, which can be done with an enucleation if there is no evidence of invasive malignant disease. Incomplete resection risks recurrence or the development of cystadenocarcinoma.

Polycystic Liver Disease

Liver cysts are commonly seen in patients with the autosomal dominant inherited adult polycystic kidney disease.[62] The cysts are histologically similar to simple cysts (see earlier). The main difference between the two entities is the number of cysts. When liver cysts are present in patients with adult polycystic kidney disease, they are always multiple in number. Also, there are usually numerous microscopic hepatic cysts as well as the grossly visible macrocysts. Despite the large number of liver cysts, hepatic parenchyma and function are usually preserved. When polycystic liver disease is associated with polycystic kidney disease, liver cysts are always preceded by kidney cysts, and their prevalence in adult polycystic kidney disease increases with age. Molecular diagnostic tests of autosomal dominant mutations causing the disease (*PKD1* and *PKD2*) can be used to confirm the clinical diagnosis. In those younger than 20 years, the prevalence of liver cysts is 0%, whereas in those older than 60 years, it is 80%.

Liver cysts in patients with adult polycystic kidney disease are generally asymptomatic, but in a few patients, numerous large cysts may cause abdominal pain and distention. LFT results are almost always normal. Rare complications can occur; these include infection and intracystic bleeding. Ultrasound and CT reveal multiple simple cysts throughout the liver and kidneys. Treatment of polycystic liver disease is reserved for severe symptoms related to large cysts and complications. Treatment includes percutaneous aspiration with or without sclerotherapy, cyst fenestration (by laparotomy or laparoscopy), hepatic resection, and orthotopic liver transplantation. Liver transplantation is used only with progressive disease after fenestration or resection with liver or renal dysfunction. In the context of renal failure, a combined kidney and liver transplantation may be appropriate.

Bile Duct Cysts

Bile duct cysts or choledochal cysts are congenital dilations of the biliary tree that are usually diagnosed in childhood but can present in adulthood. Because of the risk of malignancy and recurrent cholangitis, treatment is excision with reestablishment of biliary-enteric continuity. Most bile duct cysts involve the extrahepatic biliary tree, but in type IV cysts, there is involvement of the extrahepatic bile duct and intrahepatic ducts. In contrast, Caroli disease (type V) is characterized by multiple intrahepatic cysts. Thus, bile duct cysts must be considered in the differential diagnosis of a patient with multiple hepatic cystic lesions. The intrahepatic lesions of type IV bile duct cysts and Caroli disease are multifocal dilations of the segmental bile ducts separated by portions of normal-caliber bile ducts. Approximately 50% of cases of Caroli disease are associated with congenital hepatic fibrosis; the cysts are diffusely located throughout the liver. In the other 50% of cases, the dilations may be confined to a portion of the liver, usually the left hemiliver. Recurrent bacterial cholangitis usually dominates the clinical course of these diseases, and death generally ensues within 5 to 10 years without adequate treatment. When intrahepatic bile duct cysts are localized, hepatic resection, with or without biliary reconstruction, is the treatment of choice. Treatment of diffuse hepatic involvement is poor; in complicated cases, the only probably effective treatment is transplantation.

Principles of Hepatic Resection

Although liver resections were performed in the late 1800s, it was not until 1952 that Lortat-Jacob was given credit for the first true anatomic right hepatectomy. This event ushered in the modern era of hepatic surgery. However, early series were plagued by high morbidity and mortality, which were largely related to massive intraoperative blood loss. Series from the 1970s and 1980s often reported mortality rates in excess of 10%, often as high as 20%, especially for major resections. This high mortality limited the use of liver resection, and there was reluctance to refer patients for such operations. During the past three decades, a number of advances have improved perioperative outcomes dramatically for patients undergoing major hepatic surgery. The understanding that most blood loss during a liver resection comes from the hepatic veins has prompted surgeons to perform these operations with a low central venous pressure. We perform partial hepatectomy with a central line in place, with the patient in a mild Trendelenburg position, and fluid restriction and venodilators if necessary to maintain a central venous pressure lower than 5 mm Hg. The other major advance has been an improved understanding of the segmental anatomy of the liver, making intrahepatic dissection safer and more precise. There are numerous techniques to transect liver tissue and many methods to coagulate and to control vessels. The most important concept, however, is that dividing liver tissue is a dissection done by a surgeon with complete understanding of the liver's vascular anatomy.

In experienced centers, perioperative mortality is routinely 5% or less and depends on a number of factors. The three most critical factors related to perioperative morbidity are blood loss, the amount of normal liver resected, and the condition of the liver itself (e.g., cirrhosis). A partial hepatectomy must be performed with these factors in mind to minimize morbidity. In a review of more than 1800 liver resections during a 10-year period from MSKCC, the operative mortality was 3.1%.[63] The median blood loss was 600 mL, and two-thirds of patients did not require a red blood cell transfusion. Overall, postoperative morbidity was 45%, but the median hospital stay was 8 days. Morbidity was mostly related to blood loss and the extent of resection. Minor resections were associated with a mortality of 1%. Most complications and deaths were seen in complex biliary tumors, people with cirrhosis and HCC, and extensive resections. Improving outcomes after partial hepatectomy continues, and experienced hepatobiliary centers have reported mortality rates that approach 1% to 2%, with fewer patients now requiring perioperative blood transfusions. As a result of the increasing safety of hepatic surgery, liver resection has become the treatment of choice for many malignant and benign hepatic conditions.

Bile leaks are a problem in cases requiring complex biliary reconstruction but can also occur in approximately 10% to 20% of hepatectomies without biliary reconstruction. Careful ligation of biliary radicals is of obvious importance in minimizing this complication. Because of the regenerative capacity of the liver, resections of up to 80% of normal noncirrhotic livers can be performed, with functional compensation within a few weeks. Because many resections encompass tumors and normal liver, the concepts of functional liver parenchyma and FLR volume are important because there is often compensatory hypertrophy of normal liver when tumors occupy a significant amount of the liver volume. The risk of hepatic dysfunction is minimal if the reduction of functional liver parenchyma is less than 50% but begins to rise when this figure approaches 20% to 25%. Patients with cirrhosis have much higher rates of postoperative liver dysfunction because of impaired regenerative capacity and impaired primary liver function. Liver failure, extrahepatic multiorgan failure, and death are serious hazards to performance of major liver resections in patients with cirrhosis. In general, patients with Child-Pugh class B or C cirrhosis or portal hypertension do not tolerate liver resections, and selection of patients is therefore critical. Ascites and infectious complications are also common problems after major liver resection. One strategy to minimize postoperative liver dysfunction and morbidity after major hepatectomy is to embolize the portal vein percutaneously on the side of the liver to be resected. In approximately 4 weeks, this induces atrophy of the liver parenchyma to be resected and hypertrophy of the FLR. In turn, this increases the relative volume of the FLR.

Techniques of liver resection differ according to the disease being treated. In benign hepatic diseases requiring resection, the indications for operation are usually symptoms or infection. Removal of normal liver should be kept to a minimum in these cases, and techniques such as enucleation are appropriate, although a major resection is occasionally necessary. For malignant disease, a margin of normal tissue is important, and formal anatomic resections yield the best results. Techniques such as wedge resection often result in higher rates of margin involvement and disease recurrence and should therefore be used carefully and sparingly. It must be noted that for colorectal liver metastases, parenchymal-sparing nonanatomic resection provides comparable oncologic outcomes with marked reduction in complications when compared with major hepatic resections.

Detailed knowledge of liver anatomy is essential to the practice of safe hepatic surgery (see earlier). Unfortunately, detailed and complicated descriptions of liver anatomy and common liver resections can be confusing to the student. A 2000 consensus conference conducted in Brisbane, Australia, with the assistance of the Americas Hepato-Pancreato-Biliary Association has published guidelines for this terminology (Table 89.10 and Fig. 89.36). In general, the term *lobectomy* is not preferred because there are no external markings on the liver denoting a lobe. When in doubt, one should always revert to the numeric segments of the liver if there is any confusion about the description of a liver resection. Recall that the right liver is composed of segments V through VIII, and *right hepatectomy* and *right hemihepatectomy* are appropriate terms for resection of these segments. Segments II through IV compose the left liver, and *left hepatectomy* and *left hemihepatectomy* are appropriate terms for resection of these segments. A right hepatectomy can be extended farther to the left to include segment IV, and a left hepatectomy can be extended farther to the right to include segments V and VIII. Terms such as *extended right-left hepatectomy, right-left trisectionectomy,* and *trisegmentectomy* are appropriate to describe these resections. Resection of segments II and III is a commonly performed sublobar resection and is often referred to as a *left lateral segmentectomy* or *left lateral sectionectomy.* Other common sublobar resections, such as that of the right posterior sector (segments VI and VII) or the right anterior sector (segments V and VIII), are referred to as a *right posterior sectorectomy-sectionectomy* and *right anterior sectorectomy-sectionectomy,* respectively. Single or bisegmental resections can always be simply referred to by a numeric description of the segments to be resected.

A detailed discussion of the techniques of liver resection is beyond the scope of this chapter; in general, it requires specialty training, but general principles can be discussed. A liver resection must consider the disease to be treated and the goal of the operation, whether that is a margin-negative resection of a malignant neoplasm or the removal of benign tissue to alleviate symptoms. The most basic steps can be distilled down to inflow control (portal vein, hepatic artery, bile duct), outflow control (hepatic veins), and parenchymal transection, with preservation of a liver remnant

TABLE 89.10 **Nomenclature for Most Common Major Anatomic Hepatic Resections**[a]

SEGMENTS[b]	COUINAUD, 1957	GOLDSMITH AND WOODBURNE, 1957	BRISBANE, 2000
V–VIII	Right hepatectomy	Right hepatic lobectomy	Right hemihepatectomy
IV–VIII[c]	Right lobectomy	Extended right hepatic lobectomy	Right trisectionectomy
II–IV	Left hepatectomy	Left hepatic lobectomy	Left hemihepatectomy
II, III	Left lobectomy	Left lateral segmentectomy	Left lateral sectionectomy
II, III, IV, V, VIII[c]	Extended left hepatectomy	Extended left lobectomy	Left trisectionectomy

[a] The original terminology is based on the anatomic descriptions of Couinaud and of Goldsmith and Woodburne.

[b] See Figure 89.5.

[c] Another common name for these operations is right or left trisegmentectomy.

Adapted from the Terminology Committee of the International Hepato-Pancreatico-Biliary Association: The Brisbane 2000 Terminology of Liver Anatomy and Resections, 2000. http://www.ahpba.org/assets/documents/Brisbane_Article.pdf.

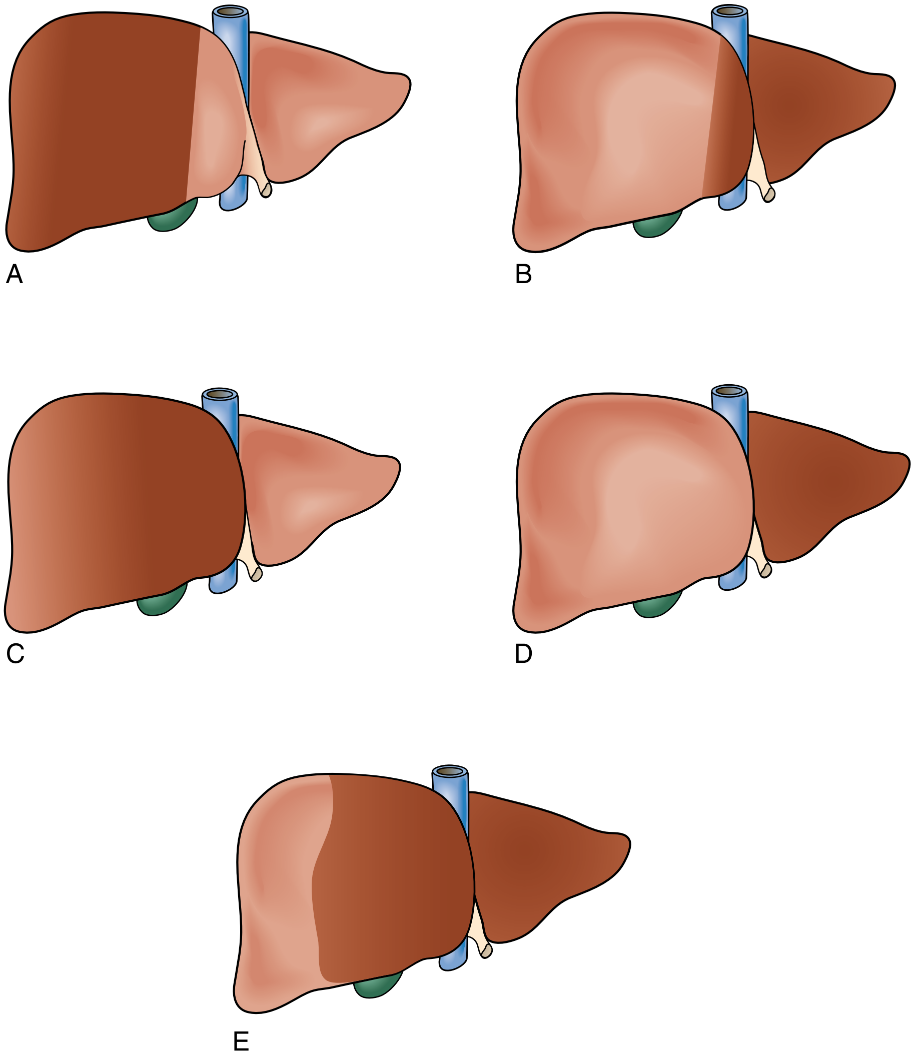

FIGURE 89.36 Commonly performed major hepatic resections are indicated by the *shaded areas.* (A) Right hepatectomy, right hepatic lobectomy, or right hemihepatectomy (segments V–VIII). (B) Left hepatectomy, left hepatic lobectomy, or left hemihepatectomy (segments II–IV). (C) Right lobectomy, extended right hepatic lobectomy, or right trisectionectomy (trisegmentectomy; segments IV–VIII). (D) Left lobectomy, left lateral segmentectomy, or left lateral sectionectomy (segments II–III). (E) Extended left hepatectomy, extended left lobectomy, or left trisectionectomy (trisegmentectomy; segments II–V and VIII). See Table 54.11. (From Blumgart LH, Jarnagin W, Fong Y. Liver resection for benign disease and for liver and biliary tumors. In: Blumgart LH, Fong Y, eds. *Surgery of the Liver and Biliary Tract.* London: WB Saunders; 2000:1639-1714.)

of adequate size with intact inflow, biliary drainage, and venous outflow.

The most common approach to an anatomic resection, in the most common order, is mobilization of the liver to be resected, dissection of inflow and outflow structures, division of the inflow, division of the outflow, and parenchymal transection. Mobilization of the liver involves division of the right or left triangular ligaments, freeing up the liver from the diaphragm. Often, the liver must be mobilized completely off the vena cava, which it straddles, and this requires careful dissection and division of multiple retrohepatic caval venous branches. For major resections, the hepatic vein of the resected portion of liver is often encircled before the resection. There are various techniques to dissect, control, and divide inflow vessels. Classic inflow control is obtained by dissection of the liver hilum, with control of the portal vein and hepatic artery to the hemiliver to be resected. These can be suture ligated or divided with vascular staplers. Unless tumor proximity mandates, we advocate dividing the bile duct within the liver substance to minimize absolutely contralateral biliary injuries related to anatomic anomalies. Inflow control can also be obtained by dissection of the intrahepatic inflow pedicle to the anatomic section of liver to be resected. Recall that the inflow structures invaginate peritoneum at the hepatic hilum and run intrahepatically as an invested pedicle of the three inflow structures. The inflow pedicles can be encircled by making flanking hepatotomies or by splitting parenchyma down to the pedicle of interest. The pedicle can usually be divided with a vascular stapler, but suture ligation is sometimes necessary. Typically, the hepatic vein is divided in its extrahepatic position, which can also usually be done with a vascular stapler.

The hepatic vein can also be divided within the substance of the liver during parenchymal transection. There are a number of methods of parenchymal transection, ranging from complex ultrasonic irrigators, to radiofrequency energy coagulators, to a simple clamp-crushing technique. In experienced hands, these can all be used effectively to minimize blood loss, and it is important to develop a specific technique that one is comfortable performing. Ultimately, parenchymal transection is about dissecting intrahepatic anatomy, controlling vascular and biliary structures, minimizing blood loss, and avoiding injury to the FLR.

Recent years have seen the adoption of minimally invasive surgery (MIS) for the liver. In addition to the open surgical approach, many hepatectomies are now performed via laparoscopy[18] or robotic assistance.[1] These MIS approaches have converted what once was a daunting operation to outpatient surgery. Choice of open, laparoscopic, or robotic approach should be based on best patient outcome, guided by expertise of the surgeon.

HEMOBILIA

A case of lethal hemobilia secondary to penetrating abdominal trauma was first described by Glisson in 1654. It was not until 1948 that Sandblom coined the term *hemobilia* in his seminal paper on the subject. Hemobilia is defined as bleeding into the biliary tree from an abnormal communication between a blood vessel and bile duct. It is a rare condition that is often difficult to distinguish from common causes of gastrointestinal bleeding. The most common causes of hemobilia are iatrogenic trauma, accidental trauma, gallstones, tumors, inflammatory disorders, and vascular disorders. Major hemobilia is relatively uncommon, whereas minor inconsequential hemobilia is a common consequence of gallstone disease or interventional radiologic hepatic procedures.

Causes

The most common cause of hemobilia is iatrogenic trauma to the liver and biliary tree. Before the 1980s, the ratio of hemobilia attributed to accidental trauma compared with iatrogenic trauma was 2:1, but iatrogenic trauma is now regarded as the cause of hemobilia in 40% to 60% of cases. Percutaneous liver biopsy results in hemobilia in less than 1% of cases, but percutaneous transhepatic biliary drainage procedures have an incidence of 2% to 10%. Similarly, surgical exploration of the biliary tree can result in hemobilia from direct injury or arterial pseudoaneurysm. A number of cases of hemobilia after cholecystectomy have been reported. Hemobilia secondary to accidental trauma is more common with blunt than with penetrating abdominal trauma and occurs with a reported incidence of 0.2% to 3%. Risk factors for the development of hemobilia after accidental trauma are central hepatic rupture with a cavity, the use of packs, and inadequate drainage. The gallbladder can be a source of bleeding from trauma, gallstones, or acalculous cholecystitis. Primary vascular diseases, such as aneurysms, angiodysplasia, and hemangiomas, are rare causes of hemobilia. Malignant tumors of the liver, biliary tree, gallbladder, and pancreas as well as parasitic infections, hepatic abscesses, and cholangitis are uncommon causes of hemobilia.

Clinical Presentation

Portal venous bleeding into the biliary tree is rare and often self-limited unless the portal pressure is elevated. Minor hemobilia generally runs an uneventful asymptomatic clinical course. However, arterial hemobilia, the most common source, can be dramatic. Clinical sequelae of hemobilia are related to blood loss and the formation of potentially occlusive blood clots in the biliary tree. The classic triad of symptoms and signs of hemobilia is upper abdominal pain, upper gastrointestinal hemorrhage, and jaundice. In one report, all three were present in 22% of patients. The symptoms and signs of major hemobilia are melena (90% of cases), hematemesis (60% of cases), biliary colic (70% of cases), and jaundice (60% of cases). Upper gastrointestinal bleeding seen in conjunction with biliary symptoms must always raise the suspicion of hemobilia. One interesting aspect of hemobilia is the tendency for delayed presentations, up to weeks after the inciting causal event, as well as recurrent and brisk but limited bleeding during months and even years. Blood clots in the biliary tree can masquerade as stones if hemobilia goes unrecognized. These clots can cause cholangitis, pancreatitis, and cholecystitis.

Diagnostic Workup

Once hemobilia is suspected, the first evaluation should be upper gastrointestinal endoscopy, which rules out other sources of hemorrhage and may visualize bleeding from the ampulla of Vater. However, upper endoscopy is diagnostic of hemobilia in only approximately 10% of cases. If upper endoscopy is diagnostic and conservative management is planned, no further studies are necessary. Ultrasound or CT may be helpful in demonstrating intrahepatic tumor or hematoma. Evidence of active bleeding into the biliary tree may be seen on contrast-enhanced CT in the form of pooling contrast material, intraluminal clots, or biliary dilation. CT may also show risk factors associated with hemobilia, such as cavitating central lesions and aneurysms. Arterial angiography is now recognized as the test of choice when significant hemobilia is suspected and will reveal the source of bleeding in approximately 90% of cases. Cholangiography demonstrates blood clots in the biliary tree that may appear as stringy defects or smaller spherical defects that may be difficult to distinguish from stones.

Treatment and Outcomes

The treatment of hemobilia must be focused on stopping the bleeding and relieving biliary obstruction. Most cases of minor hemobilia can be managed conservatively with correction of coagulopathy, adequate biliary drainage (only if necessary), and close observation. In a review of 171 reported cases from 1996–99, 43% were successfully managed conservatively. The first line of therapy for major hemobilia was transarterial embolization, and success rates of 80% to 100% were reported. Angiography with transarterial embolization is indicated for major hemobilia requiring blood transfusion (Fig. 89.37).

Surgery is indicated when conservative therapy and transarterial embolization have failed. Surgical treatment of hemobilia is rarely necessary, and even in cases in which a laparotomy may be mandated for other reasons, transarterial embolization is still the therapy of choice for hemobilia because of its lower morbidity. Surgical approaches generally involve ligation of bleeding vessels, excision of aneurysms, or nonselective ligation of a main hepatic artery. Hepatic resection may be necessary for failed arterial ligation or for cases of severe trauma or tumor. Hemorrhage from the gallbladder or hemorrhagic cholecystitis mandates cholecystectomy. There have been isolated reports of successful management of hemobilia with endoscopic coagulation, somatostatin, and vasopressin. The management of hemobilia after percutaneous transhepatic biliary drainage usually consists of removal of the catheter or replacement with larger catheters but may require transarterial embolization.

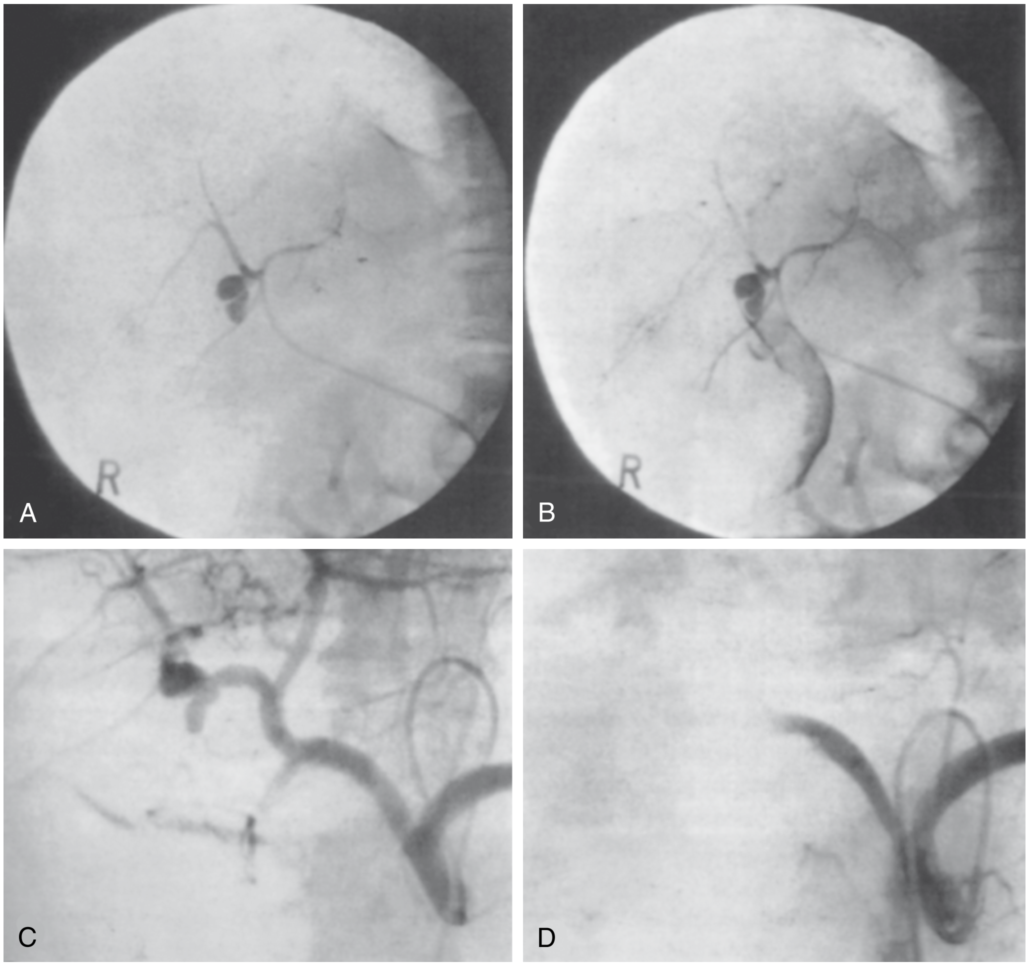

FIGURE 89.37 Classic findings of hemobilia. After a complicated cholecystectomy, an iatrogenic pseudoaneurysm developed and ruptured into the biliary tree. Exsanguinating hemobilia ensued; the diagnosis was made by endoscopy and then treated by arterial embolization. (A) Arteriogram demonstrating a pseudoaneurysm of the hepatic artery at the hilum. (B) A few seconds later, the contrast material is seen flowing down the hepatic duct, with evidence of clot in the biliary tree. (C–D) The same aneurysm before (C) and after (D) successful embolization. (From Sandblom JP. Hemobilia and bilhemia. In: Blumgart LH, Fong Y, eds. *Surgery of the Liver and Biliary Tract*. London: WB Saunders; 2000:1319-1342.)

At the time of Sandblom's report from the early 1970s, the mortality for hemobilia was at least 25%. A report from 1987 noted a mortality of 12%. In a review of cases from 1996 through 1999, only four deaths were reported. There has clearly been a reduction in mortality from hemobilia, which is probably related to two factors. First, the incidence of minor self-limited hemobilia has increased secondary to the rising number of percutaneous hepatic procedures. Second, improvements in selective angiography and transarterial embolization have greatly improved the treatment of major hemobilia.

BILHEMIA

Bilhemia is an extremely rare condition in which bile flows into the bloodstream through the hepatic veins or portal vein branches. This flow occurs in the context of a high intrabiliary pressure exceeding that of the venous system. The cause can be gallstones eroding into the portal vein or accidental or iatrogenic trauma. The condition can be fatal secondary to embolization of large amounts of bile into the lungs. Usually, however, bile flow is low, and the fistulas close spontaneously. The clinical presentation is that of rapidly increasing jaundice, marked direct hyperbilirubinemia without elevation of hepatocellular enzyme levels (e.g., AST, ALT), and septicemia. This diagnosis is best determined by ERCP. Treatment is directed at lowering intrabiliary pressures through stents or sphincterotomy.

VIRAL HEPATITIS AND THE SURGEON

Viral hepatitis is a major health problem and is the most common cause of liver disease worldwide.[64] More than 5 million people suffer from chronic hepatitis, and it is estimated that more than 1.1 million patients die each year of viral hepatitis globally. Viral hepatitis is not a surgical disease, but it can lead to the development of cirrhosis and HCC, two diseases that can be amenable to surgical therapy. Furthermore, for any surgeon performing hepatic surgery, the functional state of the liver is extremely important, and patients with chronic viral hepatitis may experience declines in synthetic and metabolic function. Finally, the risk of transmission from patient to surgeon and vice versa is an issue with which all surgeons should be familiar.

Definition

Viral hepatitis is an infection of the liver by one of six known viruses that have diverse genetic compositions and structures. HAV, HCV, HDV, HEV, and HGV have RNA genomes, whereas HBV has a DNA genome that replicates through RNA intermediates. HAV and HEV are both responsible for forms of epidemic hepatitis and are transmitted through the fecal-oral route. The remainder are spread via blood-borne transmission. HBV has a circular DNA genome and has the potential to integrate into host genomes, although this is not required for replication. HCV replicates in the cytoplasm of hepatocytes and has complex mechanisms of evading host immunity through hypervariable areas in its genome. HDV requires the presence of HBV coinfection for replication and infectivity and can alter the clinical course of HBV infection. HGV was discovered more recently and has similarities to HCV but has no definitive association with clinical hepatitis.

Diagnosis

Table 89.11 summarizes the serologic tests and their implications for HAV, HBV, and HCV.

The diagnosis of HAV infection relies on the identification of antibodies to HAV. Both IgM and IgG antibodies are present early in the infection, but only IgG persists long-term. HAV antigens and tests for HAV RNA have been developed but are generally restricted to research laboratories.

HBV infection is characterized by the presence or absence of several antigens and antibodies (Fig. 89.38). Hepatitis B serum antigen (HBsAg) is the hallmark of an acute HBV infection and appears in the serum 1 to 10 weeks after infection. It usually disappears in 4 to 6 months, but persistence beyond 6 months defines chronic infection. Anti-HBs antibodies (HBsAbs) are usually present in the serum after the disappearance of serum HBsAg and indicate recovery from acute HBV infection. HBsAbs are also induced by the HBV vaccine and indicate prior immunization or infection. The hepatitis core antigen (HBcAg) is an intracellular antigen that is not detectable in serum. On the other hand, anti-HBc antibodies are detectable early after infection and persist after recovery and in chronic infections. Therefore, the presence of HBcAb and HBsAb indicates prior HBV infection, whereas the presence of HBsAb alone indicates prior HBV vaccination. Hepatitis B e antigen (HBeAg) is a secretory protein that is a marker of HBV replication and infectivity. It is usually present early and may persist for years in chronic infection but generally disappears within months in the absence of chronic infection. Seroconversion to anti-HBe antibodies is usually associated with resolution of infection. Determining the presence of HBeAg or anti-HBe antibodies helps decipher the phases of infection described later. It has also been shown that many patients who have seroconverted often have measurable HBV DNA, albeit at low levels. Quantification of HBV DNA in the serum has become the most accurate way of assessing HBV activity. Evidence has shown that many patients thought to have resolved acute HBV infection may have persistent viral infection and may be at risk for ongoing hepatitis or reactivation.

The diagnosis of HCV infection relies on the detection of antibodies to a number of HCV antigens. Current immunoassays are highly specific and sensitive. No specific HCV antigen tests exist, but in patients at high risk for HCV, screening for chronic infection is performed with anti-HCV antibody test followed by polymerase chain reaction testing for HCV RNA. In patients with known HCV infection, there are a variety of quantitative and qualitative tests for HCV RNA, which are important in confirming the diagnosis in unclear cases and assessing responses to therapy.

HDV coinfection of HBV-infected patients is best diagnosed by measuring HDV RNA in serum. The HDV antigen can be detected in liver specimens. HEV infection can be diagnosed by measuring antibodies in serum or detecting the virus or its components in feces, serum, or the liver itself.

Epidemiology and Transmission

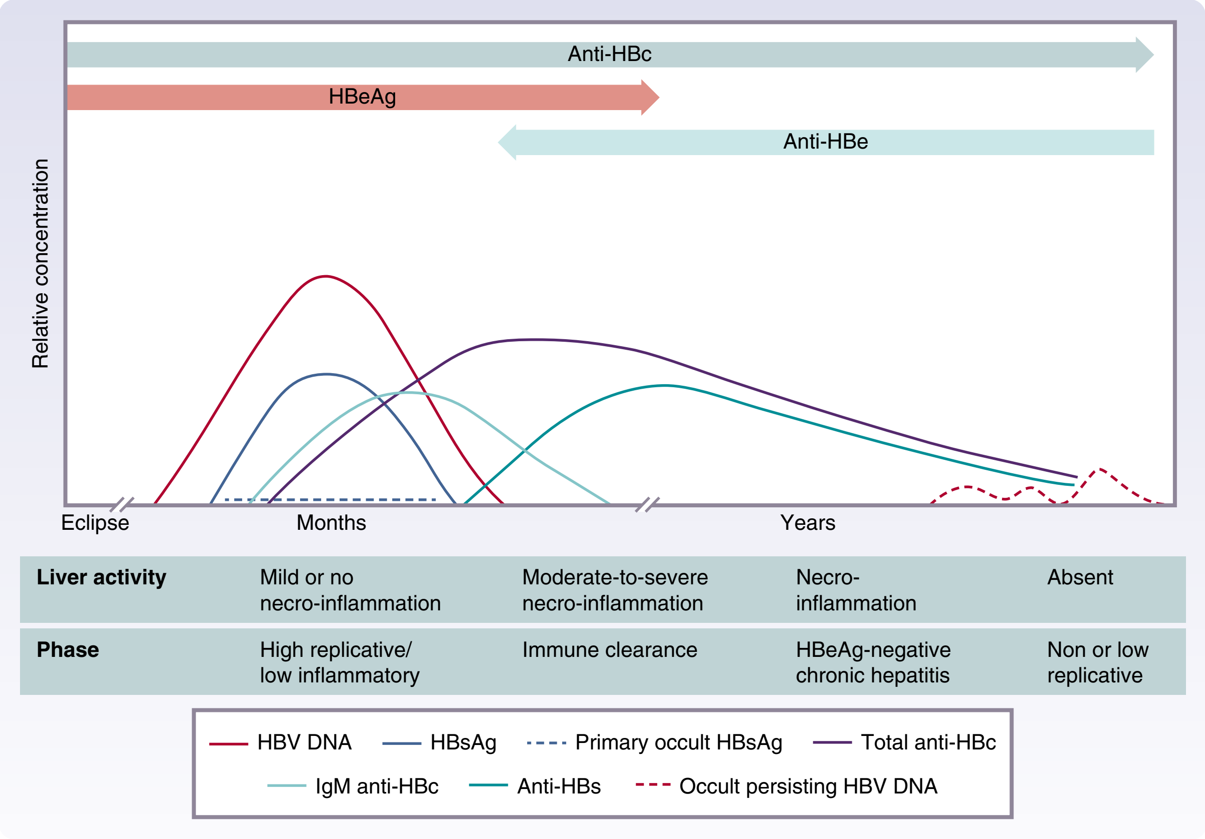
Hepatitis A is a highly contagious virus that is transmitted primarily through the fecal-oral route. Most cases of HAV occur because of ingestion of contaminated water or food and person-to-person contact. Parenteral transmission is possible but uncommon. Sexual transmission has been documented in homosexual males. The incidence of hepatitis A has fallen dramatically since the introduction of effective vaccines, but vaccination is not routine in all countries. Hepatitis A is common in third-world countries and overlaps with seropositivity rates approaching 100% in some populations. Infection rates are much lower in developed countries. In the United States, approximately 10% of children and 35% of adults have been infected with HAV. Despite vaccination availability, 5700 cases were reported in the United States in 2021, four times higher than in 2015.

Hepatitis B is a major worldwide health problem with approximately 296 million people affected. Hepatitis B contributes to an estimated 820,000 deaths every year, and 25% of chronic hepatitis B infections can progress to liver cancer. The prevalence of HBV infection has considerable geographic variation. Low-prevalence areas such as the United States and Western Europe have carrier rates of 0.1% to 2%. Carrier rates in intermediate-prevalence areas such as Japan and Singapore range from 3% to 5%. In high-prevalence areas such as Southeast Asia and sub-Saharan Africa, carrier rates range from 10% to 20%. Transmission in high-prevalence areas is largely perinatal and horizontal during childhood. In low-prevalence areas, transmission is generally through sexual intercourse or IV drug abuse. In the United

TABLE 89.11 **Serologic Evaluation of the Most Common Viral Hepatitides**

VIRUS	ANTIGEN NAME	INTERPRETATION	ANTIBODY NAME	INTERPRETATION
HAV	HAV antigen	Acute infection	Anti-HAV IgM	Acute infection
			Anti-HAV IgG	Immunity
HBV	HBsAg	Acute or chronic infection	Anti-HBs	Immunity
	HBeAg	HBV replication, infectivity	Anti-HBc	All phases of infection
			Anti-HBe	Late convalescence
HCV	None	—	Anti-HCV	Late convalescence or chronic infection

HAV, Hepatitis A virus; *HBc,* hepatitis B core; *HBe,* hepatitis e-antigen; *HBeAg,* hepatitis Be antigen; *HBs,* hepatitis surface antigen; *HBsAg,* hepatitis B surface antigen; *HBV,* hepatitis B virus; *HCV,* hepatitis C virus; *IgG,* immunoglobulin G; *IgM,* immunoglobulin M.



Liver activity	Mild or no necro-inflammation	Moderate-to-severe necro-inflammation	Necro-inflammation	Absent
Phase	High replicative/ low inflammatory	Immune clearance	HBeAg-negative chronic hepatitis	Non or low replicative

States, racial and ethnic disparities exist regarding HBV infection. In 2019, the rate of HBV infection among non-Hispanic Black adults was triple that of Asian or Pacific Islander adults and twice that of Hispanic adults.

Transfusion-associated HBV infection was common in the 1960s, and the risk has been estimated to be as high as 50% at that time. Currently, HBV nucleic acid testing and blood donor screening have decreased the risk of acquiring HBV from a blood transfusion to 1 in 63,000. Percutaneous transmission through the use of any contaminated needle is a major route of HBV infection and is common in IV drug abusers. Sexual transmission is common in low-prevalence countries and is estimated to account for approximately 30% of cases in the United States. There is a particularly high incidence in male homosexuals and heterosexuals with multiple sexual partners. Perinatal HBV infection accounts for less than 10% of cases in the United States but is common in endemic regions, with rates of transmission of 90% in some areas. Horizontal transmission among children is common and is probably related to minor breaks in the skin and mucous membranes. HBV is the most commonly transmitted virus among healthcare personnel, and transmission is usually patient to patient or patient to worker. Needle-stick risk has been related to HbeAg positivity. Rare cases of physician-to-patient transmission have been reported.

Hepatitis C is the most common cause of chronic liver disease in the United States, with an estimated prevalence of 1.8% accounting for 3.9 million infected people. New infections typically occur at a younger age (20–39 years), and the most common risk factor is IV drug abuse. Healthcare workers have higher carrier rates than the general public. Transmission among healthcare workers is usually related to needle-stick incidents, and the risk of transmission is higher than that of HBV and HIV. In the past, blood transfusion was the major cause of HCV infection, accounting for at least 85% of cases. Currently, less than 2% of acute infections are caused by transfusions, and the risk of transfusion-associated transmission is estimated to be about 1 in 10,000. Although HCV has never been documented in semen, it is estimated that approximately 20% of HCV infections are caused by sexual transmission. Risk of sexual transmission appears to be related to the number of partners and presence of other sexually transmitted diseases. Monogamous sexual partners of HCV-infected people occasionally test positive for HCV in the absence of other risk factors, but this appears to be rare. Perinatal transmission has been documented but is also rare. No identifiable risk factors are found in 30% to 40% of HCV cases. The introduction of direct-acting antiviral (DAA) agents has dramatically improved treatment of HCV and will be discussed later.

HDV infection occurs worldwide, with a variable distribution that parallels that of HBV infection. Approximately 5% of HbsAg-positive patients also harbor HDV infection. Transmission of HDV is parenteral and can occur only in patients previously infected with HBV.

HEV is endemic in Southeast Asia and Central Asia and occurs with low frequency in other areas of the world. HEV infection outbreaks are usually large, affecting hundreds to thousands of people at once, and often follow large rains and flooding. There is a particularly high incidence and mortality in pregnant females. Transmission is fecal-oral and usually related to contaminated drinking water or food. Person-to-person transmission and vertical transmission are rare.

Pathogenesis and Clinical Presentation

The pathogenesis of hepatic injury from these viral infections is not completely understood. For all the viruses discussed in this section, hepatic inflammation appears to be caused by direct hepatocellular cytotoxicity or immune-related phenomena. A combination of these two mechanisms probably underlies the cause of hepatic damage.

HAV is a member of the Picornaviridae family, a family of small RNA viruses. Humans are the only host for HAV, and no reservoir of infection has been identified. After oral intake, HAV can survive the acidic gastric pH, but the mechanism of hepatic uptake is not known. HAV infection results in acute inflammation of the liver but does not lead to chronic liver dysfunction. The most recent data suggest that hepatocyte damage is most likely an immunopathologic response rather than direct hepatotoxicity. Most children with HAV infection younger than 2 years are asymptomatic, whereas in pediatric patients older than 5 years, 80% will develop symptoms. Fulminant hepatitis develops in 1% to 5% of cases, and mortality is generally below 1%.

HBV is a member of the Hepadnaviridae family that is characterized by a genome consisting of partially double-stranded, circular DNA. After viral entry into the hepatocyte, the viral genome is delivered into the nucleus, where it is converted into fully double-stranded DNA and then covalently closed circular DNA. This stable form of HBV DNA is responsible for its persistence in infected hepatocytes. HBV also has the ability of integrating into the hepatocyte genome.

Approximately 70% of patients with acute HBV infection have subclinical or anicteric hepatitis; the other 30% have icteric hepatitis. The incubation period for HBV infection ranges from 1 to 4 months. A prodromal serum sickness–like syndrome may develop, followed by a multitude of constitutional symptoms, such as malaise, anorexia, and nausea. The constitutional symptoms last about 10 days and are followed by jaundice in 30% of patients. Clinical symptoms usually disappear within 3 months. Fulminant hepatic failure develops in 0.1% to 0.5% of patients. Almost 80% of patients with fulminant HBV-related hepatitis will die unless liver transplantation is performed.

Risk of chronic HBV infection is related to immunocompetence and age. Immunocompetent adults have a risk of less than 5%, whereas 30% of children and 90% of infants will develop chronic disease. The effect of age on HBV persistence is most likely caused by differences in immune maturity between adults and young children. The natural history and disease course of chronic HBV infection are the result of complex interactions between the virus and host immune response. A substantial proportion of patients will develop liver injury, cirrhosis and its complications, and HCC, whereas others will harbor the virus with limited, if any, injury.

Different phases of HBV infection, each with unique viral and biochemical profiles, have been described (see Table 89.11)[65] However, it must be noted that these phases are not necessarily sequential and can be reversed. The first phase, **HBeAg-positive chronic infection** (previously known as *immune tolerant phase*), is characterized by high serum HBV DNA but normal liver enzymes. There is a high serum level of HbeAg, and patients in this phase are highly contagious because of the high level of HBV DNA. The second phase, **HbeAg-positive chronic hepatitis B,** is characterized by all the features of phase I along with elevated ALT, suggesting liver damage. Liver biopsy at this stage will demonstrate moderate or severe liver necroinflammation. The third phase, **HbeAg-negative chronic HBV infection** (previously termed *inactive carrier phase*), is characterized by absence of HbeAg, presence of serum antibodies to HbeAg, undetectable or low levels of HBV DNA, and normal liver enzymes. The fourth phase is termed **HbeAg-negative chronic hepatitis B** and is characterized by the lack of serum HbeAg, detectable anti-Hbe levels, persistent moderate to high levels of serum HBV DNA, and fluctuating or persistently elevated ALT levels.

Most patients with chronic HBV infection are asymptomatic, but some may experience exacerbations of symptoms. Progression to cirrhosis is marked by hepatic synthetic dysfunction and often cytopenias related to hypersplenism. Extrahepatic manifestations of HBV infection, caused by circulating immune complexes, occur in approximately 10% to 20% of patients; these include polyarteritis nodosa, glomerulonephritis, essential mixed cryoglobulinemia, and papular acrodermatitis. The sequelae of chronic HBV infection range from none to cirrhosis, HCC, hepatic failure, and death. It has been noted that patients thought to have previously cleared the infection can have a reactivation, especially during a period of immunosuppression. In nonendemic areas, the long-term risk appears to be low, but in endemic areas, chronic HBV infection is a significant cause of morbidity and mortality.

HCV is an RNA virus with a single-stranded RNA genome. This genomic RNA encodes a single protein that can be cleaved by a protease enzyme into its components. HCV replicates in the hepatocyte cytoplasm. The components of viral replication are targeted by the recently successful DAAs. For instance, protease inhibitors target the protease responsible for cleaving the initial protein into the various viral components. Acute HCV infection generally is manifested with mild elevation of hepatocellular enzyme levels. In general, 80% of cases occur 5 to 12 weeks after infection. Symptoms occur in less than 30% of patients and are usually so mild and nonspecific that they do not affect daily life. Jaundice occurs in less than 20% of patients, and fulminant hepatic failure caused by HCV is extremely uncommon. Chronic HCV infection develops in approximately two-thirds of patients; the other third appear to clear the infection. Most patients with chronic HCV infection are asymptomatic without evidence of overt liver disease and present with only mildly elevated hepatocellular enzyme levels. Despite this quiet clinical course, patients with chronic HCV infection are at risk for development of cirrhosis and HCC. Estimates place the risk of cirrhosis at 2% to 20% at a 20- to 30-year interval. The risk for development of HCC from that point has been estimated at 1% to 4% per year. Progression of liver damage can be variable, and several factors appear to affect its rate. Factors associated with a more rapid progression include male sex, older age at infection, immunosuppression (e.g., HIV infection), coinfection with HBV, moderate alcohol intake, and obesity. Extrahepatic manifestations, such as autoimmune disorders and lymphoma, can occur with HCV infection and are likely related to circulating immune complexes.

The clinical presentation of HDV infection is related to a complex relationship between the degree of HBV and HDV infection. Simultaneous coinfection with high expression of HBV and HDV results in higher rates of acute fulminant hepatitis. Superinfection in a previous HBV carrier generally results in more rapidly progressive chronic liver damage. Some milder forms of acute HDV infection are associated with decreased expression of HDV and repression of HBV infection.

Hepatitis E has a histologic picture different from that of the other viral hepatitides in that a cholestatic type of hepatitis is seen in more than 50% of patients. HEV is introduced orally, and it is not known how the virus travels to the liver. The incubation period of HEV infection ranges from 2 to 9 weeks. The most common form of illness is acute icteric hepatitis; most series report jaundice in more than 90% of patients. Asymptomatic forms of the disease occur and are probably more common than the icteric form, but the actual frequency is unknown. The disease is usually self-limited, but fulminant hepatic failure can occur in a small percentage of patients. Overall, the mortality rate is probably significantly less than 1%. Pregnant females tend to have a more severe clinical course; mortality rates range from 5% to 25%.

Prevention

HAV infection prophylaxis relies on sanitary measures and administration of serum immunoglobulin. The development of safe and effective HAV vaccines, however, has made the use of preexposure immunoglobulin unnecessary. Serum immunoglobulin is still the therapy of choice for postexposure prophylaxis and may be safely given, along with active immunization. In the United States, the Centers for Disease Control and Prevention (CDC) has recommended universal vaccination of children on the basis of the safety and efficacy of the vaccine in high-risk populations. Public health researchers are investigating vaccination schemes to eradicate HAV infection in high-risk populations throughout the world. However, cost-benefit analyses have not supported universal vaccination worldwide. Similarly, HEV infection prophylaxis has focused on sanitary measures, particularly strategies aimed at drinking water. Unfortunately, HEV immunoglobulin has not been successful in preexposure or postexposure prevention of HEV infection, whereas anti-HEV antibodies appear to be effective at attenuating the clinical syndrome. Vaccines for HEV infection have been developed and evaluated in clinical trials.

Remarkable advances have been made in the prevention of HBV infection. In the past, prevention of HBV infection was limited to passive immunization with immunoglobulin containing high titers of antibody to HBsAg. Currently, immunoglobulin immunization is used only in postexposure prophylaxis. HBsAg-containing vaccines have been developed, with good safety and efficacy profiles. These vaccines are used primarily for preexposure prophylaxis but can also be used in a postexposure setting along with immunoglobulin. Currently, CDC recommends a three-dose HBV vaccination for all children, with the first dose being administered preferably within 24 hours after birth followed by two subsequent booster doses. Universal adult HBV vaccination through age 59 and in adults greater than 60 years of age is also advocated by the CDC. Revaccination is generally not indicated but can be considered in certain patients who are at high risk for reinfection including healthcare workers, persons on hemodialysis, and nonresponder infants born to persons testing positive for HBsAg. Although no vaccine is available for HDV infection, effective prevention of HBV infection prevents HDV infection.

The only effective way to prevent HCV infection is to avoid behaviors that can spread the disease and to expand public health strategies mitigating major risk factors for transmission. Conventionally prepared anti-HCV immunoglobulin has been evaluated in a number of trials and has not been demonstrated to prevent transfusion-related non-A, non-B hepatitis. Screening of blood donors has rendered this issue irrelevant today. Unfortunately, because of various obstacles, a successful HCV vaccine has not been developed.

Treatment

Treatment of HAV or HEV infection is supportive in nature and is generally aimed at correcting dehydration and providing adequate calorie intake. Although fatigue may mandate significant periods of rest, hospitalization is usually not necessary, except in cases of fulminant liver failure.

The treatment of HBV infection is largely aimed at patients with chronic active disease. Interferon alfa and the nucleoside analogue lamivudine used to be the only two approved therapies for the treatment of HBV. Now, many nucleoside analogues for the treatment of HBV infection have been developed and probably work through inhibition of DNA synthesis. Interferon alfa is an immunomodulatory agent with some antiviral properties that can induce a virologic response in 35% to 40% of patients. However, long-term benefits with interferon therapy have not been proven. Oral nucleoside analogues are currently the main form of anti-HBV treatment, which include entecavir and two prodrugs of tenofovir. These three drugs are very effective in inducing virologic suppression in a high proportion of patients with favorable safety and tolerability profiles. Long-term viral suppression with nucleoside analog therapy leads to significant histologic improvement, including regression of cirrhosis,[66] reduced complications of cirrhosis, and decreased risk of developing HCC. Indication for treatment of HBV infection is based on three parameters: serum HBV DNA, serum ALT levels, and severity of liver disease. All experts agree that patients with cirrhosis, with or without decompensation, should be treated when serum HBV DNA is detectable. Most experts will also suggest treatment with higher levels of HBV DNA with ALT elevations or with moderately elevated levels of HBV DNA with evidence of liver fibrosis.

During the last 20 years, tremendous advances in the treatment of HCV infection have occurred. Interferon alfa and ribavirin were the recommended treatment for hepatitis C for decades after a benefit for interferon-α in the treatment of non-A, non-B hepatitis was originally demonstrated in 1986, before the discovery of HCV. With interferon-α treatment regimens, complete viral response, defined as sustained loss of serum viral RNA, occurs in 12% to 20% of patients. The addition of ribavirin to interferon-α resulted in response rates of 35% to 45%. In the most recent trials, treatment with pegylated interferon-α and ribavirin for 48 weeks resulted in viral clearance in 55% of patients. The specific genotype appears to be predictive of response, with some types resulting in response rates of 80% and others of 45%. Relapse can occur, but it usually occurs with monotherapy and shortened courses of therapy. Interferon-α regimens had significant side effects.

Over the past 10 years, the treatment of chronic HCV infection has been revolutionized by the introduction of DAAs (e.g., ledipasvir, sofosbuvir, glecaprevir, pibrentasvir, velpatasvir) (Table 89.12) that target specific nonstructural proteins of HCV and thus disrupt viral replication and infection. First developed in 2014, combinations of these medications have now become the first-line treatment and have replaced prior regimens containing pegylated interferon-α and ribavirin where available. The current all-oral treatments are of shorter duration and have fewer side effects and higher cure rates. By tailoring the combination of DAA agents to patient factors and the specific HCV genotype, a sustained virologic response can be achieved in more than 90% of patients.

TABLE 89.12 **Treatments Available for Hepatitis C**

DAA TRADE NAME	DAA GENERIC NAME	TREATMENT CLASS
Harvoni	Ledipasvir/sofosbuvir	NS5A, NS5B Inhibitor
Mavyret	Glecaprevir/pibrentasvir	NS5A, NS3/4A Inhibitor
Vosevi	Sofosbuvir/velpatasvir/ voxilaprevir	NS5A, NS5B Inhibitor
Epclusa	Sofosbuvir/velpatasvir	NS5A, NS5B Inhibitor
Zepatier	Elbasvir/grazoprevir	NS5A, NS3/N4a Inhibitor

DAA, Direct-acting antiviral.

The therapeutic efficacy of DAAs has resulted in dramatic declines in the incidence of decompensated cirrhosis and, to a lesser extent, HCC secondary to HCV infection.[67] This has led to a decrease in the number of liver transplants performed for HCV-related decompensated cirrhosis and HCC.[68,69] In the United States, the proportion of liver transplants for HCV-related disease has declined to 7% in 2020, from 27% in 2010 (Fig. 89.39). In Europe, it has been estimated that at least 600 liver grafts can be allocated to patients with indications other than HCV each year, such as NASH, which is increasing in incidence. Furthermore, availability of DAA has shifted attitudes toward accepting HCV-positive donor liver grafts, with 60% of liver transplant candidates willing to accept HCV-positive donor grafts in 2020 compared with 21% in 2015, thus increasing the liver graft donor pool.

Needle-Stick Injuries and Viral Hepatitis

Exposure to hepatitis viruses remains an occupational risk for surgeons and healthcare personnel. Viral transmission may occur after percutaneous or mucocutaneous exposure to the blood or body fluids of an infected patient. Hepatitis B virus is one of the most readily transmissible viruses after percutaneous exposure. In patients with HBeAg-positive blood, the rate of transmission via needle stick is nearly 20%. If exposed, HBV vaccination and hepatis B immune globulin are typically used together for postexposure treatment.

HCV is less readily transmitted than HBV, and the risk of acquiring the infection after exposure is low. In a source patient with anti-HCV–positive blood, the risk of transmission after percutaneous or mucocutaneous exposure is 0.2% and 0%, respectively. If an occupational exposure is sustained, baseline testing of the healthcare personnel and source patient is recommended to detect the presence of HCV RNA or anti-HCV antibodies. This will determine subsequent testing and treatment. Routine postexposure prophylaxis is not currently recommended by the CDC.

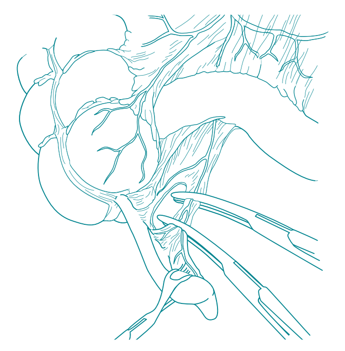
90 CHAPTER



Secondary Tumors of the Liver

Reed I. Ayabe, Mengyuan Liu, Michael I. D'Angelica, and Yun Shin Chun

OUTLINE

Pathogenesis of Liver Metastases
Clinical Presentation and Diagnosis
Perioperative Considerations
- Parenchymal-Sparing Hepatectomy
- Intraoperative Ultrasound
- Remnant Liver Volume
- Strategies to Increase Future Liver Remnant Volume
- Bilateral Liver Metastases

Colorectal Liver Metastases
- Systemic Therapy
- Chemotherapy-Associated Hepatotoxicity
- Synchronous Primary Colorectal Cancer and Liver Metastases
- Role of Diagnostic Laparoscopy
- Prognostic Factors
- Biomarkers
- Extrahepatic Disease
- Resection Margin
- Liver-Directed Therapies
- Liver Transplantation
- Memorial Sloan Kettering Cancer Approach
- MD Anderson Cancer Center Approach

Neuroendocrine Liver Metastases
- Surgical Cytoreduction
- Perioperative Considerations
- Nonsurgical Management

Noncolorectal Nonneuroendocrine Liver Metastases
- Gastric and Gastroesophageal Junction
- Breast Cancer
- Gastrointestinal Stromal Tumor
- Pancreas
- Melanoma
- Gynecologic Malignancies

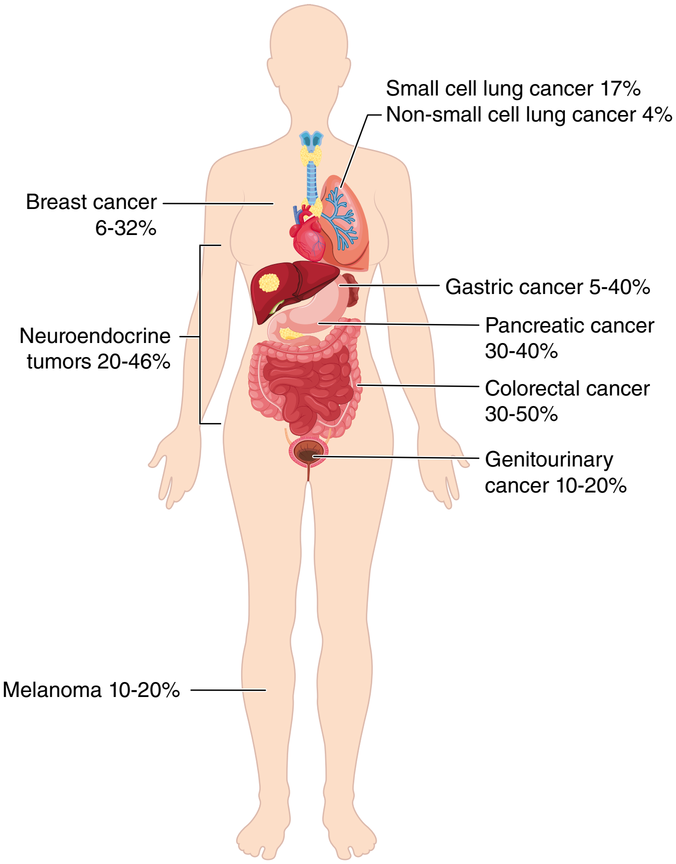
The liver is the solid organ most frequently affected by metastases, due to its rich blood supply, anatomy, and immunosuppressive environment.[1] Liver metastases will develop in up to 50% of all cancer patients throughout the course of their disease, resulting in significant reduction in survival and quality of life (Fig. 90.1).[2] Among patients with primary tumors in the gastrointestinal tract, the liver is the second most common site of metastases after lymph nodes, likely due to hematogenous dissemination via the portal venous system. Colorectal cancer is the leading cause of liver metastases, followed by lung, pancreas, and breast cancer.[3]

Most patients with liver metastases are not candidates for metastasectomy due to disseminated disease and poor tumor biology. However, well-selected patients with colorectal liver metastases (CLMs) may derive significant benefit and even cure from hepatic resection. In fact, CLM is the most frequent indication for liver resection in the United States. Although relatively uncommon, neuroendocrine liver metastases (NELMs) are also managed surgically in appropriately selected patients. Both diseases represent exceptions to the historical dogma that stage IV disease should be managed nonoperatively. Indeed, advances in systemic and regional therapies and an improved understanding of the natural history of these tumors have expanded the pool of patients who are candidates for surgery. This chapter will review pathogenesis, clinical presentation and diagnosis, and perioperative considerations, particularly for CLMs and NELMs. In addition, we summarize treatment strategies for CLMs used by two high-volume, tertiary cancer centers, highlighting the complexity and diversity of surgical management of liver metastases.

PATHOGENESIS OF LIVER METASTASES

The pathogenesis of liver metastases involves a multistep process of invasion, extravasation, and colonization necessary for metastasis formation in any organ (see Chapter 60). After cancer cells from the primary organ invade through the extracellular matrix into the blood or lymphatic vessels, these circulating tumor cells (CTCs) must arrest and extravasate between endothelial cells of a distant organ to form micrometastatic colonies.[4] The liver provides a particularly hospitable environment for metastatic seeding due to direct hematogenous access for cancers of the gastrointestinal tract via the portal venous system, microscopic anatomy, and immunotolerogenic milieu.

The liver's microscopic anatomy is conducive to extravasation and metastasis formation (see Chapter 89). The liver is organized into lobules, which are centered around the terminal tributaries of the hepatic vein, termed *central veins* (Fig. 90.2). Portal tracts lie at the periphery of the lobule. Within each lobule, hepatocytes are organized into plates that extend from the portal tracts to the central vein. Sinusoids are unique capillaries of the liver located between the plates of hepatocytes that carry a mixture of arterial and venous blood from the portal tract to the central vein. Liver sinusoidal endothelial cells (LSECs) lining the sinusoids are fenestrated and, therefore, highly permeable to extravasation of CTCs.[5]



Small cell lung cancer 17%
Non-small cell lung cancer 4%
Breast cancer 6-32%
Neuroendocrine tumors 20-46%
Gastric cancer 5-40%
Pancreatic cancer 30-40%
Colorectal cancer 30-50%
Genitourinary cancer 10-20%
Melanoma 10-20%

FIGURE 90.1 Incidence of liver metastases from primary tumors.

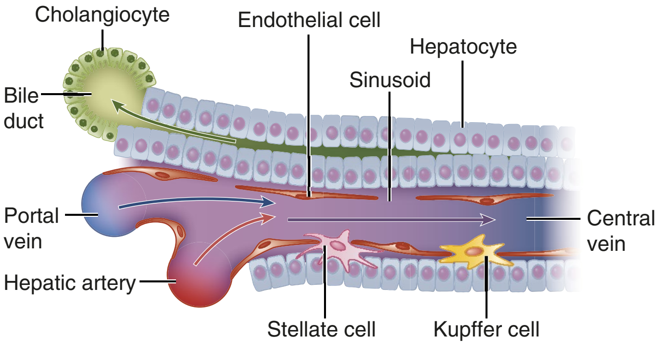


FIGURE 90.2 Microscopic anatomy of the liver. (From Trefts E, Gannon M, Wasserman DH. The liver. *Curr Biol.* 2017;27:R1147-R1151.)

In addition to its rich blood supply and fenestrated LSECs, the liver is a frequent site of metastases due to its favorable microenvironment, which provides a fertile "soil" for the "seeds" of cancer cells. In 1889, Paget proposed in his seed-and-soil hypothesis that CTCs from a particular primary site will form metastases only in organs with specific tumor-permissive environments.[6] More recently, emerging evidence suggests that primary tumors can release circulating factors that induce a favorable microenvironment for metastatic growth in secondary organs, termed *premetastatic niches*.[7] The liver microenvironment is geared toward immune tolerance due to the constant exposure to circulating nutrients and endotoxins entering from the gut via the portal circulation.[8] This tolerogenic milieu promotes the survival of disseminated tumor cells and metastatic outgrowth. The highly complex and multifactorial response of the liver microenvironment is orchestrated by various resident and recruited cells that have both prometastatic and antimetastatic effects.[9] An increasing understanding of the role of the liver microenvironment may elucidate novel approaches to prevent and treat liver metastases.

CLINICAL PRESENTATION AND DIAGNOSIS

Symptoms in patients with liver metastases arise more often from their primary tumors, such as bleeding or obstruction from a colorectal cancer. The liver metastases themselves typically do not cause symptoms unless the tumor burden is extensive or there is underlying liver disease, such as portal hypertension and cirrhosis. An important exception is NELMs, which can cause carcinoid syndrome or other symptoms of hormone excess from functional islet cell tumors. Patients with extensive hepatic metastases may present with abdominal pain, weight loss, and malaise. Tumors obstructing the biliary tree can cause jaundice.

Laboratory evaluation should include a complete blood count, comprehensive metabolic panel, and coagulation panel. Increases in bilirubin and prothrombin time should prompt suspicion for hepatic dysfunction, whereas thrombocytopenia may be indicative of portal hypertension. Tumor markers pertinent for liver metastases are carcinoembryonic antigen (CEA) in patients with known or suspected colorectal cancer, chromogranin A for neuroendocrine tumor (NET), CA 19-9 for pancreatobiliary tumors, CA 15-3 for breast cancer, and CA 125 for ovarian cancer. Clinical correlation is needed when interpreting tumor marker levels because of potential false-positive and false-negative results.[10,11] CEA may be elevated in epithelial cancers other than colorectal cancer as well as nonneoplastic processes, including chronic inflammation and smoking.

High-quality cross-sectional imaging is critical for accurate assessment of liver metastases and their relationship to hepatic vasculature, presence of extrahepatic disease (EHD), and anticipated volume of the remnant liver after resection. Multidetector contrast-enhanced computed tomography (CT) scan is the preferred imaging modality to evaluate liver metastases due to the ability to capture high-resolution images of the liver and extrahepatic organs and tissues, wide availability, and fast scanning speed. At a minimum, CT scans to evaluate liver metastases should include arterial and portal venous phases with a slice thickness of 5 mm or less. For preoperative planning and indeterminate lesions, quadruple-phase CT, which includes unenhanced and delayed phases, is preferred.[12] Most hepatic metastases are hypovascular and appear dark relative to background liver on the portal venous phase (Fig. 90.3). On the arterial phase, metastases may exhibit a peripheral rim of enhancement due to desmoplastic reaction, vascular proliferation, and/or abundant cancer cells at the tumor-normal interface.[13,14] The most common causes of hypovascular liver metastases are colon, lung, breast, and gastric cancer. Hypervascular liver metastases, which appear bright relative to surrounding liver on the arterial phase, occur with NETs, renal cell carcinoma, and melanoma.

Magnetic resonance imaging (MRI) with diffusion-weighted sequences may be appropriate for patients with abnormal renal function, extensive hepatic steatosis, or significant contrast allergy. The sensitivity of MRI compared with CT in the detection and characterization of liver metastases depends upon underlying

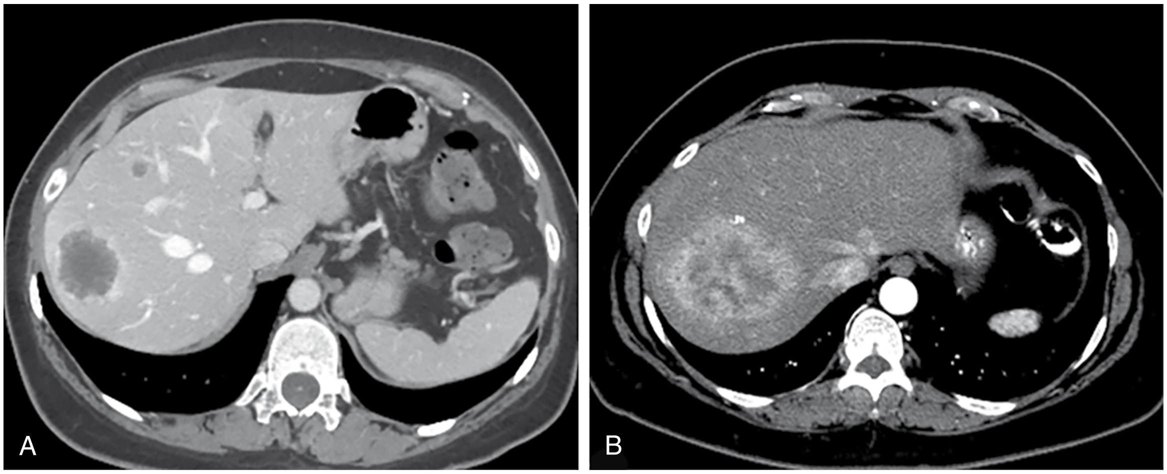

FIGURE 90.3 Contrast-enhanced computed tomography scans showing (A) hypovascular colorectal liver metastases on portal venous phase and (B) hypervascular neuroendocrine liver metastases on arterial phase.

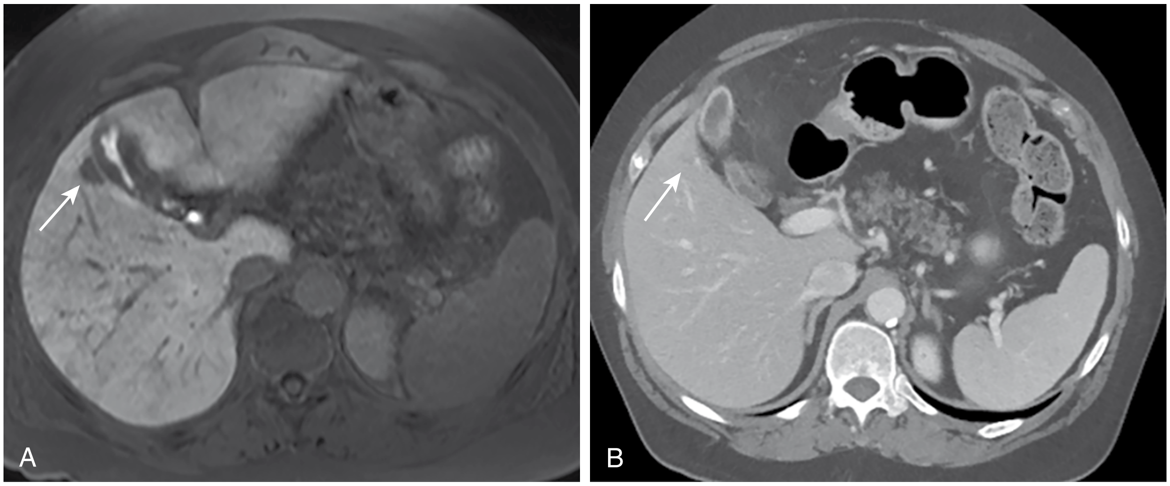

FIGURE 90.4 Colorectal liver metastasis *(arrows)* in background of hepatic steatosis that is clearly seen on delayed hepatobiliary phase magnetic resonance imaging (A) and barely perceptible on contrast-enhanced computed tomography (B).

liver disease, imaging techniques and protocols, and use of hepatocyte-specific contrast agents.[15,16] On T2-weighted images, liver metastases tend to be mildly hyperintense, in contrast with cysts and hemangiomas, which are markedly hyperintense. On contrast-enhanced MRI, patterns of enhancement are similar to those seen on CT scans. Gadoxetic acid (Eovist, Bayer Healthcare LLC, Whippany, NJ) is a hepatocyte-specific MRI contrast agent available in the United States. After administration of Eovist, 50% is taken up by hepatocytes and eliminated by biliary excretion. Liver metastases, which lack functioning hepatocytes, do not take up Eovist and appear as hypoattenuating lesions in the delayed hepatobiliary phase of the MRI (Fig. 90.4). In patients with significant hepatic steatosis, liver metastases may be difficult to detect with CT; therefore, MRI with hepatobiliary contrast agents is the preferred imaging modality.

Commonly used nuclear medicine scans to evaluate liver metastases include fluorodeoxyglucose–positron emission tomography (FDG/PET) for diverse tumor types and gallium-68 DOTATATE-PET, specifically for NETs. FDG/PET is not routinely indicated for liver metastases but may be used to characterize indeterminate lesions that may alter the course of care. Limitations of PET include false-positive results with inflammation, poor sensitivity for tumors <1 cm, and low anatomic detail. With DOTATATE-PET, the DOTA-conjugate peptide is labeled with gallium-68 and binds to somatostatin receptors (SSTRs), which are expressed by NETs (Fig. 90.5). DOTATATE-PET results are used not only for tumor detection but also for assessment of response to SSTR-targeted therapy.

Percutaneous biopsy is not mandatory to diagnose liver metastases, particularly when the primary tumor site is known and the clinical and imaging features are consistent with metastatic disease. However, tissue diagnosis of either the primary and/or metastasis may be helpful to assess disease biology by analyzing factors such as tumor grade and molecular/genomic markers. This, in turn, can help select effective systemic therapy regimens.

PERIOPERATIVE CONSIDERATIONS

Perioperative principles for resection of liver metastases are similar to surgery for primary liver cancer, as described in Chapter 89. These include assessment of patient fitness and liver function, low central venous pressure anesthesia, and intraoperative techniques

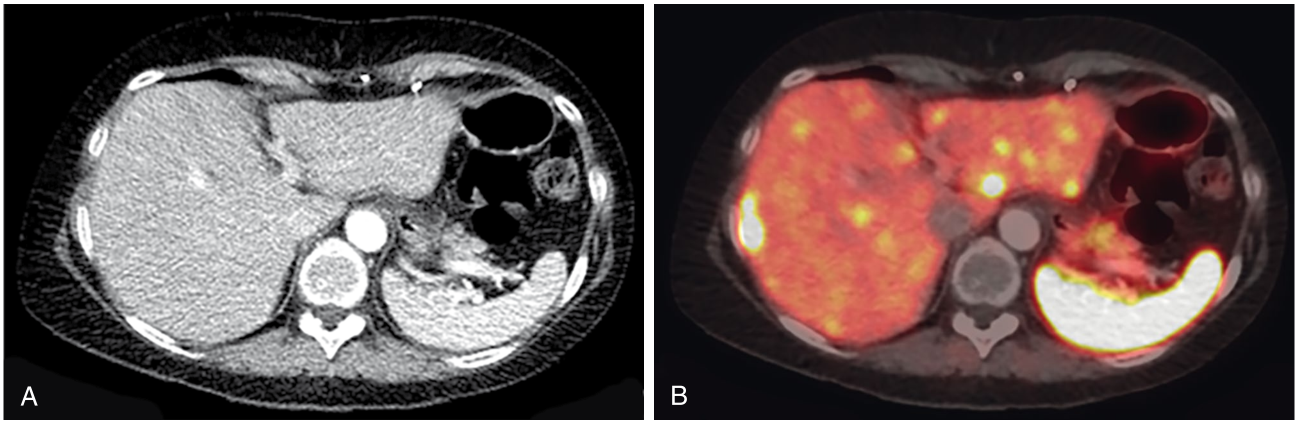

FIGURE 90.5 Contrast-enhanced gallium-68 DOTATATE positron emission tomography–computed tomography (B) delineates neuroendocrine liver metastases compared to computed tomography (A).

to reduce blood loss and bile leak. Technical resectability of liver metastases is defined as the ability to resect all intrahepatic disease while preserving adequate biliary drainage and vascular inflow and outflow, and sparing at least two contiguous hepatic segments with adequate remnant liver volume.[17] Important perioperative considerations for resection of liver metastases include parenchymal-sparing hepatectomy, systematic intraoperative ultrasound (IOUS), and assessment of remnant liver volume.

Parenchymal-Sparing Hepatectomy

Wide resection margins are typically not necessary for liver metastases, and thus, nonanatomic resections that spare nontumoral liver parenchyma are favored when possible over major hepatectomy.[18,19] A systematic review of over 2500 patients undergoing resection of CLM found that parenchymal-sparing hepatectomy resulted in similar rates of R0 resection and overall survival (OS) compared with anatomic resection.[20] For NELMs, a microscopically positive R1 margin is not associated with worse outcomes compared with R0 margin.[21]

Ablation can be used for small, deep metastases that would require sacrifice of a large volume of liver parenchyma to resect. Depending on institutional practice, ablation can be performed intraoperatively under ultrasound or percutaneously under CT guidance. Microwave is preferred over radiofrequency ablation (RFA) due to more efficient heat generation and less susceptibility to the heat sink effect near major blood vessels.[22,23] The efficacy of ablation over resection depends upon tumor size, ablation margin, and tumor type, with NELMs having lower local recurrence after ablation than CLMs.[24]

Intraoperative Ultrasound

IOUS is critical to define intrahepatic anatomy, identify metastases missed on preoperative imaging, and to guide resection margins for parenchymal-sparing hepatectomy. For metastases located deep in the parenchyma, IOUS is necessary to localize the tumor and guide the lines of transection (Fig. 90.6). While visualizing the tumor with ultrasound, the capsule of the liver is scored with cautery, marking the intended lines of transection. The ultrasound probe is placed perpendicular to the cautery line to confirm sufficient margin from the tumor to the transection line. As parenchymal transection progresses, IOUS is repeated to evaluate intrahepatic vessels and adequacy of margins.

Remnant Liver Volume

Accurate assessment of the volume of the liver that will remain after surgery, termed the *future liver remnant (FLR),* is critical to avoid hepatic insufficiency and liver failure, which occur in 3% to 8% of patients after major hepatectomy.[25,26] The FLR is calculated using contrast-enhanced CT or MRI images and involves outlining the contours of each hepatic segment in cross section,

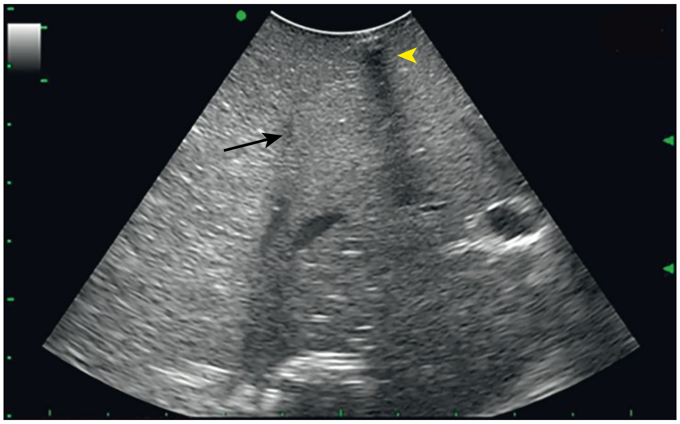

FIGURE 90.6 Intraoperative ultrasound showing hyperechoic tumor *(black arrow)* and intended transection line marked by cautery on the liver capsule, resulting in hypoechoic line *(yellow arrowhead).*

calculating the enclosed area, and multiplying by the thickness of each slice. Tumor volumes are subtracted.[27] This measurement can be performed manually or with specialized software (Fig. 90.7). The calculated FLR is standardized to the total liver volume (TLV) to yield the standardized FLR (sFLR). TLV can be measured directly on CT scans or estimated by patients' body weight or body surface area (BSA). The following formula based on BSA has been found to be a precise, unbiased method to calculate TLV: $\text{TLV} = 1267.28 \times \text{BSA}\ (\text{m}^2) - 794.41$.[28,29]

The minimum sFLR to avoid posthepatectomy liver failure depends upon the function and health of the liver. Most patients undergoing resection of liver metastases do not have cirrhosis but may have chemotherapy-induced hepatotoxicity. In patients without chronic liver disease, sFLR $<$20% predicts liver failure and postoperative mortality. Patients with liver injury from chemotherapy require sFLR of 30%, whereas those with cirrhosis require at least 40%.

Strategies to Increase Future Liver Remnant Volume

For patients with insufficient sFLR, strategies to induce liver hypertrophy for safe hepatectomy include portal vein embolization (PVE) and liver venous deprivation (LVD). First described in 1984 by Makuuchi et al., PVE is the most well-established method for inducing FLR hypertrophy.[30] During PVE, the portal system supplying the hemiliver intended for resection is embolized, which leads to atrophy of the embolized liver and compensatory hypertrophy of the nonembolized liver (see Fig. 90.7). The choice of embolic agent depends upon cost, availability, and operator preference. A combination of microspheres for embolization of distal portal branches and coils proximally has been shown to be safe and effective.[31]

After PVE, the FLR volume is expected to increase significantly the first 3 weeks, followed by a plateau.[32] Comparing the sFLR before and after PVE allows a dynamic assessment of the capacity of the liver to regenerate The kinetic growth rate (KGR) is calculated by dividing the difference in sFLR before and after PVE by the elapsed time in weeks after PVE.[33] KGR provides a powerful predictor of liver regenerative capacity and posthepatectomy liver failure. KGR $\geq$2% per week is associated with 0% postoperative hepatic insufficiency.

PVE alone fails to induce adequate hypertrophy in approximately 5% of patients.[34] For these patients, hepatic vein embolization (HVE) can augment the hypertrophy induced by PVE. HVE can be used as a salvage procedure following inadequate hypertrophy from PVE, as well as up front in patients with a particularly limited sFLR, a procedure known as *liver venous deprivation* (Fig. 90.8). A retrospective comparison of patients who underwent LVD ($n = 37$) and PVE ($n = 36$) in preparation for right or extended right hepatectomy found that LVD was associated with superior increase in liver volume (61% vs. 29%, $p < 0.0001$) and a reduced rate of postoperative liver failure.[30] A recent retrospective analysis suggests that patients with a starting sFLR $<$19% or those that need staged hepatectomy for bilateral CLM may benefit from upfront LVD.[35]

Bilateral Liver Metastases

Two-stage hepatectomy involves a sequential approach for bilateral liver metastases that cannot be safely removed in a single procedure. In the first stage, tumors are removed from the FLR, typically the left liver. If needed, PVE is performed after the first-stage hepatectomy. The second-stage hepatectomy, typically right

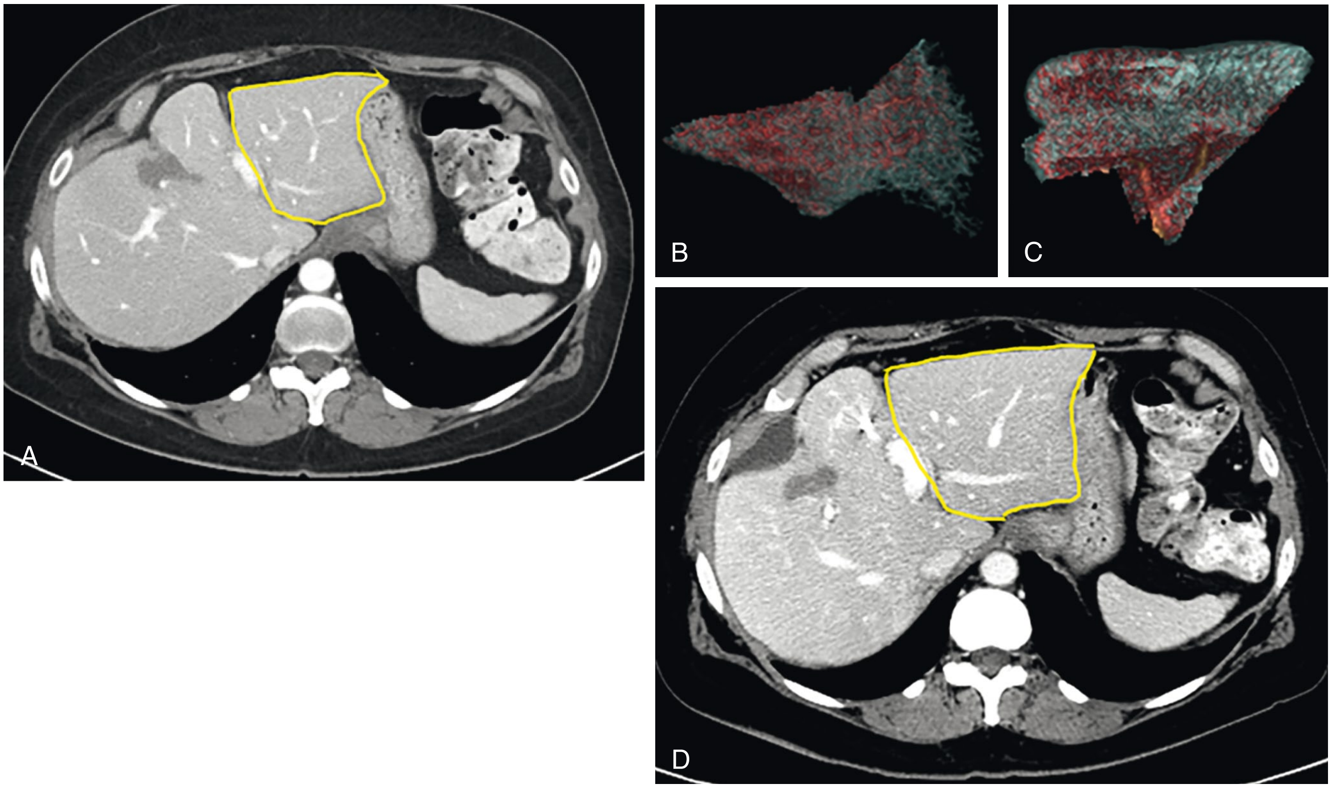

FIGURE 90.7 The volume of the future liver remnant, outlined in *yellow,* is measured on computed tomography (CT) scan (A) using specialized software to calculate the volumes of segments 2 and 3 (B–C). CT after portal vein embolization (D) shows hypertrophy of segments 2 and 3.

or extended right hepatectomy, is performed 6 to 8 weeks after the first stage.

The associating liver partition and portal vein ligation for staged hepatectomy (ALPPS) procedure has been proposed as an alternative to conventional two-stage hepatectomy. In the first stage of ALPPS, as initially described, the right portal vein is ligated and the liver parenchyma transected, leading to rapid FLR hypertrophy.[36] A median of 9 days later completion hepatectomy is performed, including arterial, biliary, and hepatic vein division. ALPPS remains a controversial procedure due to high rates of major morbidity and mortality and unclear survival benefit over conventional two-stage hepatectomy.

COLORECTAL LIVER METASTASES

In patients with colorectal cancer, the liver is the most common site of distant metastases, developing in nearly 50% of patients.[1] One in four patients with colorectal cancer present with synchronous liver metastases, and another quarter go on to develop metachronous disease. Liver disease is directly linked to mortality in over 50% of patients with CLMs.[37] Complete resection is the cornerstone of curative-intent treatment for CLM and is associated with 5-year OS rates between 51% and 58% in well-selected patients.[38,39] Historically, liver resection carried a significant risk of morbidity and mortality, with 30-day mortality rates exceeding 5%. However, with improvements in understanding of hepatic anatomy, surgical technique, and perioperative fluid management, mortality rates after major hepatectomy have fallen to less than 2%.[40] Unfortunately, surgery is underutilized in the treatment of CLM on a national level, with population-based studies reporting resection rates as low as 10%.[41]

Systemic Therapy

Survival for patients with metastatic colorectal cancer has increased significantly due to advances in systemic therapy. First-line chemotherapy regimens are 5-fluorouracil, leucovorin, and oxaliplatin (FOLFOX) and 5-fluorouracil, leucovorin, and irinotecan (FOLFIRIee), resulting in response rates exceeding 50%.[42] The addition of vascular endothelial growth factor (VEGF) blockade with bevacizumab is associated with improved survival when added to oxaliplatin or irinotecan-based regimens.[43] For patients whose tumors do not have mutations in the *KRAS* gene, targeted therapies against epidermal growth factor receptor (anti-EGFR), such as cetuximab and panitumumab, can improve response rates and extend progression-free survival (PFS) when added to standard chemotherapy.[44]

In patients with initially unresectable CLM, response to chemotherapy correlates with future resectability. In a 2004 retrospective series by Adam et al. of 1439 consecutive patients with CLM, 77% were initially unresectable.[45] Among those with unresectable disease, 12.5% had sufficient response to chemotherapy to undergo hepatic resection. Their 5-year OS was 33%, which was significantly lower than that of patients with initially resectable disease (48%) but higher than patients treated with chemotherapy alone during the same era (16%).

For patients with resectable CLM, the addition of perioperative and adjuvant chemotherapy is controversial (Table 90.1). The EORTC intergroup 40983 trial recruited 364 patients from 78 institutions and randomized patients to receive either surgery alone or surgery with preoperative and postoperative FOLFOX.[46] The majority of patients had only one CLM, and 43% had an objective response to chemotherapy with an average 25% reduction in tumor diameter. Analysis of randomized patients showed a nonstatistically significant higher 3-year PFS with chemotherapy (28% vs. 35%, $P = 0.06$). When adjusted for patients who underwent resection, the difference in 3-year PFS was significant, favoring the chemotherapy group (33% vs. 42%, $P = 0.03$). The long-term 5-year results showed no difference in OS between the groups (49% vs. 51%, $P = 0.34$).[47] Together, these results suggest that perioperative chemotherapy does not influence OS.

More recently, a large prospective trial from Japan randomized 300 patients to observation or 12 cycles of FOLFOX after complete resection of CLM.[49] The primary end point was disease-free survival (DFS), and there was a significant difference favoring adjuvant chemotherapy at 3 years (43% vs. 53%) and 5 years (39% vs. 50%, $P = 0.006$). However, the OS analysis favored the hepatectomy-only group at 3 years (92% vs. 87%) and 5 years (83% vs. 71%, $P = 0.42$). These contradictory results may be explained by the pattern of recurrence. The chemotherapy group experienced later recurrences that were more prevalent in the lungs or other distant sites, whereas the observation group had

earlier recurrences in the remnant liver that could be salvaged with additional resections.

Chemotherapy-Associated Hepatotoxicity

When treating CLM patients with perioperative chemotherapy, it is important to note that chemotherapy causes liver damage. Oxaliplatin injures LSECs, leading to hepatic sinusoidal obstruction syndrome, whereas irinotecan is associated with steatosis and steatohepatitis.[50] These patterns of injury can be recognized intraoperatively as a "blue" liver with sinusoidal injury and "yellow" liver with steatohepatitis and significant steatosis (Fig. 90.9). Steatohepatitis has been associated with increased mortality after CLM resection, whereas sinusoidal injury can progress to clinically significant portal hypertension. FOLFOXIRI, a regimen that combines 5-fluorouracil (5-FU) with both oxaliplatin and irinotecan, is associated with high response rates but increased hepatotoxicity. Among 37 patients who underwent hepatectomy after FOLFOXIRI for initially unresectable CLM, rates of sinusoidal injury and steatohepatitis were 100% and 76%, respectively.[51] Chemotherapy-associated hepatotoxicity can be mitigated by limiting the duration of preoperative therapy to 2 to 3 months and by waiting >4 weeks after chemotherapy before liver resection.[52] A study from Memorial Sloan Kettering Cancer Center (MSKCC) showed that maximum radiologic response occurs after 2 to 4 months of chemotherapy, with little therapeutic benefit when continued beyond 4 months.[53] In addition, for patients receiving FOLFOX, the addition of bevacizumab has been shown to have a protective effect from oxaliplatin-induced sinusoidal injury.[54]

Synchronous Primary Colorectal Cancer and Liver Metastases

For patients presenting with synchronous CLM, defined as liver metastases detected at the time of primary colorectal cancer diagnosis, the sequencing of liver and primary tumor resection must be decided on a case-by-case basis.[2] No series has demonstrated superiority of combined or staged resection, either primary-first or liver-first. The combined approach is attractive because it reduces the number of operations patients must undergo and, thus, decreases both hospital costs and time off systemic chemotherapy. However, it may be associated with increased complication rates.[55] A recent multicenter trial randomized 85 patients with resectable CLM to simultaneous or staged, primary-first resection and found comparable rates of major complications (49%, simultaneous vs. 46%, staged, $P = 0.70$). Limitations of this trial include patients in the staged group having more advanced disease and long study duration of 10 years. An analysis of the American College of Surgeons National Surgical Quality Improvement Program database reported that patients undergoing combined major hepatectomy and high-risk colectomy had major morbidity and mortality rates of 55% and 5%.[56] However, at high-volume centers, combined resection can be performed safely, with a series from MSKCC of simultaneous rectal and major liver resection having a grade 3 to 4 morbidity rate of 23% and 0% mortality.[57,58] Thus, simultaneous high-risk colorectal and hepatic resections must be approached with caution or referred to high-volume centers.

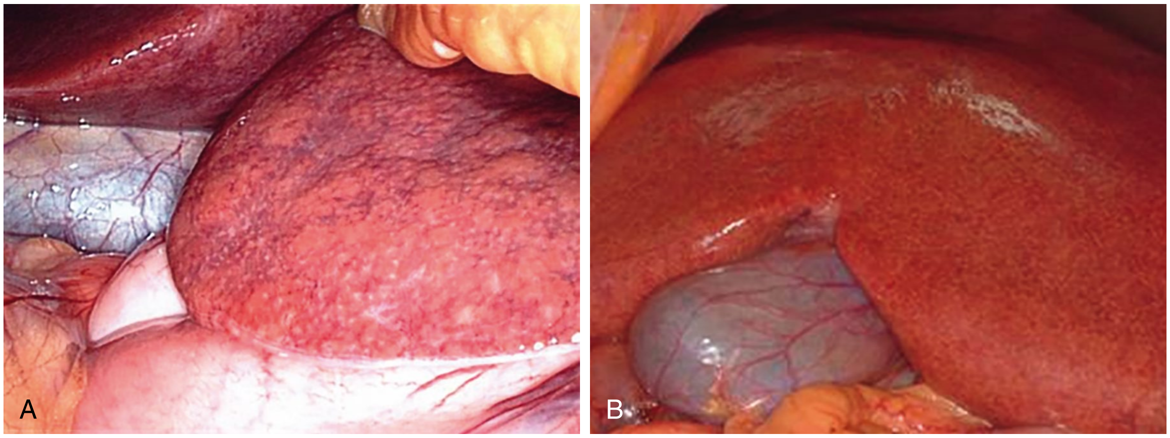

FIGURE 90.9 Intraoperative photos showing (A) blue liver from oxaliplatin-induced sinusoidal injury and (B) yellow liver due to steatosis and steatohepatitis, associated with irinotecan. (From Chun YS, Kawaguchi Y, and Vauthey JN. Hepatic metastasis from colorectal cancer. In: Jarnagin WR, ed. *Blumgart's Surgery of the Liver, Biliary Tract and Pancreas.* Elsevier; 2023:1226-1238.)

For patients undergoing staged resection, factors to consider include primary tumor symptoms, extent of liver disease, and sequencing of radiotherapy for rectal tumors. Patients who have bleeding or obstruction from their primary tumors and limited liver disease may benefit from primary resection first. However, for patients with extensive hepatic metastases, the liver-first approach is favored because their hepatic disease drives prognosis.[59] For patients with obstructing primary tumors, laparoscopic diversion will allow early initiation of systemic therapy. Bleeding from primary tumors can be treated with transfusions as indicated and will usually improve with systemic therapy. The liver-first approach is particularly important for patients with low rectal tumors, given the high incidence of complications and quality of life concerns associated with low anterior and abdominoperineal resections, and the potential for complete response after neoadjuvant chemoradiation.[60]

Role of Diagnostic Laparoscopy

Diagnostic laparoscopy allows for direct visual inspection of the liver and peritoneal cavity, and use of IOUS to evaluate for underlying liver disease or occult metastases not appreciated on CT scans. Although early reports found that staging laparoscopy helped circumvent unnecessary laparotomy in a significant proportion of CLM cases, more contemporary series suggest that the role of laparoscopy is limited due to improvements in preoperative cross-sectional imaging.[61,62] Thus, diagnostic laparoscopy is used selectively in patients with high burdens of systemic disease felt by the surgeon to be at risk of peritoneal dissemination and in patients who have received extensive preoperative chemotherapy and may have more severe chemotherapy-associated liver injury than is apparent on imaging and laboratory studies.

Prognostic Factors

A number of prognostic indicators based on clinicopathologic variables have been defined and validated in the literature (Table 90.2). One of the earliest and most well-known prognostic scores, the clinical risk score, was published by Fong and colleagues in 1999.[63] The authors evaluated 1001 consecutive patients undergoing CLM resection and identified seven factors that were independently predictive of shorter OS. These factors are positive hepatectomy margin, node-positive primary tumor, disease-free interval between primary resection and presentation of liver metastasis $<$12 months, more than one hepatic metastasis, liver metastasis size $>$5 cm, CEA $>$200 ng/mL, and extrahepatic disease (EHD). For patients receiving preoperative chemotherapy, pathologic and radiologic response to therapy are strong predictors of survival after CLM resection.[64,65]

Biomarkers

Biopsy is not mandatory before resection of CLM. However, tissue acquisition, often from the primary tumor via endoscopy, is helpful in assessing disease biology and selecting systemic therapy regimens. Genotyping can be performed from either the primary colorectal cancer or liver metastasis due to $>$90% concordance in mutation status of *RAS, BRAF,* and *TP53* between the primary tumor and CLM.[71] Advances in next-generation sequencing have led to the discovery of distinct molecular subtypes of colorectal cancer that drive prognosis and response to therapy. Assessment of microsatellite instability (MSI) and molecular testing for somatic mutations in the genes *KRAS, NRAS, BRAF,* and *ERBB2* are standard of care for metastatic colorectal cancer.[72] With the widespread availability of next-generation sequencing, it is becoming increasingly important for surgeons to be familiar with these molecular determinants of prognosis, both to guide multidisciplinary clinical decision-making and patient expectations (see Table 90.2).

TABLE 90.2 Clinicopathologic and Molecular Prognostic Factors After Resection of Colorectal Liver Metastases

AUTHOR (YEAR)	*N*	PROGNOSTIC INDICATORS

CEA, Carcinoembryonic antigen.

Tumors with deficient DNA mismatch repair are characterized by numerous insertions and deletions in microsatellites, which are short tandem repeats of DNA prone to mismatch errors (see Chapter 61). MSI-high (MSI-H) tumors, occurring in 15% of all colorectal cancers, are associated with a high mutational burden, a more robust inflammatory response, and potential sensitivity to immune checkpoint blockade. Patients with MSI-H colorectal cancer are less likely to present with liver metastases and comprise $<$2% of CLM resection series. When CLM occur in the setting of MSI, they may carry a worse prognosis.[73,74]

The *RAS* genes, *KRAS, NRAS,* and *HRAS,* are the most frequently mutated family of genes in cancer.[75] They encode small GTPases in the mitogen-activated protein kinase (MAPK) signaling pathway to regulate cell proliferation, differentiation, and apoptosis. *RAS* mutations are identified in 40% to 50% of patients undergoing CLM resection and cause constitutive activation of the Ras protein, leading to resistance to therapies that block EGFR, which lies upstream of Ras in the MAPK pathway (Fig. 90.10). In addition to predicting resistance to therapy with the EGFR inhibitors, cetuximab and panitumumab, *RAS* mutations have been found to predict worse outcome after CLM resection. In 2013, Vauthey et al. evaluated 193 patients undergoing

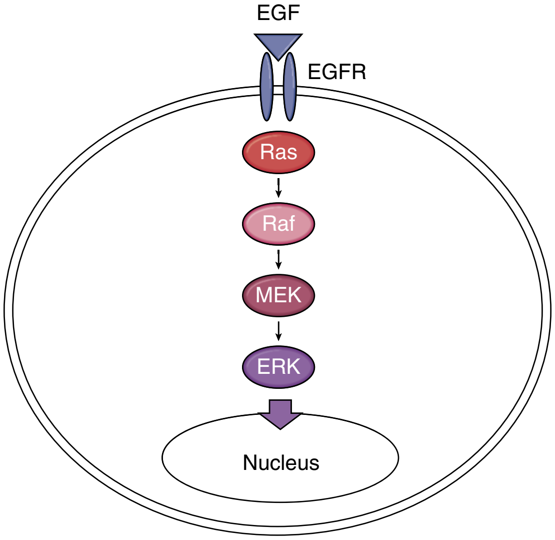

FIGURE 90.10 Schematic of mitogen-activated protein kinase pathway. *EGF,* Epidermal growth factor; *EGFR,* epidermal growth factor receptor. (From Chun YS, Kawaguchi Y, and Vauthey JN. Hepatic metastasis from colorectal cancer. In: Jarnagin WR, ed. *Blumgart's Surgery of the Liver, Biliary Tract and Pancreas.* Elsevier; 2023:1226-1238.)

CLM resection who did not receive anti-EGFR therapy and found significantly lower 3-year OS with a *RAS* mutation, compared with wild type (52% vs. 81%, $P = 0.002$).[76] Subsequent studies have shown that co-mutation of *RAS/TP53* portends even worse survival.[77,78] Other gene mutations associated with worse survival after CLM resection are *FBXW7* and *SMAD4*.[79,80]

BRAF encodes a member of the rapidly accelerated fibrosarcoma (Raf) family of protein kinases, and mutated *BRAF* leads to activation of the MAPK signaling cascade downstream of Ras. The most common *BRAF* mutation, V600E, results in a substitution of glutamic acid for valine at codon 600. *BRAF V600E* mutations are identified in 8% to 12% of metastatic colorectal cancer patients and associated with a median OS of only 11 months.[81] Patients with *BRAF* mutations are less likely to present with liver-limited disease and, thus, comprise <5% of the population in hepatectomy series. In a multicenter study of 1497 patients undergoing CLM resection, *BRAF* mutations were identified in 2% of patients and associated with significantly worse median OS, compared with *BRAF* wild type (40 vs. 81 months, $P < 0.001$).[82]

Extrahepatic Disease

The presence of EHD is associated with higher recurrence rates and worse prognosis but not an absolute contraindication to CLM resection. Studies have demonstrated favorable outcomes after CLM resection in selected patients with EHD, particularly when complete resection of all sites of disease is possible. A retrospective evaluation of 219 patients who underwent resection of CLM and synchronous EHD reported a 28% 5-year OS rate and 8 actual 10-year survivors.[83] Metastases to portal and retroperitoneal nodes, CLM size >3 cm, and progression on chemotherapy were independently associated with worse survival. Another series of 109 patients undergoing concurrent resection of CLM and EHD found that peritoneal metastases and *RAS/TP53* co-mutation were associated with worse survival on multivariable analysis.[84] Patients with EHD isolated to the lung had the longest median OS of 78 months.

Resection Margin

The optimal width of resection margin and prognostic impact of residual microscopic disease (R1 resection) is under debate. In the 1980s, published studies demonstrated improved survival with resection margins of ≥1 cm.[85] More recently, a multi-institutional report of over 500 patients found that the width of negative margin, from 1 mm to ≥1 cm, did not affect recurrence rates.[86] Fueling the controversy, De Haas et al. reported in 2008 similar OS rates after R1 and R0 resection.[87] Multiple studies have shown that the prognostic impact of a positive margin depends upon other factors such as response to systemic therapy, suggesting that the R1 margin represents a surrogate marker of worse tumor biology.[88,89] Based on available evidence, the goal of CLM resection should be a margin-negative resection with preservation of as much nontumoral liver parenchyma as possible.

Liver-Directed Therapies

Most patients with CLM will present with unresectable disease, and only 10% to 30% will have sufficient downstaging after systemic therapy to undergo resection.[45] When liver resection is not possible due to anatomic or biologic constraints, multiple liver-directed therapies are available to achieve local disease control.

Ablation

For tumors <3 cm, RFA can achieve durable tumor eradication. RFA uses high-frequency alternating currents (300–500 kHz) to heat and induce tissue coagulation necrosis. Blood vessels act as heat sinks and limit RFA effectiveness. Care should be employed around portal pedicles as potential complications include bile duct injuries, hemorrhage, and liver infarction. Subcapsular ablations have a risk for capsular rupture and bleeding. The phase II EORTC-CLOCC trial evaluated the additional benefit of RFA to chemotherapy in patients with unresectable CLM and found improved survival with RFA compared with chemotherapy alone (median OS 46 vs. 41 months, $P = 0.01$).[90] However, the trial results are confounded by half the patients in the RFA arm also undergoing hepatic resections. Microwave ablation (MWA) uses higher energy waves (900–2450 MHz) that disrupt water molecules to generate friction and heat, causing necrosis of surrounding tissue. It is less sensitive to heat sink and can propagate a larger ablation zone than RFA.[23]

Hepatic Artery Infusion Pump

The concept of delivering regional liver-directed chemotherapy dates back to the 1950s, when nitrogen mustard gas was injected directly into the hepatic artery. Around the same time, rationale for regional therapy was strengthened by the discovery that hepatic tissues mainly derive their blood supply from the portal vein, but metastases are perfused almost entirely by the hepatic artery. Modern day hepatic artery infusion chemotherapy (HAIC) is refined by two additional innovations. First, fluorodeoxyuridine (FUDR) is found to be the ideal chemotherapy agent because it is converted to the active metabolite 5-FU in the liver. It has a hepatic extraction rate of 94% to 99%, meaning most of the drug remains in the liver and very little circulates systemically. Second, the development of an implantable hepatic artery infusion pump (HAIP) allows for continuous administration of HAIC.[91]

In patients with unresectable disease, HAIC can convert half to resectable disease, even in patients who have been heavily treated previously with chemotherapy. In a prospective phase II trial at MSKCC, 47% of patients with initially unresectable CLM were able to undergo complete resection after HAIC and systemic therapy.[92] The overall response rate was 76%, and median OS was 38 months, with significantly longer survival in patients who had complete resections than those who did not undergo resection (3-year OS: 80% vs. 26%, $P = 0.005$). Those with completely resected CLM after HAIC had survival comparable to those presenting with up-front resectable disease.

After complete resection of CLM, the use of adjuvant systemic chemotherapy has not been shown to improve OS.[47] For this reason, the addition of HAIC has been investigated as an adjunct. There have been two prospective trials in which HAIC was studied in conjunction with systemic chemotherapy. The first was a prospective randomized trial from MSKCC, where patients were randomized to receive systemic 5-FU/leucovorin, with or without HAIC FUDR, after CLM resection.[93] The HAIC group showed significant improvement in 2-year OS (86% vs. 72%, $P = 0.03$) and hepatic recurrence-free survival (90% vs. 60%, $P < 0.0001$). This single-center trial was followed by a randomized multicenter trial in which adjuvant HAIC FUDR and systemic 5-FU were compared with no further therapy.[94] Although the 4-year OS was not statistically different in the adjuvant therapy arm (62% vs. 53%, $P = 0.6$), a significant difference in 4-year DFS was observed (46% vs. 25%, $P = 0.04$).

There are few contraindications to the placement of HAIP, namely the presence of multiple sites of EHD, extensive hepatic replacement by tumor, impaired liver function or evidence of portal hypertension, and main portal vein thrombus. High-quality CT angiography is required to ensure the patency of the hepatic artery, gastroduodenal artery (GDA), and assess for aberrant hepatic arterial anatomy. In most cases, the HAIP catheter is placed in the GDA (Fig. 90.11). Accessory/replaced hepatic arteries can be ligated, as flow to the contralateral lobe is maintained via cross-perfusion. HAIP can be safely placed in combination with colorectal or liver resection with minimal added morbidity. In selected patients, it can also be placed robotically with shorter recovery time.[16] After catheter placement, a methylene blue test is performed intraoperatively to evaluate for bilobar perfusion and the absence of extrahepatic perfusion. Postoperatively, a nuclear medicine perfusion scan provides additional confirmation, and sometimes angiography may be needed to address extrahepatic perfusion.

Because bile ducts also derive their blood supply from the hepatic artery, biliary complications can occur after HAIC, requiring careful monitoring of liver function. Usually, liver enzyme elevation can be mitigated by FUDR dose reduction and filling the pump with dexamethasone but rarely can progress to biliary sclerosis and cholangitis. Other HAIP complications can be categorized as those related to the pump pocket (hematomas, infections), catheter (dislodgements, erosions), or those related to the vasculature (arterial dissections, pseudoaneurysms). The majority of early pump complications are salvageable.[95]

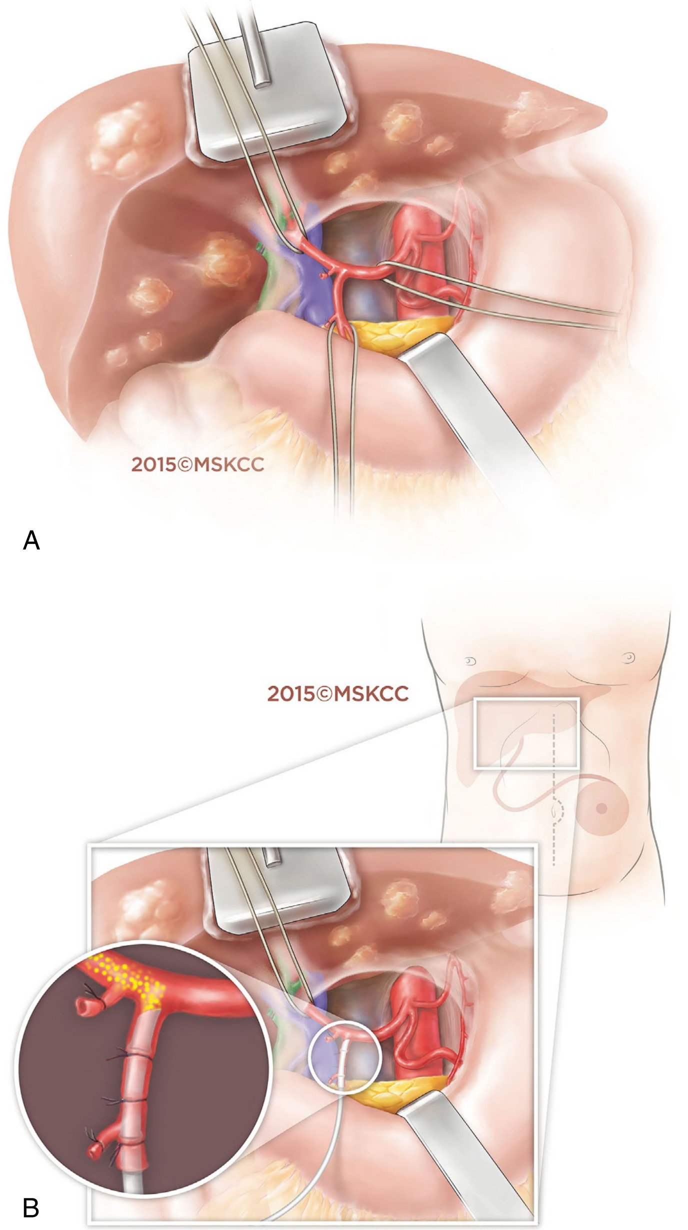

FIGURE 90.11 Placement of hepatic artery infusion pump in the gastroduodenal artery (A) and secured in place with ties (B). (From Qadan M, D'Angelica MI, Kemeny NE, Cercek A, Kingham TP. Robotic hepatic arterial infusion pump placement. *HPB*. 2017;19:429-435.)

Radioembolization

Radioembolization entails delivery of yttrium-90 microspheres, which emit β particles, through hepatic tumor-feeding arteries. It is also called transarterial radioembolization (TARE) or selective internal radiation therapy (SIRT). Yttirum-90 resin microspheres are approved in the United States for the treatment of CLM, whereas glass microspheres are approved for treatment of hepatocellular carcinoma. Because radiation is emitted, this technique is limited by tumor proximity to adjacent bowel and stomach. Randomized phase III trials of patients with liver-only or liver-dominant metastatic colorectal cancer have failed to demonstrate a survival benefit with radioembolization when added to first-line chemotherapy.[96] The benefit of radioembolization in a second-line or salvage setting remains undetermined.

Liver Transplantation

The role of liver transplantation (LT) for metastatic colorectal cancer isolated to the liver is controversial and currently undergoing investigation in multiple randomized controlled trials.[97] Metastatic cancer was traditionally considered a contraindication to LT. In the 1980s and 1990s LT for CLM was attempted, but due to a dismal 5-year OS of 18%, it was largely abandoned. However, interest in LT was rekindled by studies from Norway, which has a surplus of liver grafts and short time on the waiting list (<1 month) for a deceased donor liver. Dueland et al. pooled participants who underwent LT at Oslo University Hospital between 2006 and 2020.[98] Among 61 patients, median disease-free and OS rates were 11.8 months and 60.3 months, respectively. Excluding 1 patient who died of surgical complications, 78.3% of patients suffered disease relapse, with median time to recurrence of 9 months. Notably, four patients remained free of disease at 72 months after transplant. The authors presented factors associated with excellent prognosis after LT, including metachronous CLM, time from CLM diagnosis to LT >3 years, and clinical risk score of 1. These factors highlight the indolent tumor biology of patients with prolonged survival after LT and call into question whether they would have fared as well without transplant. LT for CLM remains an active area of investigation and may be a viable treatment option in highly selected patients.

Memorial Sloan Kettering Cancer Approach

At MSKCC, all CLMs are considered for surgical resection at diagnosis with a hepatobiliary surgery consultation. CLMs can be categorized as up-front resectable, potentially resectable, or likely unresectable. Although hepatobiliary experts may disagree on resectability, categorizing CLM along a spectrum reflects the reality that treatment and time can change definitions of resectability.

Up-front resectable patients are offered surgery with a discussion about the role of adjuvant HAIC and/or chemotherapy. We routinely preform major and minor liver resections with concomitant colorectal surgery, ablations, and HAIP placement. Patients requiring two-stage procedures are usually bridged with chemotherapy, with or without HAIC, to ensure that the liver remnant remains disease free. In the absence of adjuvant HAIC therapy, we do not routinely recommend adjuvant chemotherapy to patients who have had complete CLM resections.

On the other end, likely unresectable patients are considered for up-front HAIC with systemic chemotherapy to maximize the probability of conversion. They are followed with serial imaging for response. Occasionally, patients are unresectable due to unfavorable anatomy, not disease burden. These cases are presented at multidisciplinary conferences to discuss the role for adjunctive local therapies such as ablation, embolization, or radiotherapy.

Potentially resectable patients require detailed planning that starts with identifying the barriers to resectability. If tumor size and insufficient FLR are the main deterrents, then preoperative chemotherapy is considered, along with PVE. If disease burden and bilobar disease are the major concerns, then we would perform two-staged procedures with HAIP placement. To decide which tumors to resect in the first procedure, we identify the tumors near inflow/outflow vessels, as those lesions define the liver remnant. Typically, we clear the tumors in the FLR with a combination of resections and ablations and place an HAIP in the first procedure. Then, we wait for a period on HAIC and chemotherapy to allow for liver remnant growth and resect if disease does not progress to be unresectable.

Patients with unresectable CLM and extensive liver-only disease will die of liver failure due to tumor burden; therefore, curbing the progression of liver disease with palliative regional therapy is also of interest. In a retrospective study from MSKCC, the median survival from time of HAIP placement in patients with unresectable CLM was 32 months.[99] This included patients who had been pretreated with and progressed on first-line chemotherapy. Even patients with a single site of EHD may benefit from HAIC, with median survival of 18 months after HAIP placement. These data suggest that there is a role for HAIC in the palliative setting for unresectable patients as well.

MD Anderson Cancer Center Approach

The majority of MD Anderson Cancer Center (MDACC) patients with CLM are treated with neoadjuvant systemic therapy, typically consisting of 5-FU combined with oxaliplatin or irinotecan. The VEGF inhibitor, bevacizumab, is often included in the neoadjuvant regimen to potentially increase response to therapy and protect from oxaliplatin-associated sinusoidal injury.[54,64] Although pretreatment with systemic chemotherapy bears the risk of chemotherapy-induced liver injury, there are several important advantages to this approach. First, patients with CLMs already have disseminated disease, evidenced by the presence of micrometastases and CTCs that are not apparent on gross examination or cross-sectional imaging.[100] In theory, systemic therapy can help eliminate some or all of these cells, increasing the likelihood of cure after R0 liver resection. Second, treatment with neoadjuvant therapy serves as a valuable test of disease biology. Radiologic and pathologic response to preoperative therapy are important surrogates of tumor biology.[64,65] Patients with tumors that progress through systemic chemotherapy have aggressive biology and are unlikely to benefit from an extensive liver operation. In fact, the systemic inflammatory milieu induced by surgery may hasten the progression of their disease in the early postoperative setting.[101] Third, neoadjuvant chemotherapy affords an opportunity to test a tumor's sensitivity to cytotoxic and targeted agents. This allows for better tailoring of adjuvant regimens following surgery. Fourth, response to neoadjuvant therapy may allow for parenchymal-sparing operations in patients who might otherwise require a major hepatectomy to clear their disease.

For patients with extensive bilateral CLM and an initially insufficient FLR, our preferred approach is neoadjuvant systemic therapy followed by two-stage hepatectomy. This typically involves surgical clearance of left-sided liver lesions followed by PVE, with or without hepatic vein occlusion. After a 4-week period of hypertrophy after PVE, patients undergo a right or extended right hepatectomy to clear the remainder of their disease. We have reported favorable outcomes with this approach, even in patients with extensive bilateral disease.[102] One disadvantage to this approach is that some patients may develop disease progression while awaiting FLR hypertrophy. A strategy to minimize tumor progression between the two stages is to treat patients with systemic chemotherapy during the period of hypertrophy after PVE. It should be noted that patients who develop disease progression during the short 4-week period of hypertrophy generally have aggressive biology and may not benefit from completion of the second-stage hepatectomy.

From a technical standpoint, we generally use the Cavitron ultrasonic surgical aspirator (CUSA; Integra, Princeton, NJ) to divide the liver parenchyma and saline-linked monopolar sealer (DS3.5-C Dissecting Sealer, Medtronic, Minneapolis, MN) to seal small vessels and bile ducts. Larger vessels and bile ducts are controlled with surgical clips, suture ligature, or vascular staplers depending on the size and quality of the structure being divided. Inflow occlusion with the Pringle maneuver is used liberally, as we have found that intermittent Pringle does not increase the risk of posthepatectomy liver insufficiency. After specimen removal, intraoperative air cholangiogram is performed to detect bile leaks.[103]

Discussion

Complete resection remains indispensable for curative-intent treatment of CLM. However, treatment paradigms and, in particular, the timing of resection differs between our institutions. Although MDACC generally favors a neoadjuvant approach to test biology and potentially eliminate micrometastatic disease before surgery, patients with resectable tumors at MSKCC are commonly offered up-front surgery with consideration for adjuvant systemic or HAIC therapy. No randomized trial has demonstrated definitive superiority of one strategy over the other.

Although our institutional practices differ, both MDACC and MSKCC support the management of CLM by a multidisciplinary team, including surgeons with hepatobiliary expertise. We agree that complete resection should be the goal of every CLM operation and provides the best chance for long-term survival. Our approaches also place paramount importance on the assessment of disease biology, considering tumor burden, time (disease-free interval), mutation profile, and response to previous therapy in every treatment decision. As molecular diagnostic techniques and our understanding of CLM biology continue to evolve, so too will our ability to individualize treatment and provide a more nuanced approach to the multimodal management of this disease.

NEUROENDOCRINE LIVER METASTASES

NETs are well-differentiated, slow-growing tumors that can arise from neuroendocrine cells present throughout the body. NETs should be differentiated from neuroendocrine carcinomas, which are poorly differentiated and highly aggressive. The most common sites of primary NETs are the gastrointestinal tract (48%), lung (25%), and pancreas (9%).[104] The potential for distant metastases depends upon the primary site, with appendiceal and lung NETs having lower rates. In contrast, small bowel and pancreatic NETs (PNETs) frequently develop distant metastases, 90% in the liver, which represent the dominant driver of prognosis.

NETs are categorized by grade, based on mitotic rate and Ki-67 index, and hormone secretion.[105] Carcinoid syndrome occurs in patients with small bowel NETs that have metastasized to the liver, resulting in production of vasoactive hormones, including serotonin. Symptoms include diarrhea, flushing, and wheezing from bronchospasm. Carcinoid syndrome is rare in the absence of liver metastases due to first-pass metabolism in the liver and degradation of secreted vasoactive substances. In patients with carcinoid syndrome, plasma or 24-hour urine 5-hydroxyindoleacetic acid (5-HIAA) will be elevated. A quarter of PNETs are associated with hormone secretion, such as insulinomas, glucagonomas, somatostatinomas, and VIPomas. Insulinomas have a low risk of metastasis, whereas glucagonomas and somatostatinomas frequently metastasize to the liver (80%–90%). Nonfunctional PNETs will often have elevations in pancreatic polypeptide or chromogranin A; both can be nonspecifically elevated and should not be used to guide treatment decisions.

Surgical Cytoreduction

Given the prolonged natural history of NELMs, management of liver metastases is based on careful evaluation of treatment goals. Surgical cytoreduction is a critical consideration for patients with NELMs who are fit for surgery and have resectable disease. Although cure without recurrence is uncommon, resection is associated with improved OS and quality of life for patients with functional tumors through reduction of hormone load. Resection of NELMs has been associated with excellent 10-year survival rates as high as 79%.[106] However, the data supporting cytoreduction are all retrospective and highly confounded. Although anatomic hepatectomy may be required for lesions inseparable from vital structures, a parenchymal-sparing approach, including enucleation, is strongly preferred.

TABLE 90.3 **Selected Studies Evaluating Cytoreductive Surgery for Neuroendocrine Liver Metastases**

AUTHOR (YEAR)	*N*	GOAL % CYTOREDUCTION	SURVIVAL
Sarmiento (2003)[109]	170	90%	5-year OS 61%
Chambers (2008)[110]	30	70%	5-year OS 74%
Graff-Baker (2014)[111]	52	70%	5-year PFS 64%
Maxwell (2016)[107]	108	70%	Median PFS 3.2 years Median OS not reached after 4.1 years
Gudmundsdottir (2023)[108]	546	>90%	Median OS, 122 months Median PFS, 17 months

OS, Overall survival; *PFS*, progression-free survival.

The amount of cytoreduction necessary for the associated prolongation of survival is a matter of ongoing debate. All available data are retrospective and subject to both selection bias and subjectivity pertaining to the degree of cytoreduction achieved. Various series suggest that 70% to 90% cytoreduction of tumor burden may provide a survival benefit (Table 90.3). A series from the University of Iowa of 108 patients who underwent NELM resection, many with concomitant ablation, found improved OS and PFS for patients undergoing ≥70% reduction, compared with <70%.[107] In a study from the Mayo Clinic of 546 patients undergoing cytoreductive hepatectomy, 37% had functional disease.[108] Symptom-free interval was significantly worse for patients undergoing incomplete cytoreduction, defined as <90% debulking (median, 21 vs. 62 months, $P = 0.021$). On multivariable analysis, the Ki-67 index was the strongest predictor of OS, with markedly worse survival with Ki-67 >20%.

The biology of NELM spans a wide spectrum from indolent disease to progressive liver replacement, but the majority will fall on the indolent end. Most institutions would agree that surgery for functional tumors can mitigate symptoms and is recommended when somatostatin analogues (SSAs) are ineffective. Surgery for nonfunctional NELMs is debatable because complete debulking is rarely possible and often leaves residual nonvisible disease. At both MSKCC and MDACC, the role for surgery is considered in the context of multiple adjuncts such as systemic and liver-directed therapies, as reviewed in the following sections.

Perioperative Considerations

Patients with carcinoid syndrome undergoing hepatectomy and other procedures are at risk for release of high levels of vasoactive substances and carcinoid crisis, characterized by life-threatening hemodynamic instability, with or without bronchospasm and arrhythmias. Perioperative octreotide prophylaxis is recommended, although the optimal timing and dose are not well established.[112] In addition to intravenous octreotide, aggressive treatment with intravenous fluids and vasopressors, either phenylephrine or vasopressin, is required to treat a carcinoid crisis.

Carcinoid heart disease develops in approximately 20% of patients with carcinoid syndrome due to vasoactive substances released by NETs, leading to plaquelike deposits in the right heart, tricuspid and pulmonic regurgitation, and right heart failure.[113] First-line treatment of carcinoid heart disease is SSAs, with valve replacement reserved for patients with refractory disease. It is critical to obtain an echocardiogram preoperatively in patients with carcinoid syndrome who are considered for surgery. For the rare patient who is a candidate for cytoreductive hepatectomy but needs cardiac surgery, the sequence of operations should be individualized. Increased right atrial pressure and hepatic congestion represent contraindications to liver surgery.

Nonsurgical Management

Nonsurgical management of NELMs has been investigated in randomized trials (see Chapters 76 and 77). Given the indolent nature of low-grade NETs, most therapies have been found to improve PFS but not OS. SSAs inhibit the receptor in SSTR-avid tumors and are effective in managing hormone excess. Octreotide long-acting release (LAR) is a long-acting SSA that was shown in the PROMID trial to delay progression in metastatic midgut NETs compared with placebo (14 vs. 6 months, $P < 0.001$).[114] Most patients had liver involvement (86%) but low liver tumor burden (<10% of liver volume). Long-term results of this trial, however, failed to show an OS benefit secondary to either crossover after progression or prolonged survival even in those with progressive disease.[115] Similar results were seen in the CLARINET trial with the SSA lanreotide, suggesting that while SSAs suppress hormone hypersecretion and are cytostatic, this does not translate to improved long-term survival.[116]

Systemic therapies are also available in progressing disease. Everolimus inhibits the mTOR pathway and is approved for the treatment of PNETs based on the RADIANT-3 trial, which showed improved PFS compared with placebo alone (11 vs. 5 months, $P < 0.001$), but no difference in OS.[117] It is also approved for advanced gastrointestinal tract NETs based on the RADIANT-4 trial, in which everolimus was superior to placebo for PFS (11 vs. 4 months, $P < 0.001$).[118] Long-term survival data from this trial are not yet mature, but there may be a trend toward improved survival. More recently, the multicenter, prospective randomized trial ECOG-ACRIN E2211 showed superiority of temozolomide and capecitabine to temozolomide alone in metastatic PNETs for the primary end point of PFS (23 vs. 14 months, $P < 0.02$).[119] The majority of these patients had already progressed on SSAs. Unlike SSAs, which are mostly cytostatic, there was a 34% to 40% response rate in both cohorts, raising the possibility of tumor shrinkage with chemotherapy before cytoreduction.

For SSTR-avid tumors, radiotherapy can be added to SSAs to achieve higher response rates. Lutetium-177 (^{177}Lu)-DOTATATE is a radiolabeled SSA that delivers systemic radiotherapy to SSTR-avid tumors in a method called peptide receptor radionuclide therapy (PRRT). NETTER-1 was a phase III trial that randomized patients to receive PRRT and octreotide LAR or octreotide LAR alone in midgut NETs.[120] It met the primary end point of improved PFS in the group also receiving PRRT (not reached vs. 8 months, $P < 0.001$). There was an 18% overall response rate with the addition of PRRT, which is significant given that SSA alone is cytostatic. Long-term results showed a nonstatistically significant improvement in OS (48 vs. 36 months, $P = 0.3$). Currently, the NETTER-2 trial is accruing patients to study the benefit of PRRT in midgut NETs with higher proliferation index.

Similar to CLM, NELMs that are not amenable to surgical resection can be treated with liver-directed therapies. These tumors respond well to arterially directed therapies because they are hypervascular. In a large, multicenter retrospective analysis comparing surgery ($N = 339$) versus arterially directed therapies ($N = 414$) for NELMs, surgery was associated with improved 5-year OS (74% vs. 30%, $P < 0.001$), although patients undergoing surgery had less advanced disease.[121] In a propensity-adjusted multivariate Cox model, surgery provided a survival benefit over intraarterial therapy for symptomatic patients with >25% liver involvement but not for patients without symptoms.

NONCOLORECTAL NONNEUROENDOCRINE LIVER METASTASES

Data on outcomes after hepatectomy for noncolorectal nonneuroendocrine (NCNN) liver metastases are limited to small case series or retrospective analyses with heterogeneous patient populations. In 2006, a retrospective review of 1452 patients undergoing resection of NCNN liver metastases at 41 centers in France reported that the most common primary tumors were breast (32%), gastrointestinal (16%), genitourinary (14%), and melanoma (10%).[122] Factors independently associated with worse survival were age >60; nonbreast primary, melanoma, or squamous histology; disease-free interval <12 months; extrahepatic metastases; R2 resection; and major hepatectomy. More recently, a multicenter study from Japan by Sano et al. evaluated 1539 patients undergoing NCNN resection.[123] The most common primary tumors were gastric (35%), gastrointestinal stromal tumor (GIST) (13%), biliary (10%), and ovarian (7%). This study found that prognostic factors differed by primary tumor type.

The divergent findings in the reports from France and Japan likely reflect different patient populations and selection criteria. Patients who will derive benefit from hepatic resection for NCNN are those with favorable tumor biology, as indicated by the absence of EHD, solitary liver metastasis, and long disease-free interval from primary resection. Given the improvement in morbidity of hepatectomy and the emergence of novel therapeutics across tumor types, NCNN liver metastases are being increasingly considered for resection, including prospective randomized trials, as described in the following section.

Gastric and Gastroesophageal Junction

The role of surgical resection of metastatic gastric and gastroesophageal junction adenocarcinoma was investigated in a phase II, multicenter trial in Germany (AIO-FLOT3).[124] Patients were stratified into three arms: (A) resectable, nonmetastatic, (B) limited metastasis, and (C) extensive metastasis. Patients in arms A and B received perioperative chemotherapy and resection of all disease sites if feasible. In arm B, 18.3% of patients had liver-confined metastasis, fewer than five in number. Among 36 patients with limited metastasis undergoing surgery, those with liver metastasis had worse median OS compared with retroperitoneal nodal metastases (13.6 months vs. not reached). There are two ongoing randomized phase III trials in Europe investigating the role of metastasectomy, including liver-confined metastases, up to five in number.[125]

Breast Cancer

Hepatectomy for breast cancer liver metastases is controversial. Only 10% of patients with breast cancer have metastases isolated to the liver; thus, the role of hepatectomy is limited. Factors associated with higher survival after resection of breast cancer liver metastases include response to systemic therapy, hormone receptor status, hepatectomy margin, and number of metastases.[126,127]

Gastrointestinal Stromal Tumor

GISTs are rare mesenchymal tumors of the gastrointestinal tract that metastasize to the liver in approximately one-third of patients. A retrospective study of 239 patients who underwent resection of metastatic GIST and received imatinib therapy demonstrated 5-year OS exceeding 80% for patients with liver-limited metastases responsive to imatinib therapy.[128] However, whether hepatic resection offers a survival benefit over imatinib alone remains unclear. A randomized study of patients with metastatic GIST to the liver showed that surgery was associated with improved 3-year overall OS compared with imatinib alone (89.5% vs. 60%, $P = 0.03$).[129] However, this trial was limited by small sample size of 39 patients. Based on available evidence, hepatic resection in selected patients responding to systemic therapy with tyrosine kinase inhibitors improves outcomes. Adjuvant therapy should be continued postoperatively due to high rates of recurrence.[130]

Pancreas

Historically considered an absolute contraindication to surgery, improvements in systemic therapy and surgical outcomes have sparked interest in complete resection of pancreatic adenocarcinoma and hepatic metastasis. A retrospective study from Heidelberg University analyzed 173 patients with metastatic pancreas cancer who received preoperative chemotherapy followed by surgical exploration; 67% had liver-confined metastasis. Among patients who underwent resection of the primary tumor and metastasis, 48% of patients had a complete pathologic response in the metastasis and median OS of 25.5 months. These results raise the question whether patients with complete pathologic response to systemic therapy derive benefit from surgery. Multiple prospective trials are ongoing in China and Europe investigating the role of surgery or ablation for patients with limited hepatic metastases from pancreas cancer.[131] However, liver metastasectomy for pancreatic adenocarcinoma remains highly controversial.

Melanoma

Cutaneous melanoma represents an extremely rare indication for hepatic resection, due to widespread metastatic disease and poor tumor biology.[132] Uveal melanoma has a high predilection for liver metastasis, identified in 90% of patients with metastatic disease. Due to diffuse intrahepatic metastases, $<10\%$ of patients with liver-confined uveal metastases are candidates for surgery.[133]

Gynecologic Malignancies

Ovarian cancer often seeds the surface of the liver, but intrahepatic metastasis is uncommon. Liver resection for ovarian and other gynecologic malignancies has been shown to be safe. However, high-level evidence on patient selection criteria and survival benefit of hepatectomy is lacking.

EMBRYOLOGY

The primitive gut is formed from the endodermal lining—the yolk sac, which is enveloped by the developing embryo as a result of cranial and caudal folding during the fourth week of human fetal gestation.[1] The endodermal layer gives rise to the epithelial lining of the digestive tract, and the splanchnic mesoderm surrounding the endoderm gives rise to the muscular connective tissue and all the other layers of the intestine. The splanchnic mesoderm wraps around the gut tube to form the mesenteries that suspend the gut within the body cavity; the mesoderm immediately adjacent to the endodermal tube also contributes to most of the wall of the gut tube. Nerves and neurons found in the wall are derived from the neural crest. Except for the duodenum, which is a primitive foregut structure, the small intestine is derived from the midgut. During the fifth to sixth week of fetal development, when the intestinal length is rapidly increasing, herniation of the midgut occurs through the umbilicus (Fig. 91.1). This midgut loop has a cranial and caudal limb, with the cranial limb developing into the distal duodenum, jejunum, and proximal ileum, and the caudal limb becoming the distal ileum and proximal two-thirds of the transverse colon. The juncture of the cranial and caudal limbs is where the vitelline duct joins to the yolk sac. This duct structure normally becomes obliterated before birth; however, it can persist as a Meckel diverticulum in approximately 2% of the population. As the gut tube develops, the endoderm proliferates rapidly and temporarily occludes the lumen of the tube around the fifth week of gestation. Growth and expansion of mesoderm components in the wall, coupled with apoptosis of the endoderm during the seventh week, result in recanalization of the tube, and by the ninth week of gestation, the tube is again patent. This midgut herniation persists until about 10 weeks of fetal gestation, when the intestine returns to the abdominal cavity. Before reentering the abdomen, the midgut loop rotates 90 degrees counterclockwise around the superior mesenteric artery axis. As the small and large intestine return to the abdominal cavity, they continue to rotate in this direction for a complete 270-degree rotation from the initial starting point. Congenital anomalies of gut malrotation and fixation can occur during this process. Intestinal nonrotation occurs when the midgut loop only completes the first 90-degree rotation and returns to the abdomen without further rotation, thus leaving the small intestine in the right abdomen and large intestine in the left abdomen. When the intestine fails to complete the final 90-degree rotation, the cecum is fixed just below the stomach

FIGURE 91.1 Rotation of the intestine. (A) The intestine after a 90-degree rotation around the axis of the superior mesenteric artery, the proximal loop on the right and the distal loop on the left. (B) The intestinal loop after a further 180-degree rotation. The transverse colon passes in front of the duodenum. (C) Position of the intestinal loops after reentry into the abdominal cavity. Note the elongation of the small intestine, with formation of the small intestine loops. (D) Final position of the intestines after descent of the cecum into the right iliac fossa. (From Podolsky DK, Babyatshy MW. Growth and development of the gastrointestinal tract. In: Yamada T, ed. *Textbook of Gastroenterology.* Vol 2. Philadelphia: JB Lippincott; 1995.)

and the root of the mesentery is narrowed, leaving the bowel susceptible to midgut volvulus.

The primitive small bowel is lined by a sheet of cuboidal cells until about the ninth week of gestation, when villi begin to form in the proximal intestine and then proceed in a caudal fashion until the entire small bowel, and even the colon, for a time are lined by these finger-like projections. Crypt formation begins in the 10th to 12th weeks of gestation. The crypt layer of the small bowel is the site of continual cell renewal and proliferation. As the cells ascend the crypt-villous axis, proliferation ceases, and cells differentiate into one of the four main cell types: absorptive enterocytes, which compose about 95% of the intestinal cell population; goblet cells; Paneth cells; and enteroendocrine cells. An important distinction regarding Paneth cells is that they remain in the crypt bases, where they protect intestinal stem cells from damage by releasing signaling molecules that affect the host tissues and influence the microbial populations to maintain homeostasis in the intestine.[2] The other differentiating cells ascending the crypt-villous axis are eventually extruded into the intestinal lumen. Amazingly, with the exception of Paneth cells, epithelial cell turnover occurs rapidly, with a life span of 3 to 5 days in humans.

ANATOMY

Gross Anatomy

The entire small intestine, which extends from the pylorus to the cecum, measures differently in everyone and can range from 250 to over 800 cm, with duodenal length estimated at approximately 20 cm, jejunal length at 100 to 110 cm, and ileal length at 150 to 160 cm. The jejunum begins at the duodenojejunal angle, which is supported by a peritoneal fold known as the *ligament of Treitz*. There is no obvious demarcation between the jejunum and the ileum; by convention, the jejunum comprises the proximal two-fifths of the small intestine, and the ileum makes up the remaining three-fifths. The jejunum has a somewhat larger circumference, is thicker than the ileum, and can be identified during surgery by examining mesenteric vessels (Fig. 91.2A, *top right*). In the jejunum, only one or two arcades send out long, straight vasa recta to the mesenteric border, whereas the blood supply to the ileum may have four or five separate arcades with shorter vasa recta (see Fig. 91.2A, *bottom right*). The mucosa of the small bowel is characterized by transverse folds (plicae circulares), which are prominent in the distal duodenum and jejunum.

Neurovascular-Lymphatic Supply

The small intestine is served by rich vascular, neural, and lymphatic supplies, all traversing through the mesentery. The base of the mesentery attaches to the posterior abdominal wall to the left of the second lumbar vertebra and passes obliquely to the right and inferiorly to the right sacroiliac joint. The blood supply of the small bowel, except for the proximal duodenum, which is supplied by branches of the celiac axis, comes entirely from the superior mesenteric artery (see Fig. 91.2A, *left*). The superior mesenteric artery courses anterior to the uncinate process of the pancreas and the third portion of the duodenum, where it divides to supply the pancreas, distal duodenum, entire small intestine, and ascending and transverse colons. There is an abundant collateral blood supply to the small bowel provided by vascular arcades coursing in the mesentery. Venous drainage of the small bowel parallels the arterial supply, with blood draining into the superior mesenteric vein, which joins the splenic vein behind the neck of the pancreas to form the portal vein.

The innervation of the small bowel is provided by parasympathetic and sympathetic divisions of the autonomic nervous system that, in turn, provide efferent nerves to the small intestine. The parasympathetic fibers derive from the vagus nerve; they traverse the celiac ganglion and influence secretion, motility, and likely all phases of bowel activity. Vagal afferent fibers are present but apparently do not carry pain impulses. The sympathetic fibers come from three sets of splanchnic nerves; their ganglion cells usually are located in a plexus around the base of the superior mesenteric artery. Motor impulses affect blood vessel motility and, to some extent, gut secretion and motility. Pain from the intestine is transmitted through general visceral afferent fibers of the sympathetic system.

Small intestine lymphatics are noted as major deposits of lymphatic tissue, particularly in the Peyer patches of the distal small bowel. Lymphatic drainage proceeds from the mucosa through

the wall of the bowel to a set of nodes adjacent to the bowel in the mesentery. Drainage continues to a group of regional nodes adjacent to the mesenteric arterial arcades and then to a group at the base of the superior mesenteric vessels. From there, lymph flows into the cisterna chyli and then up the thoracic duct, ultimately to empty into the venous system at the confluence of the left internal jugular and subclavian veins. The lymphatic drainage of the small intestine plays a major role in immune defense, constitutes a major transport route of absorbed lipid into the circulation, and aids the spread of cells arising from cancers of the gut.

Microscopic Anatomy

The small bowel wall consists of four layers: serosa, muscularis propria, submucosa, and mucosa (see Fig. 91.2B).

The serosa is the outermost layer of the small intestine and consists of visceral peritoneum, a single layer of flattened mesoepithelial cells that encircles the jejunoileum, and the anterior surface of the duodenum.

The muscularis propria consists of two muscle layers: a thin outer longitudinal layer and a thicker inner circular layer of smooth muscle. Ganglion cells from the myenteric (Auerbach) plexus are interposed between the muscle layers and send neural fibers into both layers, thus providing electrical continuity between the smooth muscle cells and permitting conduction through the muscle layer.

The submucosa consists of a layer of fibroelastic connective tissue containing blood vessels and nerves. It is the strongest component of the intestinal wall and therefore must be included in anastomotic sutures. It contains elaborate networks of lymphatics, arterioles, and venules and an extensive plexus of nerve fibers and ganglion cells (Meissner plexus). The nerves from the mucosa and submucosa muscle layers are interconnected by small nerve fibers; cross-connections between adrenergic and cholinergic elements have been described.

The mucosa has three layers: muscularis mucosae, lamina propria, and epithelial layers (see Fig. 91.2C). The muscularis mucosae is a thin layer of muscle that separates the mucosa from the submucosa. The lamina propria is a connective tissue layer between the epithelial cells and muscularis mucosae that contains a variety of cells, including plasma cells, lymphocytes, mast cells, eosinophils, macrophages, fibroblasts, smooth muscle cells, and noncellular connective tissue. The lamina propria, the base on which the epithelial cells lie, performs a protective role in the intestine; because of a rich supply of immune cells, it combats microorganisms that penetrate the overlying epithelium. Plasma cells actively synthesize immunoglobulins and other immune cells in the lamina propria and release mediators (e.g., cytokines, arachidonic acid metabolites, histamines) that can modulate the cellular functions of the overlying epithelium. The epithelial layer is a continual sheet of epithelial cells covering the villi and lining the crypts. The main functions of the crypt epithelium are cell renewal as well as exocrine, endocrine, water, and ion secretion; the main functions of the villous epithelium are digestion and absorption. Four main cell types are contained in the mucosal layer: (1) absorptive enterocytes; (2) goblet cells, which secrete mucus; (3) Paneth cells, which secrete lysozyme, tumor necrosis factor (TNF), and cryptdins, which are homologues of leukocyte defensin peptides thought to be related to the host mucosal defense system; and (4) enteroendocrine cells, of which there are more than 15 distinct populations that produce the gastrointestinal hormones. The enteroendocrine cells also secrete a wide range of peptide hormones that, in a complex manner, control physiologic and homeostatic functions in the digestive tract, particularly postprandial secretion and motility.

The mucosa is designed for maximal absorptive surface area, with villi protruding into the lumen on microscopic examination. Villi are tallest in the distal duodenum and proximal jejunum and shortest in the distal ileum. Absorptive enterocytes represent the main cell type in the mucosa and are responsible for digestion and absorption. Their luminal surface is covered by microvilli that rest on a terminal web. The microvilli increase the absorptive capacity by thirtyfold. To increase absorption further, the microvilli are covered by a fuzzy coat of glycoprotein called the *glycocalyx*.

PHYSIOLOGY

Digestion and Absorption

The complex process of digestion and eventual absorption of nutrients, water, electrolytes, and minerals is the main role of the small intestine. Liters of water and hundreds of grams of chyme are delivered to the small intestine daily, and with remarkable efficiency, almost all food is absorbed, except for indigestible cellulose. The stomach initiates the process of digestion with the breakdown of solids to particles 1 mm or smaller, which are then delivered to the duodenum, where pancreatic enzymes, bile, and brush border enzymes continue the process of digestion and eventual absorption through the small intestinal wall.[3] The small bowel is primarily responsible for absorption of the dietary components (carbohydrates, proteins, and fats) as well as trace elements, vitamins, and water.

Carbohydrates

An adult consuming a normal Western diet will ingest 300 to 350 g of carbohydrates a day, with about 50% consumed as starch, 30% as sucrose, 6% as lactose, and the remainder as maltose, trehalose, glucose, fructose, sorbitol, cellulose, and pectins.[3] Dietary starch is a polysaccharide consisting of long chains of glucose molecules. Amylose makes up about 20% of starch in the diet and is broken down at the α-1,4 bonds by salivary (i.e., ptyalin) and pancreatic amylases that convert amylose to maltotriose and maltose. Amylopectin constitutes about 80% of dietary starch and has branch points every 25 molecules along the straight glucose chains; the α-1,6 glucose linkages in amylopectin identify the end products of amylase digestion—maltose, maltotriose, and the residual branch saccharides, the dextrins. In general, the starches are almost totally converted into maltose and other small glucose polymers before they reach the duodenum or upper jejunum. The remainder of carbohydrate digestion occurs as a result of brush border enzymes of the luminal surface.

The brush border of the small intestine contains the enzymes lactase, maltase, sucrase-isomaltase, and trehalase, which split the disaccharides as well as other small glucose polymers into their constituent monosaccharides (Table 91.1). Lactase hydrolyzes lactose into glucose and galactose. Maltase hydrolyzes maltose to produce glucose monomers. Sucrase-isomaltase is a complex with two subunits: sucrase hydrolyzes sucrose to yield glucose and fructose, and isomaltase hydrolyzes the α-1,6 bonds in α-limit dextrins to yield glucose. Glucose represents more than 80% of the final product of carbohydrate digestion, with galactose and fructose usually representing no more than 10% of the products of carbohydrate digestion.

From Marsh MN, Riley SA. Digestion and absorption of nutrients and vitamins. In: Feldman M, Scharschmidt BF, Sleisenger MH, eds. *Sleisenger and Fordtran's Gastrointestinal and Liver Disease: Pathophysiology, Diagnosis, Management.* Vol 2. Philadelphia: Saunders; 1998:1480.

Carbohydrates are absorbed as monosaccharides. Transport of the released hexoses (glucose, galactose, and fructose) is by specific mechanisms involved in active transport. The major routes of absorption are by three membrane carrier systems (Fig. 91.3A): sodium-glucose cotransporter-1 (SGLT1), glucose transporter 5 (GLUT5), and glucose transporter 2 (GLUT2).[3] Glucose and galactose are absorbed by a carrier-mediated active transport mechanism that involves the cotransport of sodium (SGLT1). As sodium diffuses into the cell, it pulls the glucose or galactose along with it, thus providing the energy for transport of the monosaccharide. The exit of glucose from the cytosol into the intracellular space is achieved predominantly by a sodium-independent carrier (GLUT2) located at the basolateral membrane of enterocytes. Fructose, the other significant monosaccharide, is also absorbed from the intestinal lumen through facilitated diffusion. This carrier, GLUT5, is located in the apical membrane of the enterocytes. In contrast to SGLT1, this transport process does not depend on sodium or energy. Fructose exits the basolateral membrane by another facilitated diffusion process involving the GLUT2.

Protein

Protein digestion is initiated in the stomach, where gastric acid denatures proteins.[3] Digestion continues in the small intestine, where protein comes into contact with pancreatic proteases. Pancreatic trypsinogen is secreted in the intestine by the pancreas in an inactive form but becomes activated by the enzyme enterokinase (a brush border enzyme in the duodenum) to an activated form of trypsin. Trypsin then activates the other pancreatic proteolytic enzyme precursors. The endopeptidases, which include trypsin, chymotrypsin, and elastase, act on peptide bonds at the interior of the protein molecule, producing peptides that are substrates for the exopeptidases (carboxypeptidases), which serially remove a single amino acid from the carboxyl end of the peptide (Table 91.2). This process results in splitting of the complex proteins into dipeptides, tripeptides, and some larger proteins, which are absorbed from the intestinal lumen by a sodium-mediated active transport mechanism and digested further by enzymes in the brush border and in the cytoplasm of enterocytes (see Fig. 91.3B). These peptidase enzymes include aminopeptidases and several dipeptidases, which split the remaining larger polypeptides into tripeptides, dipeptides, and some amino acids. The amino acids, dipeptides, and tripeptides are easily transported through the microvilli into the epithelial cells where, in the cytosol, additional peptidases hydrolyze the dipeptides and tripeptides into single amino acids; these molecules then pass through the epithelial cell membrane into the portal venous system. In normal humans, digestion and absorption of protein are usually 80% to 90% completed in the jejunum.

Fats

Emulsification. Most adults in North America consume 60 to 100 g/day of fat. Triglycerides, the most abundant fats, are composed of a glycerol nucleus and three fatty acids; small quantities of phospholipids, cholesterol, and cholesterol esters are also found in the normal diet. Essentially all fat digestion occurs in the small intestine, where the first step is the breakdown of fat globules into smaller sizes to facilitate further breakdown by water-soluble digestive enzymes, a process termed *emulsification*.[3] This process is facilitated by bile from the liver, which contains bile salts and the phospholipid lecithin. The polar regions of bile salts and the lecithin molecules are soluble in water, whereas the remaining portions are soluble in fat. Therefore, the fat-soluble portions interact with the surface layer of the fat globules, and the polar portions, projecting outward, are soluble in the surrounding aqueous fluids. This arrangement renders the fat globules more accessible to fragmentation by agitation in the small intestine. Therefore, a major function of bile salts, and especially lecithin, is to allow the fat globules to be fragmented by agitation in the intestinal lumen, which increases the fat globule surface area. With the increase in surface area, the fats are readily attacked by pancreatic lipase, the most crucial enzyme in the digestion of triglycerides, which splits triglycerides into free fatty acids and 2-monoglycerides.

Micelle formation. Fat digestion is accelerated by bile salts, which, secondary to their amphipathic nature, can form micelles. Micelles are small spherical globules composed of 20 to 40 molecules of bile salts with a sterol nucleus that is highly fat soluble and a hydrophilic polar group that projects outward. The mixed micelles thus formed are arrayed so that the insoluble lipid is surrounded by the bile salts oriented with their hydrophilic ends facing outward. Therefore, as quickly as the monoglycerides and free fatty acids are formed by lipolysis, they become dissolved in the central hydrophobic portion of the micelles, which then act to carry these products of fat hydrolysis to the brush borders of the epithelial cells, where absorption occurs.

Intracellular processing. The monoglycerides and free fatty acids, which are incorporated into the central lipid portion of the bile acid micelles, are absorbed through the brush border because of their highly lipid-soluble nature, then simply diffuse into the interior of the cell.[3] After disaggregation of the micelle, bile salts remain within the intestinal lumen to repeat the process by forming new micelles and carrying more monoglycerides and fatty acids to the epithelial cells. Inside the cell, the released fatty acids and monoglycerides re-form into triglycerides. This re-formation of a triglyceride occurs through the interactions of intracellular enzymes that are associated with the endoplasmic reticulum. The major pathway of triglyceride reconstruction involves 2-monoglycerides and coenzyme A (CoA)–activated fatty acids. Microsomal acyl-CoA lipase is necessary to cleave acyl-CoA from the

FIGURE 91.3 (A) Model for glucose, galactose, and fructose transport across the intestinal epithelium. Glucose and galactose are transported into the enterocyte across the brush border membrane by the sodium-glucose cotransporter *(SGLT1)* and then transported out across the basolateral membrane down their concentration gradients by glucose transporter *(GLUT)*-2. The low intracellular sodium concentration driving uphill sugar transport across the brush border is maintained by the Na^+,K^+ pump on the basolateral membrane. Glucose and galactose therefore stimulate sodium absorption across the epithelium. Fructose is transported across the cell down the concentration gradient across the brush border and basolateral membranes. GLUT5 is the brush border fructose transporter, whereas GLUT2 handles fructose transport across the basolateral membrane. (B) Digestion and absorption of proteins. Endopeptidases and exopeptidases split complex proteins into dipeptides and tripeptides that are absorbed from the intestinal lumen by a sodium-mediated active transport mechanism. These peptides are further digested by enzymes in the brush border and within enterocytes. (C) Absorption of water, electrolytes, and nutrients in the small bowel. Each segment of small intestine plays different roles in the absorption of micro- and macronutrients.

fatty acid before esterification. These reconstituted triglycerides then combine with cholesterol, phospholipids, and apoproteins to form chylomicrons, which consist of an inner core containing triglycerides and a membranous outer core of phospholipids and apoproteins. The chylomicrons pass from the epithelial cells into the lacteals and then through the lymphatics into the venous system. About 80% to 90% of all fat absorbed from the gut is absorbed in this manner and transported to the blood by way of the thoracic lymph in the form of chylomicrons. Small quantities of short- to medium-chain fatty acids may be absorbed directly into the portal blood rather than being converted into triglycerides and absorbed into the lymphatics. These shorter-chain fatty acids are more water soluble, which allows direct diffusion into the bloodstream.

Enterohepatic circulation. The proximal intestine absorbs most of the dietary fat. Although unconjugated bile acids are absorbed into the jejunum by passive diffusion, the conjugated bile acids that form micelles are absorbed in the ileum by active transport and then reabsorbed from the distal ileum and passed through the portal venous system to the liver for secretion as bile. The total bile acid pool (approximately 2–3 g) recirculates about six times every 24 hours through the enterohepatic circulation.[3] Almost all the bile salts are reabsorbed, with only about 0.5 g lost in the stool every day; this loss is replaced by newly synthesized bile acids from cholesterol.

Water, Electrolytes, and Vitamins

Every day, 8 to 10 L of water enter the small intestine. Much of this is absorbed, with approximately 500 mL or less leaving the ileum and entering the colon (see Fig. 91.3C).[3] Water may be absorbed by the process of simple diffusion. In addition, water may be drawn in and out of the cell through a process of osmotic pressure, resulting from active transport of sodium, glucose, or amino acids into cells.

Electrolytes can be absorbed in the small bowel by active transport or by coupling to an organic solute.[3] Na^+ is absorbed by active transport through the basolateral membranes. Cl^- is absorbed in the upper part of the small intestine by a process of passive diffusion. Large quantities of HCO_3^- must be reabsorbed, which is accomplished in an indirect fashion. As Na^+ is absorbed, H^+ is secreted into the lumen of the intestine. Inside the lumen, H^+ combines with HCO_3^- to form carbonic acid, which then dissociates to form water and carbon dioxide. The water remains in the chyme, but the carbon dioxide is readily absorbed into the blood and is subsequently expired. Calcium is absorbed, particularly in the proximal intestine (duodenum and jejunum), by a process of active transport; absorption appears to be facilitated by an acid environment and is enhanced by vitamin D and parathyroid hormone. Iron is absorbed as a heme or nonheme component in the duodenum by an active process. The iron is then either deposited within the cell as ferritin or transferred to the plasma bound to transferrin. The total absorption of iron is dependent on body stores of iron and the rate of erythropoiesis; any increase in erythropoiesis increases iron absorption. Potassium, magnesium, phosphate, and other ions also can be actively absorbed throughout the mucosa.

Vitamins are either fat soluble (e.g., vitamins A, D, E, and K) or water soluble (e.g., ascorbic acid [vitamin C], biotin, nicotinic acid, folic acid, riboflavin [vitamin B_2], thiamine [vitamin B_1], pyridoxine [vitamin B_6], and cobalamin [vitamin B_{12}]).[3] The fat-soluble vitamins are carried in mixed micelles and transported in chylomicrons of the lymph to the thoracic duct and into the venous system. The absorption of water-soluble vitamins appears to be more complex than originally thought. Vitamin C is absorbed by an active transport process that incorporates a sodium-coupled mechanism as well as a specific carrier system. Vitamin B_6 appears to be rapidly absorbed by simple diffusion into the proximal intestine. Vitamin B_1 is rapidly absorbed in the jejunum by an active process similar to the sodium-coupled transport system for vitamin C. Vitamin B_2 is absorbed in the upper intestine by facilitated transport. The absorption of vitamin B_{12} occurs primarily in the terminal ileum. Vitamin B_{12} is derived from cobalamin, which is freed in the duodenum by pancreatic proteases. The cobalamin binds to intrinsic factor, which is secreted by the stomach and is protected from proteolytic digestion. Specific receptors in the terminal ileum take up the cobalamin–intrinsic factor complex, probably by translocation. In the ileal enterocyte, free vitamin B_{12} is bound to an ileal pool of transcobalamin II, which transports it into the portal circulation.

MOTILITY

Food particles are propelled through the small bowel by a complex series of muscle contractions.[3] Peristalsis consists of intestinal contractions passing aborally at a rate of 1 to 2 cm/sec. The major function of peristalsis is the movement of intestinal chyme through the intestine. Motility patterns in the small bowel vary greatly between the fed and fasted states. Pacesetter potentials, which are thought to originate in the duodenum, initiate a series of contractions in the fed state that propel food through the small bowel.

During the interdigestive (fasting) period between meals, the bowel is regularly swept by cyclical contractions that move aborally along the intestine every 75 to 90 minutes. These contractions are initiated by the migrating myoelectric complex, which is under the control of neural and humoral pathways. Extrinsic nerves to the small bowel are vagal and sympathetic. The vagal fibers have two functionally different effects; one is cholinergic and excitatory, and the other is peptidergic and probably inhibitory. Sympathetic activity inhibits motor function, whereas parasympathetic activity stimulates it. Although intestinal hormones are known to affect small intestinal motility, the one peptide that has been clearly shown to function in this regard is motilin, which is found at its peak plasma level during phase III (intense bursts of myoelectrical activities resulting in regular, high-amplitude contractions) of migrating myoelectric complexes.

ENDOCRINE FUNCTION

Gastrointestinal Hormones

The gastrointestinal hormones are distributed along the length of the small bowel in a spatially specific pattern. In fact, the small bowel is the largest endocrine organ in the body. Although often classified as hormones, these agents do not always function in a true endocrine fashion (i.e., discharged into the bloodstream, where an action is produced at some distant site; see Fig. 91.3D). Sometimes, these peptides are discharged and act locally in a paracrine or autocrine manner. In contrast, some of these peptides may serve as neurotransmitters (e.g., vasoactive intestinal peptide). Gastrointestinal hormones play a major role in pancreaticobiliary and intestinal secretion, absorption, and motility. In addition, certain gastrointestinal hormones exert a trophic effect on normal and neoplastic intestinal mucosa and the pancreas. Moreover, recent studies show that certain hormones (e.g., neurotensin), when secreted in excess, can contribute to obesity, diabetes, and cardiovascular disease.[4] The location, major stimulants of release, and primary effects of the more important gastrointestinal hormones are summarized in Table 91.3. In addition, the diagnostic and therapeutic uses of gastrointestinal hormones are listed in Table 91.4.

Receptors

The gastrointestinal hormones interact with their cell surface receptors to initiate a cascade of signaling events that eventually culminate in their physiologic effects. These hormones primarily signal through G protein–coupled receptors that traverse the plasma membrane seven times and represent the largest group of receptors found in the body. The heterotrimeric G proteins, which are composed of α, β, and γ subunits, are the molecular switches for signal transduction. Agonist binding to the seven-transmembrane domain receptor is thought to cause a conformational change in the receptor that allows it to interact with the G proteins. Intracellular second messengers that are activated include cyclic adenosine monophosphate, Ca^{2+} cyclic guanosine monophosphate, and inositol phosphate.

In addition to the gastrointestinal hormones, receptors for a number of other peptides and growth factors are located in the gastrointestinal mucosa, including those for epidermal growth factor, transforming growth factor α and β, insulin-like growth factor (IGF), fibroblast growth factor, and platelet-derived growth factor (PDGF). These peptides play a role in cell growth and differentiation and act through tyrosine kinase receptors, which have a single membrane-spanning domain.

A third class of surface receptors, the ion channel–linked receptors, is found most commonly in cells of neuronal lineage and usually bind specific neurotransmitters. Examples include receptors for excitatory (acetylcholine and serotonin) and inhibitory (γ-aminobutyric acid and glycine) neurotransmitters. These receptors undergo a conformational change on binding of the mediator that allows passage of ions across the cell membrane and results in changes in voltage potential.

TABLE 91.3 Gastrointestinal Hormones

HORMONE	PRODUCED BY	MAJOR STIMULANTS OF PEPTIDE SECRETION	PRIMARY EFFECTS
Gastrin	Antrum, duodenum (G cells)	Peptides, amino acids, antral distention, vagal and adrenergic stimulation, gastrin-releasing peptide (bombesin)	• Stimulates gastric acid and pepsinogen secretion • Stimulates gastric mucosal growth
Cholecystokinin	Duodenum, jejunum (I cells)	Fats, peptides, amino acids	• Stimulates pancreatic enzyme secretion • Stimulates gallbladder contraction • Relaxes sphincter of Oddi • Inhibits gastric emptying
Secretin	Duodenum, jejunum (S cells)	Fatty acids, luminal acidity, bile salts	• Stimulates release of water and bicarbonate from pancreatic ductal cells • Stimulates flow and alkalinity of bile • Inhibits gastric acid secretion and motility and inhibits gastrin release
Somatostatin	Pancreatic islets (D cells), antrum, duodenum	• Gut: fat, protein, acid, other hormones (e.g., gastrin, cholecystokinin) • Pancreas: glucose, amino acids, cholecystokinin	• Universal “off” switch • Inhibits release of gastrointestinal hormones • Inhibits gastric acid secretion • Inhibits small bowel water and electrolyte secretion • Inhibits secretion of pancreatic hormones
Gastrin-releasing peptide (mammalian equivalent of bombesin)	Small bowel	Vagal stimulation	• Universal “on” switch • Stimulates release of all gastrointestinal hormones (except secretin) • Stimulates gastrointestinal secretion and motility • Stimulates gastric acid secretion and release of antral gastrin • Stimulates growth of intestinal mucosa and pancreas
Gastric inhibitory polypeptide	Duodenum, jejunum (K cells)	Glucose, fat, protein adrenergic stimulation	• Inhibits gastric acid and pepsin secretion • Stimulates pancreatic insulin release in response to hyperglycemia
Motilin	Duodenum, jejunum	Gastric distention, fat	• Stimulates upper gastrointestinal tract motility • May initiate the migrating motor complex
Vasoactive intestinal peptide	Neurons throughout the gastrointestinal tract	Vagal stimulation	• Primarily functions as a neuropeptide • Potent vasodilator • Stimulates pancreatic and intestinal secretion • Inhibits gastric acid secretion
Neurotensin	Small bowel (N cells)	Fat	• Stimulates growth of small and large bowel mucosa • Facilitates absorption of fats in the intestine • Stimulates growth of cancer with neurotensin receptors
Enteroglucagon	Small bowel (L cells)	Glucose, fat	• Glucagon-like peptide-1 • Stimulates insulin release • Inhibits pancreatic glucagon release • Glucagon-like peptide-2 • Potent enterotrophic factor
Peptide YY	Distal small bowel, colon	Fatty acids, cholecystokinin	• Inhibits gastric and pancreatic secretion • Inhibits gallbladder contraction

IMMUNE FUNCTION

During the course of a normal day, we ingest a number of bacteria, parasites, and viruses. The intestinal epithelium is a single layer of cells and serves as a major immunologic barrier in addition to its important role in digestion and endocrine function. The small intestine has epithelial-lined villi that are absent in the colon; these villi significantly increase the surface area for interaction with foreign pathogens. As a result of constant antigenic exposure, the intestine possesses abundant lymphoid cells (e.g., B and T lymphocytes) and myeloid cells (e.g., macrophages, neutrophils, eosinophils, and mast cells). To deal with the constant barrage of potential toxins and antigens, the gut has evolved a highly organized and efficient mechanism for antigen processing, humoral immunity, and cellular immunity. The gut-associated lymphoid tissue is localized in four areas: Peyer patches, lamina propria lymphoid cells, Paneth cells, and intraepithelial lymphocytes.

Peyer patches are unencapsulated lymphoid nodules that constitute an afferent limb of the gut-associated lymphoid tissue, which recognizes antigens through a specialized sampling mechanism by the microfold (M) cells contained within the follicle-associated epithelium (Fig. 91.4). Antigens that gain access to Peyer patches activate and prime B and T cells in that site. The M cells cover the lymphoid follicles in the gastrointestinal tract and provide a site for selective sampling of intraluminal antigens. Activated lymphocytes from the intestinal lymphoid follicles then migrate into afferent lymphatics that drain into mesenteric lymph nodes. Furthermore, some of these cells migrate into the lamina propria to interact with intestinal epithelial cells to generate the mucosal immune response. The B lymphocytes become surface IgA. IgA-bearing lymphoblasts also serve a critically important role in mucosal immunity.

B lymphocytes and plasma cells, T lymphocytes, macrophages, dendritic cells, eosinophils, and mast cells are scattered throughout the connective tissue of the lamina propria. Approximately 60% of the lymphoid cells are T cells. These T lymphocytes are a heterogeneous group of cells and can differentiate into one of several types of T effector cells. Cytotoxic T effector cells damage the target cells directly. Helper T cells are effector cells that help mediate the induction of other T cells or the induction of B cells to produce humoral antibodies. T suppressor cells perform just the opposite function. Approximately 40% of the lymphoid cells in the lamina propria are B cells, which are primarily derived from precursors in Peyer patches. These B cells and their progeny, plasma cells, are predominantly focused on IgA synthesis and, to a lesser extent, IgM, IgG, and IgE synthesis.

Paneth cells, like M cells, are unique to the small intestine. Paneth cells line the base of crypts and release antimicrobial factors to protect adjacent stem cells.[5] The intraepithelial lymphocytes are located in the space between the epithelial cells that line the mucosal surface and lie close to the basement membrane. Most of the intraepithelial lymphocytes are a unique subtype of T cells. On activation, the intraepithelial lymphocytes may acquire cytolytic functions that can contribute to epithelial cell death through apoptosis. These cells may be important in the immunosurveillance against abnormal epithelial cells.

As noted, one of the major protective immune mechanisms for the intestinal tract is the synthesis and secretion of IgA. The intestine contains more than 70% of the IgA-producing cells in the body. IgA is produced by plasma cells in the lamina propria and is secreted into the intestine, where it can bind antigens at the mucosal surface. The IgA antibody traverses the epithelial cell to the lumen by means of a protein carrier (the secretory component) that not only transports the IgA but also protects it against the intracellular lysosomes. IgA does not activate complement and does not enhance cell-mediated opsonization or destruction of infectious organisms or antigens, which is in sharp contrast to the role of other immunoglobulins. Secretory IgA inhibits the adherence of bacteria to epithelial cells and prevents their colonization and multiplication. In addition, secretory IgA neutralizes bacterial toxins and viral activity and blocks the absorption of antigens from the gut.

Recent studies demonstrated a symbiotic relationship between the intestinal microbiome and intestinal growth and function. The intestinal mucosa in germ-free mice has decreased epithelial proliferation and decreased production of mucin and immunologic mediators that result in thinning of the mucosa with decreased tissue protection and repair. In addition, microbial metabolites from anaerobes generate much of the luminal butyrate, which is a fuel source for colonic cells, and luminal lactate, which promotes small intestinal stem cell proliferation and differentiation. Essentially, a functional molecular "crosstalk" occurs between intestinal epithelial cells and the gut microbiome. Disruption of this crosstalk can lead to adverse changes to the microbiome, a process called *dysbiosis*. Enteric microbial dysbiosis has been identified in certain intestinal pathologies such as in inflammatory bowel disease.[5] Current studies focusing on the importance

of the intestinal epithelium and crosstalk with the microbiome will lead to a better understanding of many small bowel diseases and are the source of many ongoing investigational efforts.

OBSTRUCTION

The description of patients presenting with small bowel obstruction dates back to the 3rd or 4th century BCE, when Praxagoras created an enterocutaneous fistula to relieve a bowel obstruction. Despite this success with operative therapy, the nonoperative management of these patients with attempted reduction of hernias, laxatives, ingestion of heavy metals (e.g., lead, mercury), and leeches to remove toxic agents from the blood was common practice until the late 1800s, when antiseptic and aseptic surgical techniques made operative intervention safer and more acceptable. A better understanding of the pathophysiologic process of bowel obstruction, surgical advances, antibiotics, intestinal tube decompression, and use of isotonic fluid resuscitation have greatly reduced the mortality rate for patients with a mechanical bowel obstruction. However, patients with a bowel obstruction still represent some of the most difficult and vexing problems that surgeons face with regard to accurate diagnosis, optimal timing of therapy, and appropriate treatment. Ultimately, a clinical decision about the management of these patients requires a thorough history and workup with a heightened awareness of potential complications.

Causes

Small bowel obstructions continue to be a significant cause of morbidity and mortality in the United States. The most common cause of intestinal obstruction in the Western countries is adhesive disease.[6] Other causes of small bowel obstruction are many, but as a group, they can be effectively divided into three major categories:

1. Obstruction arising from extraluminal causes (e.g., adhesions, hernias, carcinomas, abscesses)
2. Obstruction intrinsic to the bowel wall (e.g., primary tumors)
3. Intraluminal obturator obstruction (e.g., gallstones, enteroliths, foreign bodies, bezoars)

Adhesions, particularly after pelvic operations (e.g., gynecologic procedures, appendectomy, colorectal resection), are responsible for more than 60% of all causes of bowel obstruction in the United States. This preponderance of lower abdominal procedures to produce adhesions that result in obstruction is thought to occur because the bowel is more mobile in the pelvis and more tethered in the upper abdomen (Box 91.1).

Hernias (typically ventral or inguinal hernias) represent the second leading cause of intestinal obstruction and account for approximately 10% of all cases. Internal hernias, generally related to prior abdominal surgery, can also result in small bowel obstruction. Less common hernias can also produce obstruction, such as femoral, obturator, lumbar, and sciatic hernias.

BOX 91.1 Causes of Mechanical Small Intestinal Obstruction in Adults

Lesions Extrinsic to the Intestinal Wall

Adhesions (usually postoperative)
Hernia
- External (e.g., inguinal, femoral, umbilical, or ventral hernias)
- Internal (e.g., congenital defects such as paraduodenal, foramen of Winslow, and diaphragmatic hernias or postoperative secondary to mesenteric defects)

Neoplastic
- Carcinomatosis
- Extraintestinal neoplasms

Intraabdominal abscess

Lesions Intrinsic to the Intestinal Wall

Congenital

Malrotation
Duplications, cysts

Inflammatory

Crohn disease
Infections
- Tuberculosis
- Actinomycosis
- Diverticulitis

Neoplastic

Primary neoplasms
Metastatic neoplasms

Traumatic

Hematoma
Ischemic stricture

Miscellaneous

Intussusception
Endometriosis
Radiation enteropathy/stricture

Intraluminal, Obturator Obstruction

Gallstone
Enterolith
Bezoar
Foreign body

Malignant tumors account for approximately 5% of the cases of small bowel obstruction. Most of these tumors are metastatic lesions that obstruct the intestine secondary to peritoneal implants that have spread from an intraabdominal primary tumor, such as ovarian, pancreatic, gastric, or colon cancer. Less often, malignant cells from distant sites, such as breast, lung, and melanoma, may metastasize hematogenously and account for peritoneal implants, resulting in an obstruction. Large intraabdominal tumors may also cause small bowel obstruction through extrinsic compression of the bowel lumen. Primary colonic cancers, particularly those arising from the cecum and ascending colon, may manifest as a small bowel obstruction. Primary small bowel tumors can cause obstruction but are exceedingly rare.

Crohn disease is the fourth leading cause of small bowel obstruction and accounts for approximately 5% of all cases. Obstruction can result from acute inflammation and edema, which may resolve with conservative management. In patients with long-standing Crohn disease, strictures can develop that may require resection and reanastomosis or strictureplasty.

An important cause of small bowel obstruction that is not routinely considered is obstruction associated with an intraabdominal abscess, commonly from a ruptured appendix, diverticulum, or dehiscence of an intestinal anastomosis. The obstruction may be a result of a local ileus in the small bowel adjacent to the abscess. In addition, the small bowel can form a portion of the wall of the abscess cavity and become obstructed by kinking of the bowel at this point.

Miscellaneous causes of bowel obstruction should be considered in the differential diagnosis. These include intussusception of the bowel, which in the adult is usually secondary to a pathologic lead point, such as a polyp or tumor; gallstones, which can enter the intestinal lumen by a cholecystoenteric fistula and cause obstruction; enteroliths originating from jejunal diverticula; foreign bodies; and phytobezoars.

Pathophysiology

Early in the course of an obstruction, intestinal motility and contractile activity increase in an effort to propel luminal contents past the obstructing point. The increase in peristalsis that occurs early in the course of bowel obstruction is present above and below the point of obstruction; this process can account for the finding of diarrhea that may accompany partial or even complete small bowel obstruction in the early period. Later in the course of obstruction, the intestine becomes fatigued and dilates, with contractions becoming less frequent and less intense.

As the bowel dilates, water and electrolytes accumulate intraluminally and in the bowel wall itself. This massive third-space fluid loss accounts for the dehydration and hypovolemia. The metabolic effects of fluid loss depend on the site and duration of the obstruction. With a proximal obstruction, dehydration may be accompanied by hypochloremia, hypokalemia, and metabolic alkalosis associated with increased vomiting. Distal obstruction of the small bowel may result in large quantities of intestinal fluid into the bowel; however, abnormalities in serum electrolyte levels are usually less dramatic. Oliguria, azotemia, and hemoconcentration can accompany the dehydration. Rarely, hypotension and shock can ensue. Other consequences of bowel obstruction include increased intraabdominal pressure, decreased venous return, and elevation of the diaphragm, compromising ventilation. These factors can serve to potentiate the effects of hypovolemia.

As the intraluminal pressure increases in the bowel, a decrease in mucosal blood flow can occur. This alteration is particularly noted in patients with a closed loop obstruction, in which greater intraluminal pressures are attained. A closed loop obstruction, produced commonly by a twist of the bowel, can progress to arterial occlusion and ischemia if it is left untreated and may potentially lead to bowel perforation and peritonitis.

In the absence of intestinal obstruction, the jejunum and proximal ileum have only 10^3 to 10^5 colony-forming units per milliliter (CFU/mL) of bacteria. With obstruction, however, the flora of the small intestine changes dramatically in both the type of organism (most commonly *Escherichia coli, Streptococcus faecalis,* and *Klebsiella* spp.) and the quantity, with organisms reaching concentrations of 10^9 to 10^{10} CFU/mL. Studies have shown an increase in the number of indigenous bacteria translocating to mesenteric lymph nodes and even systemic organs. Bacterial translocation amplifies the local inflammatory response in the gut, leading to intestinal leakage and subsequent increase in systemic inflammation. This inflammatory cascade may result in systemic sepsis and multiorgan failure if it is unrecognized and untreated.

Clinical Manifestations and Diagnosis

The major challenge in the diagnosis of intestinal obstruction is the identification of bowel incarceration or strangulation. Although a thorough history and physical examination are important, neither is sensitive nor specific to the diagnosis of ischemia. In some patients, a meticulous history and physical examination complemented by plain abdominal radiographs are all that is required to establish the diagnosis and to devise a treatment plan. More sophisticated radiographic studies, such as a computed tomography (CT) scan of the abdomen, represent invaluable tools in the identification of complications and potential causes.

History

The cardinal symptoms of intestinal obstruction include colicky abdominal pain, nausea, vomiting, abdominal distention, and obstipation. These symptoms may vary with the site and duration of obstruction. The typical crampy abdominal pain associated with intestinal obstruction occurs in paroxysms at 4- to 5-minute intervals and occurs less frequently with distal obstruction. Nausea and vomiting are more common with a higher obstruction and may be the only symptoms in patients with gastric outlet or high intestinal obstruction. An obstruction located distally is associated with less emesis; the initial and most prominent symptom is cramping abdominal pain. Abdominal distention occurs as the obstruction progresses and the proximal intestine becomes increasingly dilated. Obstipation is a later development. It must be reiterated that patients, particularly in the early stages of bowel obstruction, may relate a history of diarrhea that is secondary to increased peristalsis. Therefore, the important point to remember is that a complete bowel obstruction cannot be ruled out on the basis of a history of loose bowel movements. The character of the vomitus is also important to obtain in the history. As the obstruction becomes more complete with bacterial overgrowth, the vomitus becomes more feculent, indicating a late and established intestinal obstruction.

Physical Examination

The patient with intestinal obstruction may present with tachycardia and hypotension, demonstrating the severe dehydration that is present. Fever suggests the possibility of strangulation. Abdominal examination demonstrates a distended abdomen, with the amount of distention somewhat dependent on the level of obstruction. Previous surgical scars should be noted. Early in the course of bowel obstruction, peristaltic waves can be observed, particularly in thin patients, and auscultation of the abdomen may demonstrate hyperactive bowel sounds with audible rushes associated with vigorous peristalsis (borborygmi). Late in the obstructive course, minimal or no bowel sounds are noted. Mild abdominal tenderness may be present, with or without a palpable mass; however, localized tenderness, rebound, and guarding suggest peritonitis and the likelihood of strangulation. A careful examination must be performed to rule out incarcerated hernias in the groin, femoral triangle, and obturator foramen. A rectal examination should *always* be performed to rule out a distal colonic obstruction by intraluminal masses and to examine the stool for occult blood, which may be an indication of malignant disease, intussusception, or infarction.

Laboratory and Radiologic Studies

With a high suspicion of intestinal obstruction after a thorough history and physical examination, further studies are necessary to confirm the diagnosis. Laboratory tests are usually not helpful in the actual diagnosis of patients with small bowel obstruction but are extremely important in assessing the degree of dehydration and may help indicate signs of ischemic changes. Patients with a bowel obstruction should routinely have laboratory measurements of serum sodium, chloride, potassium, bicarbonate, and creatinine levels. The serial determination of serum electrolyte levels should be performed to assess the adequacy of fluid resuscitation. Dehydration may result in hemoconcentration, as noted by an elevated hematocrit value. This level should be monitored because fluid resuscitation results in a decrease in the hematocrit, and some patients (e.g., those with intestinal malignant neoplasms) may require blood transfusions before surgery. In addition, the white blood cell count should be assessed. Leukocytosis may be found in patients with strangulation; however, an elevated white blood cell count does not necessarily denote strangulation. Conversely, the absence of leukocytosis does not eliminate strangulation as a possibility. Elevated lactic acid levels suggest intestinal ischemia or necrosis.

Radiographic studies can be helpful in the diagnosis of small bowel obstruction. Characteristic findings on supine radiographs are dilated loops of small intestine, without evidence of colonic distention (Box 91.2). Upright radiographs demonstrate multiple air-fluid levels, which often layer in a stepwise pattern. Paucity of

BOX 91.2 **Plain Abdominal Film Signs of Small Bowel Obstruction**

Supine or Prone:
- Dilated gas or fluid filled small bowel >3 cm
- Dilated stomach
- Small bowel dilated out of proportion to colon
- Stretch sign
- Absence of rectal gas
- Gasless abdomen
- Pseudotumor sign

Upright or Left Lateral Decubitus:
- Multiple air fluid levels
- Air fluid levels longer than 2.5 cm
- Air fluid levels in same loop of small bowel of unequal lengths
- String of beads sign

(B) Intraabdominal abscess causing small bowel obstruction. CT scan of the abdomen of a patient with a mechanical bowel obstruction secondary to an abscess in the right lower quadrant *(arrow)*. Multiple dilated and fluid-filled loops of small bowel are noted. (C) Barium study demonstrates jejunojejunal intussusception. (A, Courtesy Dr. Kristin Long, University of Kentucky Medical Center, Lexington, KY. B, Courtesy Dr. Melvyn H. Schreiber, The University of Texas Medical Branch, Galveston, TX. C, Courtesy Dr. Melvyn H. Schreiber, The University of Texas Medical Branch, Galveston, TX.)

gas when supine and small pockets of air appearing like a string of beads when upright is more concerning for high-grade or closed loop obstruction. Plain abdominal films (Fig. 91.5A, *left*) may also demonstrate the cause of the obstruction (e.g., foreign bodies, gallstones; see Fig. 91.5.A, *right*). In uncertain cases or when one is unable to differentiate partial from complete obstruction, further diagnostic imaging is required.

Although plain radiographs can be diagnostic, abdominal CT imaging is the standard imaging modality for diagnosis of small bowel obstruction. CT is particularly sensitive and specific for diagnosing complete or high-grade obstruction of the small bowel and for determining the location and cause of obstruction. However, a CT scan is less sensitive in patients with partial small bowel obstruction. A dilated bowel loop of more than

2.5 cm is very concerning for high-grade small bowel obstruction. In addition, CT is helpful in identifying transition zones and extrinsic causes of bowel obstruction (e.g., abdominal tumors, inflammatory disease, or abscess; see Fig. 91.5B). CT has also been described as useful for determining bowel strangulation, most commonly seen in the presence of a hernia. Unfortunately, CT findings associated with strangulation are those of irreversible ischemia and necrosis. Importantly, the emergent surgical management of a toxic patient with a bowel obstruction identified by a thorough history and physical examination should not be delayed to perform unnecessary and costly radiographic studies.

Barium studies, namely, enteroclysis, were previously often used in certain patients with a presumed obstruction. This procedure involves the continued infusion of 500 to 1000 mL of thin barium sulfate and methylcellulose suspension into the intestine through a duodenal tube. The suspension is then viewed continuously with use of either fluoroscopy or standard radiographs taken at frequent intervals; therefore, this technique is a double-contrast procedure that allows detailed imaging of the entire small intestine, which can precisely demonstrate the level of the obstruction as well as the cause of the obstruction in certain cases (see Fig. 91.5C). The main disadvantages of enteroclysis are the need for nasoenteric intubation, slow transit of contrast material in patients with a fluid-filled hypotonic small bowel, and enhanced expertise required by the radiologist to perform this procedure. Barium studies have largely been replaced by the increasingly used Gastrografin small bowel follow-through study. Gastrografin is a water-soluble contrast agent that is similarly administered via nasogastric tube or by mouth. Radiographs are taken at timed intervals to observe the transit of the contrast and can both aid in locating the obstruction and, in some cases, expediting nonoperative resolution of an obstruction that is thought to be secondary to its osmotic effect on decreasing bowel wall edema.[6]

Ultrasound has been reported to be useful for pregnant patients because radiation exposure is a concern. Magnetic resonance imaging (MRI) has been described in patients with obstruction; however, it is not typically used in the standard diagnostic workup of patients with small bowel obstruction.

To summarize, plain abdominal radiographs can be used in the diagnostic workup of obstruction, but CT is the standard diagnostic imaging modality for small bowel obstruction. Contrast-enhanced radiograph studies can be used in tandem with bowel rest and decompression to aid in both identifying the location of the obstruction and, for some, accelerate resolution of the obstruction.

Simple Versus Strangulating Obstruction

Most patients with small bowel obstruction are classified as having simple obstructions that involve mechanical blockage of the flow of luminal contents without compromised viability of the intestinal wall. In contrast, a strangulated obstruction, which usually involves a closed loop obstruction with a compromised vascular supply to a segment of intestine, can lead to intestinal infarction. A strangulated obstruction is associated with an increased morbidity and mortality risk; therefore, recognition of early strangulation is important. In differentiating from the simple intestinal obstruction, classic signs of strangulation have been described; these include tachycardia, fever, leukocytosis, lactic acidosis, and a constant, noncramping abdominal pain. However, a number of studies have convincingly shown that no clinical parameters or laboratory measurements can accurately detect or exclude the presence of strangulation in all cases. This reinforces the dictum that a careful history and physical examination are key for an accurate and timely diagnosis.

Closed loop obstructions occur when both ends of a segment of bowel are obstructed either by an adhesive band or from an internal hernia, which may result in ischemia and necrosis. Ischemia may worsen when this loop twists, creating a volvulus (mesenteric whirl). CT examination is useful for detecting evidence of closed loop obstruction (U loop or coffee bean sign with tapering of both ends of bowel) and volvulus. CT scans also demonstrate evidence of ischemia, such as bowel wall thickening (>3 mm), mesenteric edema, fluid trapped in between loops, decreased bowel wall enhancement, pneumatosis intestinalis, and mesenteric or portovenous gas.[6] Serum levels, including lactate dehydrogenase, amylase, alkaline phosphatase, ammonia, D-lactate, creatinine kinase isoenzyme, and intestinal fatty acid–binding protein, have been investigated as predictive values for bowel ischemia in obstruction. Although outstanding values may increase a provider's clinical suspicion for ischemia, none can definitively rule in or rule out ischemia. Thus, it is important to remember that bowel ischemia and strangulation cannot be reliably diagnosed or excluded preoperatively in all cases by any known clinical parameter, combination of parameters, or current laboratory and radiographic examinations.

Treatment

Patients with symptoms of a bowel obstruction usually present to the emergency department for evaluation and often require a surgical consultation. Patients identified to have small bowel obstruction should be primarily managed by a surgical service. A large population-based study demonstrated significantly shorter length of stay, lower cost, readmission rate, and mortality rate when adhesive bowel obstruction was managed by a surgical service compared with being managed by a medicine service.[7]

Fluid Resuscitation and Antibiotics

Patients with intestinal obstruction are usually dehydrated and depleted of sodium, chloride, and potassium, requiring aggressive intravenous (IV) replacement with an isotonic saline solution such as lactated Ringer solution or normal saline. Urine output should be monitored with placement of a Foley catheter or external collection device to limit risk of catheter-associated infection. After the patient has formed adequate urine, potassium chloride can be added to the infusion, if needed. Serial electrolyte level measurements as well as hematocrit and white blood cell count are performed to assess the adequacy of fluid repletion. Broad-spectrum antibiotics are given prophylactically by some surgeons on the basis of the reported findings of bacterial translocation occurring even in simple mechanical obstructions; however, there is no substantial evidence to support the use of antimicrobial therapy in nontoxic-appearing patients or those without suspected bacterial overgrowth of the small intestine. Antibiotics should only be administered preoperatively in the event that the patient requires surgery.

Tube Decompression

In addition to IV fluid resuscitation, another important adjunct to consider in the supportive care of patients with intestinal obstruction is nasogastric decompression. Suction with a nasogastric tube empties the stomach, reducing the hazard of pulmonary aspiration of vomitus and minimizing further intestinal distention from swallowed air. Nasogastric decompression in a patient with small bowel obstruction has long been the standard of care.

However, recently, studies have been questioning the utility and benefit of nasogastric tube decompression. The evidence to support or refute the universal use of nasogastric decompression in the management of small bowel obstructions remains inconclusive. As such, although the use of tube decompression is still typically recommended, use should be determined on case-by-case basis.

The use of long intestinal tubes (e.g., Cantor or Baker tube) has been advocated by some. However, prospective randomized trials have demonstrated no significant difference regarding the decompression achieved, success of nonoperative treatment, or incidence of postoperative morbidities compared with the use of nasogastric tubes. Furthermore, the use of these long tubes has been associated with a significantly longer hospital stay, duration of postoperative ileus, and postoperative complications in some series. Therefore, it appears that long intestinal tubes offer no benefit in the preoperative setting over nasogastric tubes.

Patients with a partial intestinal obstruction may be treated conservatively with resuscitation and tube decompression alone. Resolution of symptoms and discharge without the need for surgery have been reported in up to 85% of patients with a partial obstruction. Although an initial trial of nonoperative management of most patients with partial small bowel obstruction is warranted, clinical deterioration of the patient or increasing small bowel distention on abdominal radiographs during tube decompression warrants prompt operative intervention. The decision to continue to treat a patient nonoperatively with a presumed bowel obstruction is based on clinical judgment and requires constant vigilance and reevaluation to ensure that the clinical course has not changed.

Contrast Challenge

As previously mentioned, water-soluble contrast has become more regularly used in the diagnosis and treatment of adhesive small bowel obstruction. The challenge requires 100 mL of water-soluble contrast given through the nasogastric tube or orally and follow-up radiographs obtained at timed intervals such as at 8 and 24 hours. If contrast material still has not passed into the colon after 24 hours, conservative management will probably fail and surgical intervention is likely needed.[6] Studies continue to investigate the optimal timing of administration, but, typically, it is given 24 to 48 hours after adequate decompression. Although improved outcomes with use of water-soluble contrast are evident in adhesive bowel obstructions, there is not similar evidence to support its use in nonadhesive obstructive disease.

Operative Management

As the management of intestinal obstruction has shifted more to conservative care with nasogastric tube decompression and rehydration, operative intervention is reserved for those who fail conservative management or have evidence of vascular compromise, strangulation, or perforation. A nonoperative approach for selected patients with complete small intestinal obstruction has been proposed by some surgeons, who argue that prolonged gastrointestinal decompression is safe in these patients, provided that no fever, tachycardia, tenderness, or leukocytosis is noted. Nevertheless, one must weigh the risks and benefits of nonoperative management in overlooking an underlying strangulated obstruction. Retrospective studies report that a 12- to 24-hour delay is safe but that the incidence of strangulation and other complications increases significantly after this period.

The nature of the problem dictates the approach for the obstructed patient. Patients with intestinal obstruction secondary to an adhesive band may be treated with lysis of adhesions. Great care should be used in the gentle handling of the bowel to reduce serosal trauma and to avoid unnecessary dissection and inadvertent enterotomies. Incarcerated hernias can be managed by manual reduction of the herniated segment of bowel and closure of the defect.

The treatment of patients with an obstruction and history of malignant tumors can be particularly challenging. In the terminal patient with widespread metastasis, nonoperative management, if successful, is usually the best course; however, only a small percentage of cases with complete obstruction can be successfully managed nonoperatively. In this case, an intestinal bypass of the obstructing lesion, by whatever means, may offer the best option rather than a long and complicated operation that might entail bowel resection.

An obstruction secondary to Crohn disease will often resolve with conservative management if the obstruction is acute. If a chronic fibrotic stricture is the cause of the obstruction, a bowel resection or strictureplasty may be required.

Patients with an intraabdominal abscess can present in a manner indistinguishable from those with mechanical bowel obstruction. CT is particularly useful in diagnosing the cause of the obstruction in these patients. Percutaneous drainage of the abscess may be sufficient to relieve the obstruction. Laparoscopic drainage is also an option in cases not amenable to image-guided percutaneous drainage; this procedure is associated with reduced wound morbidity, is useful in multiloculated collections, and allows a washout of the peritoneal cavity at the same time. Otherwise, laparotomy and abdominal washout may be required for large and established abscesses.

Radiation enteropathy, as a complication of radiation therapy for pelvic malignant neoplasms, may cause bowel obstruction. Most cases can be treated nonoperatively with tube decompression and the potential addition of corticosteroids, particularly during the acute setting. In the chronic setting, nonoperative management is rarely effective; laparoscopy or laparotomy will be required with possible resection of the irradiated bowel or bypass of the affected area.

At the time of exploration, it can sometimes be difficult to evaluate bowel viability after the release of a strangulation. If intestinal viability is questionable, the bowel segment should be completely released and placed in a warm, saline-moistened sponge for 15 to 20 minutes and then reexamined. If normal color has returned and peristalsis is evident, it is safe to retain the bowel. Doppler flow probe can be used to identify flow in the mesentery but has not typically added to the conventional clinical judgment of the surgeon. In difficult borderline cases, fluorescence with fluorescein or indocyanine green can help discriminate viability of bowel intraoperatively. If there remains question as to the viability of the bowel, the provider can elect to perform a temporary abdominal closure with planned second-look laparotomy 18 to 24 hours after the initial procedure. This decision should be made at the time of the initial operation. A second-look laparotomy is clearly indicated for a patient whose condition deteriorates after the initial operation.

Multiple studies have evaluated the efficacy of laparoscopic management of acute small bowel obstruction. Laparoscopic treatment of small bowel obstruction is effective and leads to lower morbidity and mortality, shorter length of stay, shorter operating time, lower reoperation rate, and reduced overall complications.[8] The patient profile appropriate for consideration of laparoscopic management includes those with the following clinical presentation: mild abdominal distention, proximal or partial obstruction, anticipated single-band obstruction, and low risk of strangulation or perforation. Patients with matted adhesions or carcinomatosis or who remain distended after nasogastric intubation may be better managed with conventional laparotomy. This is dependent on the laparoscopic skill of the surgeon, and increasingly more surgeons elect to proceed, at least initially, laparoscopically.

Management of Specific Problems

Recurrent Intestinal Obstruction

All surgeons can readily remember the complicated patient with multiple previous abdominal operations and a frozen abdomen who presents with yet another bowel obstruction. An initial nonoperative trial is usually desirable and often safe. In patients who do not respond conservatively, reoperation is required. This can often be a long and arduous procedure, with great care taken to prevent enterotomies or adjacent organ injury. In these difficult patients, various surgical procedures and pharmacologic agents have been tried in an effort to prevent recurrent adhesions and obstruction.

External plication procedures have been described in which the small intestine or its mesentery is sutured in large, gently curving loops. Common complications include the development of fistulas, gross leakage, peritonitis, and death. Because of frequent complications and low overall success rate, these procedures have largely been abandoned. Several series have reported moderate success with internal fixation or stenting procedures using a long intestinal tube inserted through the nose, a gastrostomy, or even a jejunostomy that is left in place for 2 weeks or longer. However, complications associated with these tubes include prolonged drainage of bowel contents from the tube insertion site, intussusception, and difficult removal of the tube, which may require surgical reexploration. Such means to prevent recurrent obstruction are not typically employed today.

Pharmacologic agents, including corticosteroids and other antiinflammatory agents, cytotoxic drugs, and antihistamines, have been used with limited success. The use of anticoagulants, such as heparin, dextran solutions, dicumarol, and sodium citrate, may modify the extent of adhesion formation, but their side effects far outweigh their efficacy. Investigations into intraperitoneal instillation of various proteinases (e.g., trypsin, papain, pepsin), which cause enzymatic digestion of the extracellular protein matrix, have been largely unsuccessful. Hyaluronidase has been of questionable value, and conflicting results were obtained with fibrinolytic agents such as streptokinase, urokinase, and fibrinolytic snake venoms. The use of a hyaluronate-based, bioresorbable membrane is debatable. A meta-analysis demonstrated reduced risk of adhesive bowel obstruction and less severe adhesions when they do occur, but its use may also increase the risk of anastomotic leak.[9] Therefore, the use of such a membrane may be beneficial in some patients but should be thoughtfully considered given the risk.

To date, the most effective means of limiting the number of adhesions is a good surgical technique. This includes the gentle handling of the bowel to reduce serosal trauma, avoidance of unnecessary dissection, exclusion of foreign material from the peritoneal cavity (the use of absorbable suture material when possible, avoidance of excessive gauze sponge use, and the removal of starch from gloves), adequate irrigation with removal of infectious and ischemic debris, and preservation and use of the omentum around the site of surgery or in the denuded pelvis.

Acute Postoperative Obstruction

Small bowel obstruction that occurs in the immediate postoperative period presents a challenge with regard to diagnosis and treatment. Diagnosis is often difficult because the primary symptoms of abdominal pain and nausea or emesis may be attributed to a postoperative ileus. Electrolyte deficiencies, particularly hypokalemia, can be a cause of ileus and should be corrected. Plain abdominal films are usually not helpful to distinguish an ileus from obstruction. Where there is high concern for obstruction, CT may be useful. More than 90% of early postoperative obstructions are partial and will resolve spontaneously, given ample time. Conservative management in the form of bowel rest, fluid resuscitation, electrolyte replacement, and parenteral nutrition, if necessary, is routinely successful. However, the development of complete obstruction or signs of strangulation mandates reoperative intervention. Postoperative bowel obstruction after laparoscopic surgery is more commonly associated with a definitive obstruction point, such as a port site, hernia, or an internal hernia, and should prompt a high index of suspicion for the need for operative intervention.

Ileus

An ileus is defined as intestinal distention and the slowing or absence of passage of luminal contents without a demonstrable mechanical obstruction. An ileus can result from a number of causes, including those that are drug induced or from metabolic, neurogenic, and infectious factors (Box 91.3).

Pharmacologic agents that can produce an ileus include anticholinergic drugs, autonomic blockers, antihistamines, and various psychotropic agents, such as haloperidol and tricyclic antidepressants. One of the more common causes of drug-induced ileus in the operative patient is the use of opiates, such as morphine or meperidine. Metabolic causes of ileus are common and include hypokalemia, hyponatremia, and hypomagnesemia. Other metabolic causes include uremia, diabetic coma, and hypoparathyroidism. Neurogenic causes of an ileus include postoperative ileus, which occurs after abdominal operations. Spinal injury, retroperitoneal irritation, and orthopedic procedures on the spine or pelvis can result in an ileus. Finally, infections can result in an ileus; common infectious causes include pneumonia, peritonitis, and generalized sepsis from a nonabdominal source.

Patients often present in a manner similar to those with a mechanical small bowel obstruction. Abdominal distention, usually without the colicky abdominal pain, is the typical and most notable finding. Nausea and vomiting may occur but may also be absent. Patients with an ileus may continue to pass flatus and

BOX 91.3 Causes of Ileus

After laparotomy
Metabolic and electrolyte derangements (e.g., hypokalemia, hyponatremia, hypomagnesemia, uremia, diabetic coma)
Drugs (e.g., opiates, psychotropic agents, anticholinergic agents)
Intraabdominal inflammation
Retroperitoneal hemorrhage or inflammation
Intestinal ischemia
Systemic sepsis

Adapted from Turnage RH, Bergen PC. Intestinal obstruction and ileus. In: Feldman M, Scharschmidt FG, Sleisenger MH, eds. *Sleisenger and Fordtran's Gastrointestinal and Liver Disease: Pathophysiology, Diagnosis, Management.* Philadelphia: Saunders; 1998:1799-1810.

diarrhea, which may help distinguish these patients from those with a mechanical small bowel obstruction.

Radiologic studies may help distinguish ileus from small bowel obstruction. Plain abdominal radiographs may reveal distended small bowel as well as large bowel loops. In cases that are difficult to differentiate from obstruction, CT imaging and enteral contrast studies may be beneficial.

The treatment of an ileus is entirely supportive, with nasogastric decompression and IV fluids. The most effective treatment to correct the underlying condition may be aggressive treatment of the sepsis, correction of any metabolic or electrolyte abnormalities, and discontinuation of medications that may produce an ileus. Pharmacologic agents have been used but for the most part have been ineffective. Drugs that block sympathetic input (e.g., guanethidine) or stimulate parasympathetic activity (e.g., bethanechol, neostigmine) have been tried. Hormonal manipulation, using cholecystokinin or motilin, has been evaluated, but the results have been inconsistent. Erythromycin has been ineffective, and cisapride, although apparently beneficial in stimulating gastric motility, does not appear to alter intestinal ileus. Chewing gum has been shown to be an easy and inexpensive method to stimulate the cephalic phase of digestion (e.g., vagal cholinergic stimulation and the release of gastrointestinal hormones) and therefore a potential adjunct to prevent and to treat ileus.

INFLAMMATORY AND INFECTIOUS DISEASES

Crohn Disease

Crohn disease is a chronic, transmural inflammatory disease of the gastrointestinal tract for which the definitive cause is unknown, although a combination of genetic and environmental factors has been implicated. Crohn disease can involve any part of the alimentary tract from the mouth to the anus but most commonly affects the small intestine and colon. The most common clinical manifestations are abdominal pain, diarrhea, and weight loss. Crohn disease can be complicated by intestinal obstruction or localized perforation with fistula formation. Medical and surgical treatments are palliative; however, operative therapy can provide effective symptomatic relief for patients with complications from Crohn disease and produces a reasonable long-term benefit.

History

The first documented case of Crohn disease was described by Morgagni in 1761. In 1913, the Scottish surgeon Dalziel described nine cases of intestinal inflammatory disease. However, it was the landmark paper by Crohn and colleagues in 1932 that provided, in eloquent detail, the pathologic and clinical findings of this inflammatory disease in young adults.[10] This classic paper crystallized the description of this inflammatory condition. Although many different (and sometimes misleading) terms have been used to describe this disease process, Crohn disease has been universally accepted as its name.

Incidence and Epidemiology

Crohn disease is the most common primary surgical disease of the small bowel. The annual incidence of Crohn disease, which is rising in the United States, is 6 to 24 cases per 100,000 individuals.[11] Crohn disease primarily attacks young adults in the second and third decades of life. However, all ages can be affected, and a bimodal distribution, with a second smaller peak occurring in the sixth decade of life, has classically been described. Although earlier reports suggested a somewhat higher female predominance, males and females are affected equally. The risk for development of Crohn disease is almost twice as high in smokers as in nonsmokers. Several studies indicate an increased incidence of Crohn disease in females using oral contraceptives. The condition is predominately seen in industrialized nations, and incidence increases with Westernized diets. Certain ethnic groups, particularly Ashkenazi Jews, have a higher incidence of Crohn disease than age- and sex-matched control subjects. Of note, within one generation, migrants moving from a low-risk region to a high-risk region develop Crohn disease at similar rates to those in the high-risk region. There is a strong familial association, with the risk for development of Crohn disease increased about thirtyfold in siblings and fourteenfold to fifteenfold for all first-degree relatives. Intestinal microflora and epigenetic changes induced by environmental factors play an important role in disease development and progression in genetically susceptible individuals.[12]

Etiology

The causes of Crohn disease remain unknown. A number of potential causes have been proposed, with the most likely possibilities being infectious, immunologic, and genetic. Other possibilities that have met with various levels of enthusiasm include environmental and dietary factors, smoking, and psychosocial factors. Although these factors may contribute to the overall disease process, it is unlikely that they represent the primary etiology for Crohn disease.

Infectious agents. Although a number of infectious agents have been proposed as potential causes of Crohn disease, the two that have received the most attention are mycobacterial infections, particularly *Mycobacterium paratuberculosis* and enteroadherent *E. coli*. The existence of atypical mycobacteria as a cause for Crohn disease was proposed by Dalziel in 1913. Subsequent studies using polymerase chain reaction (PCR) techniques have confirmed the presence of mycobacteria in intestinal samples of patients with Crohn disease. Transplantation of tissue from patients with the condition has resulted in ileitis, but antimicrobial therapy directed against mycobacteria has not been effective in ameliorating the established disease process. Strains of enteroadherent *E. coli* are in higher abundance in patients with Crohn disease compared with the general population based on PCR analysis. Studies using fluorescent in situ hybridization have demonstrated increased numbers of *E. coli* in the lamina propria of patients with active Crohn disease compared with those with inactive disease. Furthermore, an increased number of *E. coli* has been associated with a shorter time before relapse of the disease.

Immunologic factors. Humoral and cell-mediated immune reactions directed against intestinal cells in Crohn disease suggest an autoimmune phenomenon. Attention has focused on the role of cytokines, such as interleukin (IL)-1, IL-2, IL-8, and TNF-α, as contributing factors in the intestinal inflammatory response. The role of the immune response remains controversial in Crohn disease and may represent an effect of the disease process rather than an actual cause.

Genetic factors. Genetic factors play an important role in the pathogenesis of Crohn disease because the single strongest risk factor for its development is having a first-degree relative with the disease. Several genome-wide association sequencing studies have been performed and have identified more than 200 alleles associated with Crohn disease (Table 91.5).

More recent genome-wide association sequencing studies in monozygotic twins have shown no reproducible differences within

twin pairs in comparing whole genome sequences and tissue-specific variants in the intestinal mucosa directly affected by the inflammation of Crohn disease. These findings suggest that it is unlikely that somatic mutations have a substantial impact on the development of the disease, and simple Mendelian inheritance cannot account for the pattern of occurrence. Therefore, it is likely that multiple causes (e.g., environmental factors) contribute to the origin and pathogenesis of this disease.

Environmental factors. Low-risk countries in Asia that have adopted a more Western lifestyle have noted a significant rise in the incidence of Crohn disease. Smoking is the single largest environmental factor, with a twofold increase in risk of Crohn disease. A genetic predisposition to smoking is associated with an increased risk, identifying a genetic disposition for an environmental risk factor.[13] Other factors that increase the risk of Crohn disease include medications (oral contraceptives, aspirin, nonsteroidal antiinflammatory drugs [NSAIDs], antibiotics), decreased dietary fiber, and increased fat intake. In addition, dysbiosis with a decrease in intraluminal *Bacteroides* and *Firmicutes* and an increase in *Gammaproteobacteria* and *Actinobacteria* are associated with higher risk. Specifically, an increase of mucosal—adherent—invasive *E. coli* survive within macrophages and induce higher TNF-α production. There are numerous studies evaluating the therapeutic benefits of microbiota manipulation.[14]

Pathology

The most common sites of Crohn disease are the small intestine and colon. The location of disease involvement is biologically defined by the genetic variation. As such, a large multi-institutional study proposed a three-category model to better characterize inflammatory bowel disease into ileal Crohn disease, colonic Crohn disease, and ulcerative colitis. These categories provide risk stratification for surgical complications and genetic risk score based on location.[15] Ileal involvement has been shown with mutations of *IL10, CRP, NOD2, ZNF365,* and *STAT3;* ileocolonic involvement has been shown with mutations of *ATG16L1, TCF4,* and *TCF7L2;* and colonic involvement has been associated with mutations of *HLA, TLR4, TLR1, TLR2,* and *TLR6.* The involvement of the large and small intestine has been noted in about 55% of patients. Thirty percent of patients present with small bowel disease alone, and in 15%, the disease appears limited to the large intestine. The disease process is discontinuous and segmental. In patients with colonic disease, rectal sparing is characteristic of Crohn disease and helps distinguish it from ulcerative colitis. Perirectal and perianal involvement occurs in about one-third of patients with Crohn disease, particularly those with colonic involvement. The disease can also involve the mouth, esophagus, stomach, duodenum, and appendix. Involvement of these sites can accompany disease in the small or large intestine, but in rare cases these locations have been the only apparent sites of involvement.

Gross pathologic features. At exploration, thickened gray-pink or dull purple-red loops of bowel are noted, with areas of thick gray-white exudate or fibrosis of the serosa. Areas of diseased bowel separated by areas of grossly appearing normal bowel, called *skip areas,* are commonly encountered. A striking finding of Crohn disease is the presence of extensive fat wrapping caused by the circumferential growth of the mesenteric fat around the bowel wall, also known as *creeping fat* (Fig. 91.6A). As the disease progresses, the bowel wall becomes increasingly thickened, firm, rubbery, and almost incompressible (see Fig. 91.6B). The uninvolved proximal bowel may be dilated secondary to obstruction of the diseased segment. Involved segments often are adherent to adjacent intestinal loops or other viscera, with internal fistulas common in these areas. The mesentery of the involved segment is usually thickened, with enlarged lymph nodes often noted.

On opening of the bowel, the earliest gross pathologic lesion is a superficial aphthous ulcer noted in the mucosa. With increasing disease progression, the ulceration becomes pronounced, and complete transmural inflammation results. The ulcers are characteristically linear and may coalesce to produce transverse sinuses with islands of normal mucosa in between, thus giving the characteristic cobblestone appearance.

Microscopic features. Mucosal and submucosal edema may be noted microscopically before any gross changes. A chronic inflammatory infiltrate appears in the mucosa and submucosa and extends transmurally. This inflammatory reaction is characterized by extensive edema, hyperemia, lymphangiectasia, intense infiltration of mononuclear cells, and lymphoid hyperplasia. Characteristic histologic lesions of Crohn disease are noncaseating granulomas with Langerhans giant cells. Granulomas appear later in the course and are found in the wall of the bowel or in regional lymph nodes in 60% to 70% of patients (see Fig. 91.6C).

Clinical Manifestations

Crohn disease can occur at any age, but the typical patient is a young adult in the second or third decade of life. The onset of disease is often insidious, with a slow and protracted course. Characteristically, there are symptomatic periods of abdominal pain and diarrhea interspersed with asymptomatic periods of varying lengths. With time, the symptomatic periods gradually become more frequent, more severe, and longer lasting. The most common symptom of Crohn disease is chronic diarrhea, followed by intermittent and colicky abdominal pain, most commonly noted in the lower abdomen. The pain, however, may be more severe and localized in the right lower quadrant and may mimic the signs and symptoms of acute appendicitis.[11] In contrast to ulcerative colitis, patients with Crohn disease typically have fewer bowel movements, and the stools rarely contain mucus, pus, or blood. Systemic nonspecific symptoms include a low-grade fever present in about one-third of the patients, weight loss, loss of strength, and malaise.

Clinically, Crohn disease is often classified on the basis of age at onset, behavior, and site of origin. The Montreal classification

(Table 91.6) divides all patients into distinct categories based on symptom onset (before or after the age of 40 years), disease behavior (nonstricturing/nonpenetrating, stricturing, or penetrating), and disease site (terminal ileum, colon, ileocolonic, upper gastrointestinal tract). This classification was developed to provide a reproducible staging of the disease, to help predict remission and relapse, and to direct therapy. The main intestinal complications of Crohn disease include obstruction and perforation. Obstruction can occur as a manifestation of an acute exacerbation of active disease or as the result of chronic fibrosing lesions, which eventually narrow the lumen of the bowel, producing partial or near-complete obstruction. Free perforations into the peritoneal cavity leading to a generalized peritonitis can occur in patients with Crohn disease, but this presentation is rare. More commonly, fistulas occur between the sites of perforation and adjacent organs, such as loops of small and large intestine, urinary bladder, vagina, stomach, and sometimes the skin, usually at the site of a previous laparotomy. Localized abscesses can occur near the sites of perforation. Patients with Crohn colitis may develop toxic megacolon and present with a marked colonic dilation, abdominal tenderness, fever, and leukocytosis. Bleeding is typically indolent and chronic, but massive gastrointestinal bleeding can occasionally occur, particularly in duodenal Crohn disease associated with chronic ulcer formation.

Long-standing Crohn disease predisposes the patient to cancer of the small intestine and colon. These carcinomas typically arise

TABLE 91.6 **Montreal Classification of Crohn Disease**

Age at diagnosis (yr)	A1: ≤16 A3: 17–40 A2: >40
Behavior	B1: Nonstricturing/nonpenetrating B2: Stricturing B3: Penetrating P: Perianal disease modifier (can add to B1–B3)
Location	L1: Ileal L2: Colonic L3: Ileocolonic L4: Isolated upper gastrointestinal tract (can add to L1–L3)

at sites of chronic disease and more commonly occur in the ileum as a result of the chronic inflammation of the mucosa. Most are not detected until the advanced stages, and the prognosis is poor. Although the relative risk for small bowel cancer in Crohn disease is approximately thirtyfold, the absolute risk is still small. Of greater concern is the development of colorectal cancer in patients with colonic involvement and a long duration of disease. Dysplasia is the putative precursor lesion for Crohn disease–associated cancer. Patients with long-standing disease should have an equally aggressive colonoscopic surveillance regimen as patients with extensive ulcerative colitis.[11] Small bowel adenocarcinoma associated with Crohn disease has an aggressive behavior and a strong probability of extracellular mucin. In surgical specimens from patients with Crohn disease, mucinous-appearing anal fistulas and ileal areas of adhesion/retraction should always be closely examined by a pathologist to evaluate for dysplasia or malignancy.

Extraintestinal cancer, such as squamous cell carcinoma of the vulva and anal canal as well as Hodgkin and non-Hodgkin lymphomas, may be more frequent in patients with Crohn disease, especially those treated with immunomodulators.

Crohn disease is not limited to the small intestine, with 41% of patients presenting with ileocolitis and 48% of patients with colonic involvement alone. Perianal disease (fissure, fistula, stricture, or abscess) is common and occurs in 25% of patients with the disease. Perianal disease may be the sole presenting feature in 5% of patients and may precede the onset of intestinal disease by months or even years. In 10% to 30% of patients, perianal disease will be the first presenting symptom. Crohn disease should be suspected in any patient with multiple chronic perianal fistulas.[16]

Extraintestinal manifestations of Crohn disease may be present in 30% of patients. Common findings are skin lesions (Fig. 91.7), which include erythema nodosum and pyoderma gangrenosum, arthritis and arthralgias, uveitis and iritis, hepatitis, pericholangitis, and aphthous stomatitis. In addition, amyloidosis, pancreatitis, and nephrotic syndrome may occur in these patients. These symptoms may precede, accompany, or appear independently of the underlying bowel disease.

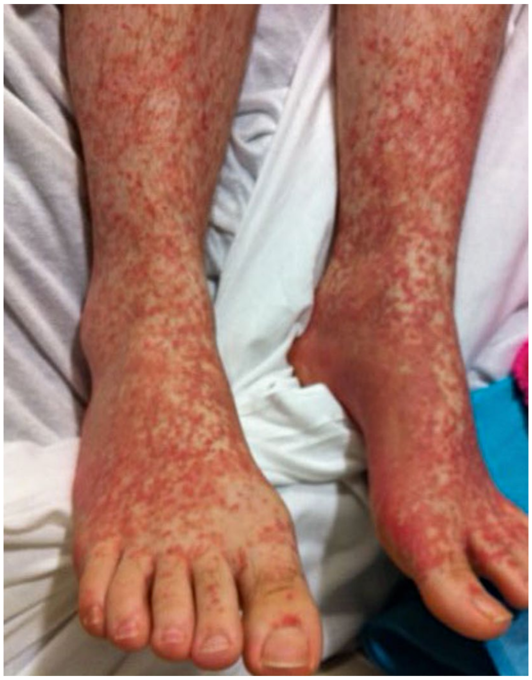

FIGURE 91.7 Patient with Crohn disease with erythema nodosum. The most common extraintestinal presentations of Crohn disease are skin lesions, which include erythema nodosum and pyoderma gangrenosum.

Diagnosis

A diagnosis of Crohn disease should be considered in patients with chronic recurring episodes of abdominal pain, diarrhea, and weight loss. However, there is not a single diagnostic test for the condition; a multimodal approach of laboratory testing, endoscopy, radiology, and pathology is required.

Laboratory. Serologic markers may be useful in the diagnosis of Crohn disease. In particular, perinuclear antineutrophil cytoplasmic antibody and its target proteins (bactericidal/permeability increasing protein [BPI], lactoferrin, cathepsin G, and elastase), anti–*Saccharomyces cerevisiae* antibody (ASCA), outer membrane porin of flagellin (anti-CBir1), and outer membrane porin of *E. coli* (OmpC-IgG) can predict the development of inflammatory bowel disease even in patients thought to be at low risk for developing it.[17] ASCA is also useful in differentiating Crohn disease from ulcerative colitis as well as playing a role in determining patients who will require surgery in the future.

Noninvasive inflammatory markers (historically, C-reactive protein and erythrocyte sedimentation rate) were used to aid in the initial diagnosis, to rule out exacerbations, to monitor response to systemic therapy, and to predict relapse; however, these markers were generally nonspecific and have largely been abandoned. Stool lactoferrin, an iron-binding protein in the secretory granules of neutrophils, and fecal calprotectin, a protein with antimicrobial properties released by squamous cells in response to inflammation, are inflammatory markers specific to the intestine that have shown promising results for the detection and surveillance of Crohn disease. A prospective study showed that both calprotectin and lactoferrin levels correlate well with CT enterography (CTE) images of small bowel inflammation (mucosal irregularity, hyperdensity, stenosis, prestenotic dilation, and mesenteric hypervascularity [i.e., comb sign]). Elevated fecal calprotectin is predictive of small bowel inflammation with a sensitivity of 87% and specificity of 67%. Fecal lactoferrin (>6 ng/mL) has been found to be similarly predictive with a lower sensitivity but higher specificity for small bowel inflammation. Together, these findings identify fecal calprotectin and lactoferrin as helpful screening tools for detecting early small bowel Crohn disease.[11]

Radiology. CTE or magnetic resonance enterography (MRE) are often used as the initial assessment of Crohn disease to complement direct ileocolonoscopy. Imaging studies can provide information regarding severity of inflammation, length, and focality and can identify complications (e.g., obstruction or fistula). In addition, these studies support surgical planning and the evaluation of response to medical therapy. Previously, barium enema was commonly used to identify features of Crohn disease. For example, long lengths of narrowed terminal ileum (Kantor string sign) may be present with long-standing disease (Fig. 91.8A). Segmental and irregular patterns of bowel involvement may be noted. Fistulas between adjacent bowel loops and organs may be apparent (see Fig. 91.8B).

CTE may be useful in demonstrating the marked transmural thickening; it can also greatly aid in diagnosing extramural complications of Crohn disease, especially in the acute setting (see Fig. 91.8C). MRE and CTE are equally accurate in assessing disease activity and bowel damage; however, MRE may be superior to CTE in detecting intestinal strictures and ileal wall enhancement.[18] Recent studies suggest limiting the use of CTE in patients with long-standing Crohn disease because of its significant radiation exposure and need for numerous studies during the course of the disease. MRE is a useful adjunct to determine intestinal strictures as well as fistulas and sinus tracts; however, the relatively high cost, prolonged examination time, and limited availability may preclude many patients from receiving this procedure. Intestinal ultrasound is increasing in utility for the diagnosis and assessment of severity of Crohn disease, with the

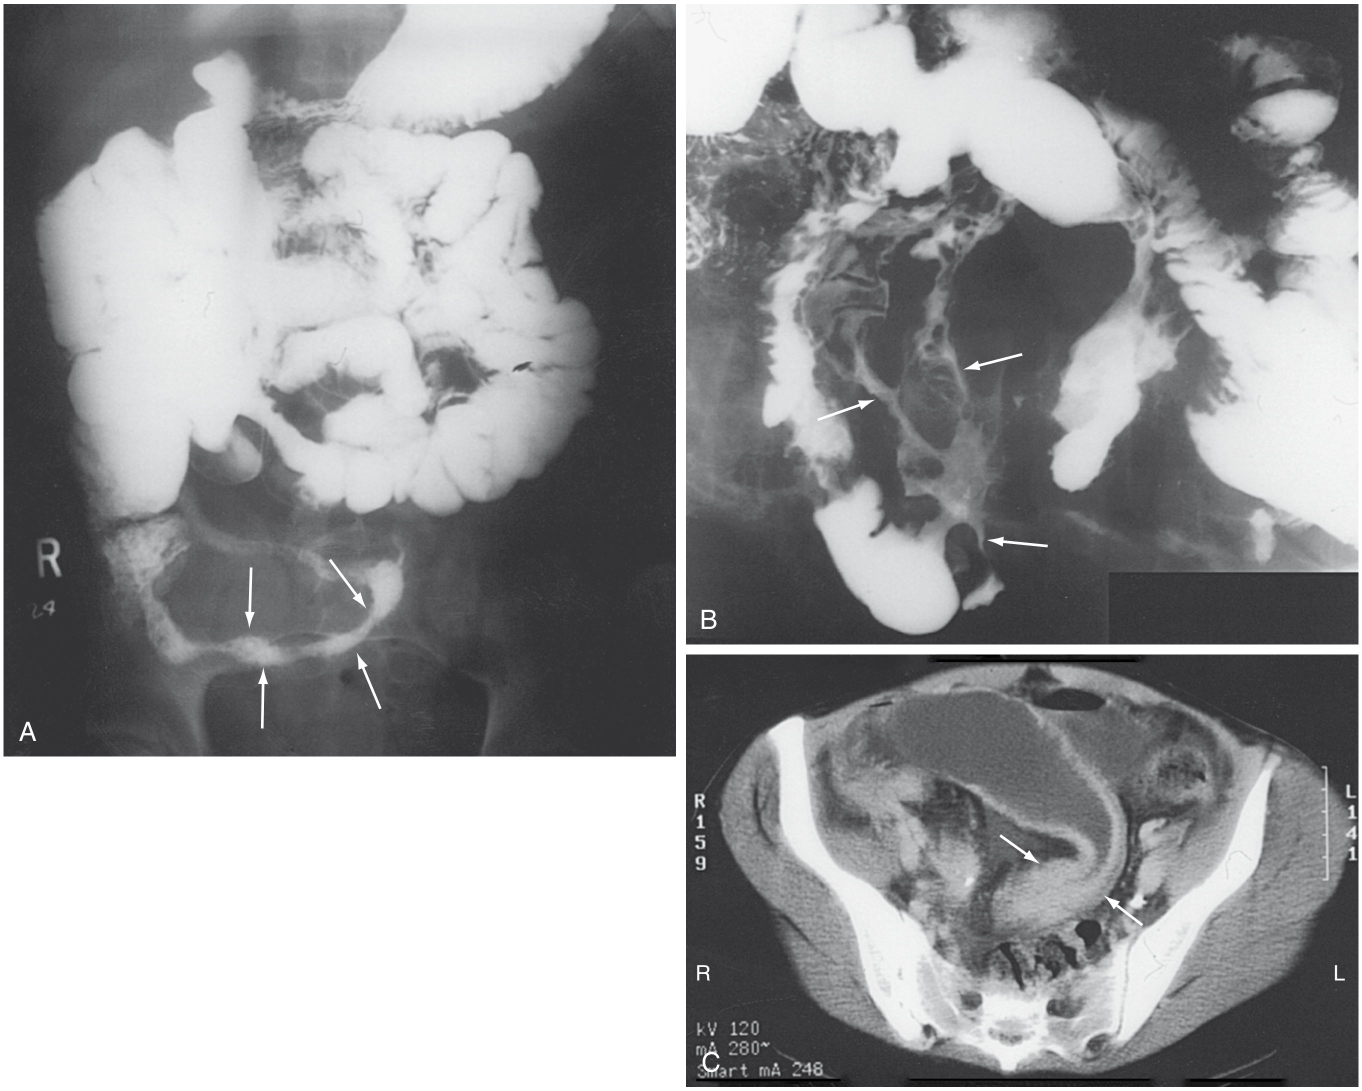

FIGURE 91.8 (A) Small bowel obstruction secondary to Crohn disease. In: Schwartz SI, ed. *Principles of Surgery*. 7th ed. New York: McGraw-Hill; 1999:1233.)

recent development of scoring systems based on ultrasound findings. Being noninvasive, low cost, and accessible makes ultrasound a potentially advantageous tool in the management of these patients. However, its use is new, and validation studies are ongoing.

Endoscopy. Ileocolonoscopy with biopsies of the terminal ileum are the gold standard for the diagnosis of Crohn disease. When the colon is involved, sigmoidoscopy or colonoscopy may reveal characteristic aphthous ulcers with granularity and a normal-appearing surrounding mucosa. Intubation of the ileocecal valve during colonoscopy allows examination and biopsy of the terminal ileum but fails to evaluate other segments of the small intestine. With more advanced and severe disease, the ulcerations involve progressively more of the bowel lumen, and it may be difficult to distinguish Crohn disease from ulcerative colitis. However, the presence of discrete ulcers and cobblestoning as well as the discontinuous segments of involved bowel favor a diagnosis of Crohn disease. Endoscopic advances that allow better evaluation of the small intestine include single-balloon enteroscopy, double-balloon enteroscopy, and spiral enteroscopy; the most well-established technique is double-balloon enteroscopy, which allows increased enteral intubation (240–360 cm) compared with push enteroscopy (90–150 cm) or ileocolonoscopy (50–80 cm). Limitations include specialized examiner skills and equipment, prolonged procedure times, and a 1% risk of complications (e.g., pancreatitis, perforation, or bleeding). After the diagnosis is confirmed, the Crohn's Disease Endoscopic Index of Severity (CDEIS) or the Simple Endoscopic Score for Crohn's Disease (SES-CD) is used to define extent of disease and severity.

Capsule endoscopy was approved by the US Food and Drug Administration (FDA) in 2001 and is helpful in the diagnosis of superficial mucosal abnormalities. The most commonly used criterion for an abnormal finding is the presence of three or more ulcers in the absence of NSAID use. The use of this modality is limited because of concern for capsule retention, defined as the presence of the capsule in the gastrointestinal tract for more than 2 weeks. The risk of retention is higher in patients with Crohn disease, averaging about 3%, but has been reported to be as high as 13%. However, perforation or other major adverse events from retention are rare. Capsule endoscopy has been found to be superior to any other modality in the identification of intestinal ulceration.[19] Severity can be measured using the Capsule Endoscopy Crohn's Disease Activity Index (CECDAI or Niv score). As endoscopic technology advances, studies continue to be developed to further characterize Crohn disease throughout the entirety of the gastrointestinal tract.

Histology

Differential diagnosis. The differential diagnosis of Crohn disease includes specific and nonspecific causes of intestinal inflammation. Bacterial inflammation (such as that caused by *Salmonella* and *Shigella*), intestinal tuberculosis, and protozoan infections (such as amebiasis) may manifest as an ileitis. In the immunocompromised host, rare infections, particularly mycobacterial and cytomegalovirus (CMV) infections, have become more common and may cause ileitis. Acute distal ileitis may be a manifestation of early Crohn disease, but it also may be unrelated, such as when it is caused by a bacteriologic agent (e.g., *Campylobacter, Yersinia*). Patients usually present in a similar fashion to those with acute appendicitis, with a sudden onset of right lower quadrant pain, nausea, vomiting, and fever. These entities normally resolve spontaneously, and when they are noted during surgery, no biopsy or resection should be performed.

In most cases, Crohn disease of the colon can be readily distinguished from ulcerative colitis; however, in 5% to 10% of patients, the delineation between Crohn disease and ulcerative colitis may be difficult, if not impossible, to make (see Table 91.7). Ulcerative colitis almost always involves the rectum most severely, with lessening inflammation from the rectum to the ileocolic area. In contrast, Crohn disease may be worse on the right side of the colon than on the left side, and sometimes the rectum is spared. Ulcerative colitis also demonstrates continuous involvement from rectum to proximal segments, whereas Crohn disease is segmental. Although ulcerative colitis involves the mucosa of the large intestine, it does not extend deep into the wall of the bowel as does Crohn disease. Bleeding is a more common symptom in ulcerative colitis. Perianal involvement and rectovaginal fistulas are unusual in ulcerative colitis but are more common in Crohn disease. Other endoscopic features of Crohn disease are skip lesions, asymmetric involvement of bowel, and the cobblestone appearance that results from ulcerations interspersed with islands of edematous mucosa.

Management

Medical therapy. There is no cure for Crohn disease. Therefore, medical therapies are directed toward inducing and maintaining steroid-free remission as well as preventing acute exacerbations or

TABLE 91.7 Diagnosis of Crohn Colitis Versus Ulcerative Colitis

PARAMETER	CROHN COLITIS	ULCERATIVE COLITIS
Symptoms and Signs		
Diarrhea	Common	Common
Rectal bleeding	Less common	Almost always
Abdominal pain (cramps)	Moderate to severe	Mild to moderate
Palpable mass	At times	No (unless large cancer)
Anal complaints	Frequent (>50%)	Infrequent (<20%)
Radiologic Findings		
Ileal disease	Common	Rare (backwash ileitis)
Nodularity, fuzziness	No	Yes
Distribution	Skip lesions	Rectum extending proximally and continuously
Ulcers	Linear, cobblestone, fissures	Collar-button
Toxic dilation	Rare	Uncommon
Proctoscopic Findings		
Anal fissure, fistula, abscess	Common	Rare
Rectal sparing	Common (50%)	Rare (5%)
Granular mucosa	No	Yes
Ulceration	Linear, deep, scattered	Superficial, universal

complications of the disease. However, it is important to note that endoscopic healing has emerged as the therapeutic goal because of poor association of inflammation with symptoms. Surgery is advocated for neoplastic and preneoplastic lesions, obstructing stenoses, suppurative complications, or medically intractable disease. Narcotic analgesia should be avoided except during the perioperative period because of the potential for tolerance and abuse in the setting of chronic disease. Drugs that have demonstrated efficacy in the induction or maintenance of remission in Crohn disease include aminosalicylates, such as sulfasalazine and mesalamine; corticosteroids; TNF antagonists, such as infliximab, adalimumab, and certolizumab; immunosuppressive agents, such as azathioprine (AZT), 6-mercaptopurine (6-MP), methotrexate (MTX), and tacrolimus (FK-506); antiadhesion molecules such as vedolizumab, etrolizumab, and natalizumab; the IL inhibitor ustekinumab; and antibiotics. The recent increase in the use of immunomodulators and biologic agents has significantly reduced surgery rates. The primary target of medical treatment is reduction of the Crohn's Disease Activity Index (CDAI), which uses eight major clinical factors to evaluate disease severity (Box 91.4). Clinical remission is achieved when CDAI is below 150, and clinical response to therapy occurs with a drop of 100 points.[17] A score between 150 and 220 is considered mild to moderate disease and can be followed by outpatient visits; a score between 220 and 450 is considered moderate to severe disease and occurs after failure with first-line therapy; a score greater than 450 is considered severe fulminant disease with failed medical therapy and complications of obstruction, peritonitis, and abscess. Other innovative therapies such as MadCAM-1 (mucosal addressin cell adhesion molecule 1 inhibitor), tofacitinib (JAK3 pathway inhibitor), mongersen (SMAD7 inhibitor), and ozanimod (S1P1 inhibitor) continue to be investigated in clinical trials with variable results thus far. Upadacitinib, a JAK inhibitor, has demonstrated promising results in two phase III induction trials (U-EXCEL and U-EXCEED) with increased remission rates and endoscopic response in patients with moderate to severe Crohn disease when compared with placebo.[20]

Aminosalicylates. Sulfasalazine (azulfidine) is an aminosalicylate with 5-aminosalicylic acid as the active moiety. Although a clear benefit has been noted in patients with colonic involvement, the effectiveness of sulfasalazine alone in the treatment of small bowel Crohn disease is controversial, and its use in maintenance therapy has fallen out of favor. Mesalamine, which is also an aminosalicylate, provides a slow release of 5-aminosalicylic acid with passage through the small bowel and colon. However, high-dose mesalamine has not been shown to be more effective than placebo at achieving remission and is not typically employed in treating patients with Crohn disease.[11]

Corticosteroids. Steroids are fast acting and effective at inducing remission but are not ideal as maintenance therapy. Given advances in alternative treatment options with improved efficacy in steroid-sparing therapies, the use of steroids is declining. Budesonide, a corticosteroid, has a high first-pass hepatic metabolism, which allows targeted delivery to the intestine while mitigating the systemic effects of steroid therapy. Controlled ileal-release budesonide (9 mg/day) is effective when active disease is confined to the ileum or right colon and has been shown to be more effective than either placebo or mesalamine.[21] Given a relatively good response and its relative safety, budesonide is recommended as the preferred primary treatment over mesalamine for patients with mild to moderately active Crohn disease with localized ileal disease.

An alternative corticosteroid, prednisone, can be beneficial in moderate to severe Crohn disease. Patients with moderate to severe disease should be treated with high-dose (40–60 mg daily) prednisone until resolution of symptoms and resumption of weight gain. Parenteral corticosteroids are indicated for patients with severe disease once the presence of an abscess has been excluded. Steroids should be tapered once the patient experiences clinical improvement. Currently, there are no standards for corticosteroid taper, but doses are generally tapered by 5 to 10 mg/week until 20 mg and then by 2.5 to 5 mg weekly until cessation. Dual-energy x-ray absorptiometry scan, calcium and vitamin D supplementation, and consideration of bisphosphonate therapy are warranted once corticosteroid therapy is initiated to identify baseline bone density and to prevent steroid-induced loss of bone mineral density.[11]

Antibiotics. Antibiotics are useful as an adjunct therapy in the treatment of Crohn disease. Although initially thought to help promote remission, antibiotics were found to be no more effective than placebo for inducing remission and are no longer considered as the primary therapy for induction of remission. Classically, metronidazole and ciprofloxacin are used in the treatment of complications from Crohn disease. Other antibiotics that have been used with varying success include rifaximin, clofazimine, ethambutol, isoniazid, and rifabutin. Antibiotic therapy has a clear role in the septic complications associated with Crohn disease, perianal disease, and fistulizing disease.[21] However, antibiotics are associated with side effects (i.e., *Clostridioides difficile* infection) and should not be used for long-term maintenance or as the primary treatment to induce remission.

Immunosuppressive agents. The immunosuppressive agents AZT, 6-MP, and MTX are effective in maintenance therapy and for the treatment of moderate to severe Crohn disease. AZT and 6-MP are effective for maintaining steroid-induced remission, and weekly IV MTX is effective for both induction and maintenance therapy but is less effective than biologics.[11] Because of the slow onset of action of immunosuppressive agents and to prevent flares, steroids are needed from induction until the transition to immunosuppressive agents is complete. Despite their potential toxicity, these drugs have proved to be relatively safe in patients with Crohn disease; the most common side effects are pancreatitis, hepatitis, fever, and rash. The more disconcerting complications of immunosuppressants include chronic liver disease, bone

BOX 91.4 Crohn Disease Activity Index (CDAI)

Number of liquid or soft stools (each day for 7 days)
Abdominal pain, sum of 7 daily ratings (0 = none, 1 = mild, 2 = moderate, 3 = severe)
General well-being, sum of 7 daily ratings (0 = generally well, 1 = slightly under par, 2 = poor, 3 = very poor, 4 = terrible)
Number of listed complications (arthritis or arthralgia, iritis, uveitis, erythema nodosum or pyoderma gangrenosum, aphthous stomatitis, anal fissure, fistula or abscess, fever greater than 37.8°C [100°F]).
Use of diphenoxylate or loperamide for diarrhea (0 = no, 1 = year)
Abdominal mass (0 = no, 2 = questionable, 5 = definite)
Hematocrit (males >47% or females >42%)
Body weight (1 − weight/standard weight) × 100 (add or subtract according to sign)

marrow suppression, and the potential for malignant transformation. Genetic polymorphisms for thiopurine methyltransferase (TPMT), which is the primary enzyme that metabolizes AZT and 6-MP, have been identified and suggested for use to regulate therapy according to the measurement of their metabolites (6-thioguanine nucleotides). Patients with decreased TPMT activity have a significantly increased risk of fatal bone marrow suppression. Previous studies reported severe myelosuppression in patients who are wild-type or heterozygous carriers for TPMT variant alleles; these findings suggest that TPMT genotype testing may be a safe screening tool to determine which patients may have a genetic predisposition to adverse outcomes. MTX also has side effects of hepatotoxicity, can cause myelosuppression, and should not be used in pregnant females.

Anti–tumor necrosis factor therapy. The introduction of anti-TNF therapy for Crohn disease was considered a breakthrough in medical management. The first anti-TNF agent introduced was infliximab, a chimeric monoclonal antibody to TNF-α. Infliximab is efficacious and safe as a monotherapy in the treatment of moderate to severe Crohn disease and is effective as an induction and maintenance agent. Multiple studies demonstrated that treatment with infliximab results in perineal fistula closure in approximately two-thirds of patients. Although it is highly effective in certain patients with penetrating and extraintestinal disease, not every patient responds to infliximab. Other FDA-approved TNF antagonists include adalimumab (humanized IgG1 monoclonal antibody), which is an effective maintenance agent that can be self-administered, and certolizumab (humanized antibody fragment), which is ideal in pregnant and nursing females, as it is linked to a polyethylene glycol moiety, does not cross the placenta, and is not excreted in breast milk. Safety profiles for these three anti-TNF medications are similar. There is an increased risk for tuberculosis reactivation, invasive fungal and other opportunistic infections, demyelinating central nervous system lesions, activation of latent multiple sclerosis, exacerbation of congestive heart failure, and concerns for increased risk of melanoma. Patients who develop a flare while on anti-TNF agents require measurement of serum drug concentrations and antidrug antibodies (antibodies binding to competitive and noncompetitive sites to inhibit drug function). Measured levels would indicate the need to increase dosage (if low drug concentration and low antibodies), switch to another anti-TNF agent (high antidrug antibodies), or switch to another drug class (normal drug concentration). Because of the potential for immunogenicity of monoclonal antibodies, the combination of an anti-TNF agent and an immunosuppressive provides optimal drug levels and low antidrug antibodies.[11]

Novel therapies. Other therapeutic agents for Crohn disease include leukocyte trafficking inhibitors, IL inhibitors, and antibodies to antiadhesion molecules. These agents are often used if the patient has failed or is unable to tolerate anti-TNF therapy. Natalizumab, a recombinant humanized monoclonal antibody against α_4 integrin, showed effectiveness in the induction and maintenance of remission in patients with active Crohn disease. It was removed from the market after several patients developed progressive multifocal leukoencephalopathy but was later reinstated for refractory Crohn disease and approved for use in 2008. Similarly, vedolizumab is a humanized monoclonal antibody that specifically binds to $\alpha_4\beta_7$ integrin and blocks its interaction with MadCAM-1; this action inhibits the translocation of memory T lymphocytes into inflamed gastrointestinal parenchymal tissues. Vedolizumab can be used for induction of remission, but it has a very slow onset of action. Because MadCAM-1 is preferentially expressed on blood vessels in the gastrointestinal tract, vedolizumab is more gut specific and therefore a more targeted form of immunosuppression.[11] Also, vedolizumab prevents the gastrointestinal mucosal or transmural inflammation without the nonspecific neurologic side effects seen in less selective α_4 integrin inhibitors, such as natalizumab. Ustekinumab is a humanized IgG1 monoclonal antibody that inhibits IL-12/23 through targeting of a shared p40 subunit that has been shown to be effective in severe Crohn disease that is refractory to anti-TNF therapies with similar efficacy.

Nutritional therapy. Nutritional therapy in patients with Crohn disease has been used with varying success. The use of chemically defined elemental diets has been shown in some studies to reduce disease activity, particularly in patients with disease localized to the small bowel, and they can reduce corticosteroid-induced toxicities. Liquid polymeric diets may be as effective as elemental feedings and are more acceptable to patients. With few exceptions, standard elemental diets have not been effective to prevent relapse of Crohn disease. Total parenteral nutrition (TPN) was also useful in patients with active Crohn disease; however, complication rates exceed those for enteral nutrition. There remains interest in investigating different modified diets to improve outcomes in patients with Crohn disease. Although the primary role of nutritional therapy is questionable in patients with inflammatory bowel disease, there is definitely a secondary role for nutritional supplementation to replenish depleted nutrient stores, to allow intestinal protein synthesis and healing, and to prepare patients for surgery.[17]

Smoking cessation. Although the implication of tobacco abuse as a causative factor in the development of Crohn disease has been difficult to prove, smoking clearly affects the disease course. Smoking is associated with the late bimodal onset of disease and has been shown to increase the incidence of relapse, failure of maintenance therapy, and increased need for surgery. It also appears to be associated with the severity of disease in a linear dose-response relationship. Tobacco exposure is an independent predictor of the need for maintenance treatment, specifically biologic therapy. Therefore, smoking cessation therapy is an important component of medical therapy.

Surgical treatment. Although medical management is indicated during acute exacerbations of disease, most patients with chronic Crohn disease will require surgery at some time during the course of their illness. The goals are to preserve bowel length while minimizing postoperative complications and disease recurrence. With the advancements made in the management of patients with Crohn disease, the rate of surgical intervention has decreased. However, approximately 75% of patients will require surgical resection within their lifetime. Indications for surgery include failure of medical treatment, bowel obstruction, perforation, fistula or abscess formation, steroid dependence, dysplasia, or malignancy. Most patients can be treated with elective surgery, especially with the improvement of medical management in the past decade. However, patients with intestinal perforation, peritonitis, excessive bleeding, or toxic megacolon require urgent surgery.[22] Children with Crohn disease and resulting systemic symptoms, such as growth retardation, may benefit from resection. The extraintestinal complications of Crohn disease, although not primary indications for operation, often subside after resection of the involved bowel; exceptions are that problems may continue with ankylosing spondylitis and hepatic complications.

The aim of surgery for Crohn disease has shifted from a radical operation to one that achieves inflammation-free margins with minimal surgery, intended to remove just grossly inflamed tissue or to increase the luminal diameter of the bowel (i.e., dilation or strictureplasty). Even if adjacent areas of bowel are clearly diseased, they should be ignored. Fistulizing disease rarely requires operative intervention unless the fistula involves the bladder, vagina, or skin. A bowel resection with fistulotomy may be needed. Early in the history of surgical therapy for Crohn disease, surgeons tended to perform wider resections with the hope of cure or significant remission. However, recurring wide resections resulted in neither cure nor a greater incidence of remissions and led to short bowel syndrome, a devastating surgical complication. Frozen sections to determine microscopic disease are unreliable and should be performed only when malignant disease is suspected. It must be emphasized that operative treatment of a complication must be limited to that segment of bowel involved with the complication, and no attempt should be made to resect more bowel, even though grossly evident disease may be apparent.

Laparoscopic surgery for patients with Crohn disease is most used today. The advantages of minimally invasive approaches and the advances in this technology have made laparoscopy feasible for the operative treatment of Crohn disease. Studies reveal only a 10% conversion rate of laparoscopic to open for ileocolic resections in Crohn disease. Advantages to laparoscopy include shorter median operative time, earlier return of bowel function, less pain, and shorter hospital stays. Multiple randomized clinical trials verified that laparoscopic surgery is associated with a more rapid recovery of bowel function and shorter hospital stay; importantly, the rate of disease recurrence is similar when compared with open procedures. Randomized controlled trials with long-term follow-up have demonstrated that patients undergoing laparoscopic ileocolonic resection for Crohn disease had improved body image and satisfaction with cosmesis of surgery and less incidence of incisional hernia compared with the open surgery group. Additional options that have shown similar outcomes to laparoscopic intervention include hand-assisted laparoscopic surgery, single-incision laparoscopic surgery, and robot-assisted laparoscopic surgery. Each patient should be carefully evaluated for appropriate operative technique, as not every patient is appropriate for minimally invasive techniques. In general, the rate of open intervention is decreasing as laparoscopy has become favored, even in the treatment of complex Crohn disease.[23]

Another difficult surgical decision important in Crohn disease involves performing a primary anastomosis versus initial ostomy formation with delayed reconstruction. Patients with this condition are often malnourished and receive intensive immunosuppressive therapy or present with an element of intraabdominal sepsis. In general, standard surgical principles should direct this decision. Patients with adequate nutrition and minimal intraabdominal sepsis can safely undergo primary anastomosis at the initial operation, whereas malnourished and septic patients are best served by diversion, if possible. Although caution should be exercised in performing an anastomosis in the setting of high-dose immunosuppression, large series have confirmed that surgery is safe for patients with Crohn disease while they are receiving perioperative infliximab or immunosuppressive therapy. Regarding the anastomotic technique, previous studies suggested that creating a wider anastomosis with a stapled functional end-to-end anastomosis may decrease fecal stasis and subsequent bacterial overgrowth, which are implicated in anastomotic recurrence in Crohn disease. However, a randomized controlled trial comparing side-to-side anastomosis versus end-to-end anastomosis determined that there was no difference in overall complication rates, anastomotic leak rates, or rates of symptomatic recurrence, with only a slight increase in endoscopic recurrence seen in the end-to-end anastomosis group (43% vs. 38%). Additionally, a new antimesenteric, functional, end-to-end, hand-sewn anastomosis (known as *Kono-S anastomosis*) was created to minimize anastomotic restenosis in Crohn disease. This technique was demonstrated to have a significantly lower rate of stenosis and recurrence compared with conventional end-to-end anastomosis. Although further randomized control trials are needed, these findings demonstrate a promising novel surgical approach that may decrease the need for additional biologic therapy.[24]

An evolving consideration in surgical resection is the management of the mesentery of the diseased bowel. Although still under investigation, the mesentery, as a site of inflammatory cells and nerves, is proposed as a source for recurrent and spreading disease. As such, during any resection for diseased bowel, the surgeon should also consider what the appropriate mesenteric resection should be to reduce future disease.[22]

Specific Problems

Acute ileitis (nonstricturing, nonpenetrating). Patients can present with acute abdominal pain localized to the right lower quadrant, signs and symptoms consistent with a diagnosis of acute appendicitis. At exploration, the appendix is found to be normal, but the terminal ileum is edematous and beefy red with a thickened mesentery and enlarged lymph nodes. This condition, known as *acute ileitis,* is a self-limited disease. Acute ileitis may be a manifestation of early Crohn disease but is most often unrelated. Bacteriologic agents such as *Campylobacter* and *Yersinia* may cause acute ileitis. Intestinal resection should not be performed. In the absence of acute inflammatory involvement of the appendix or the cecum, appendectomy has been recommended to eliminate the appendix as a source of abdominal pain in the future. However, this continues to be controversial, and each patient should be evaluated individually for risk from surgery versus leaving the appendix in situ.

Stricturing disease. Intestinal obstruction is the most common indication for surgical therapy in patients with Crohn disease. Obstruction in these patients is often partial, and nonoperative management is initially indicated. The success of nonoperative management can often be predicted on the basis of the chronicity of symptoms at the affected site. In patients for whom it is difficult to determine whether the site of obstruction is caused by an acute exacerbation or a chronically structured segment, stool lactoferrin and calprotectin levels may help identify acute inflammation, whereas certain genetic markers (e.g., *NOD2, TLR4, CX3CR1*) may predict potential success of medical therapy. In the case of a chronically strictured segment, medical therapy is rarely effective. Operative intervention is required for patients with complete obstruction and partial obstruction whose condition does not resolve with nonoperative management. The treatment of choice for intestinal obstruction in patients with Crohn disease is segmental resection of the involved segment with primary anastomosis. This may involve segmental resection and primary anastomosis of a short segment of ileum or an ileocecectomy if both the ileum and cecum are involved (Fig. 91.9A).

In selected patients with obstruction caused by strictures (single or multiple), one option is to perform a strictureplasty that effectively widens the lumen but avoids intestinal resection. Strictureplasty is performed by making a longitudinal incision through the narrowed area of the intestine, followed by closure in a transverse fashion, termed a *Heineke-Mikulicz strictureplasty*

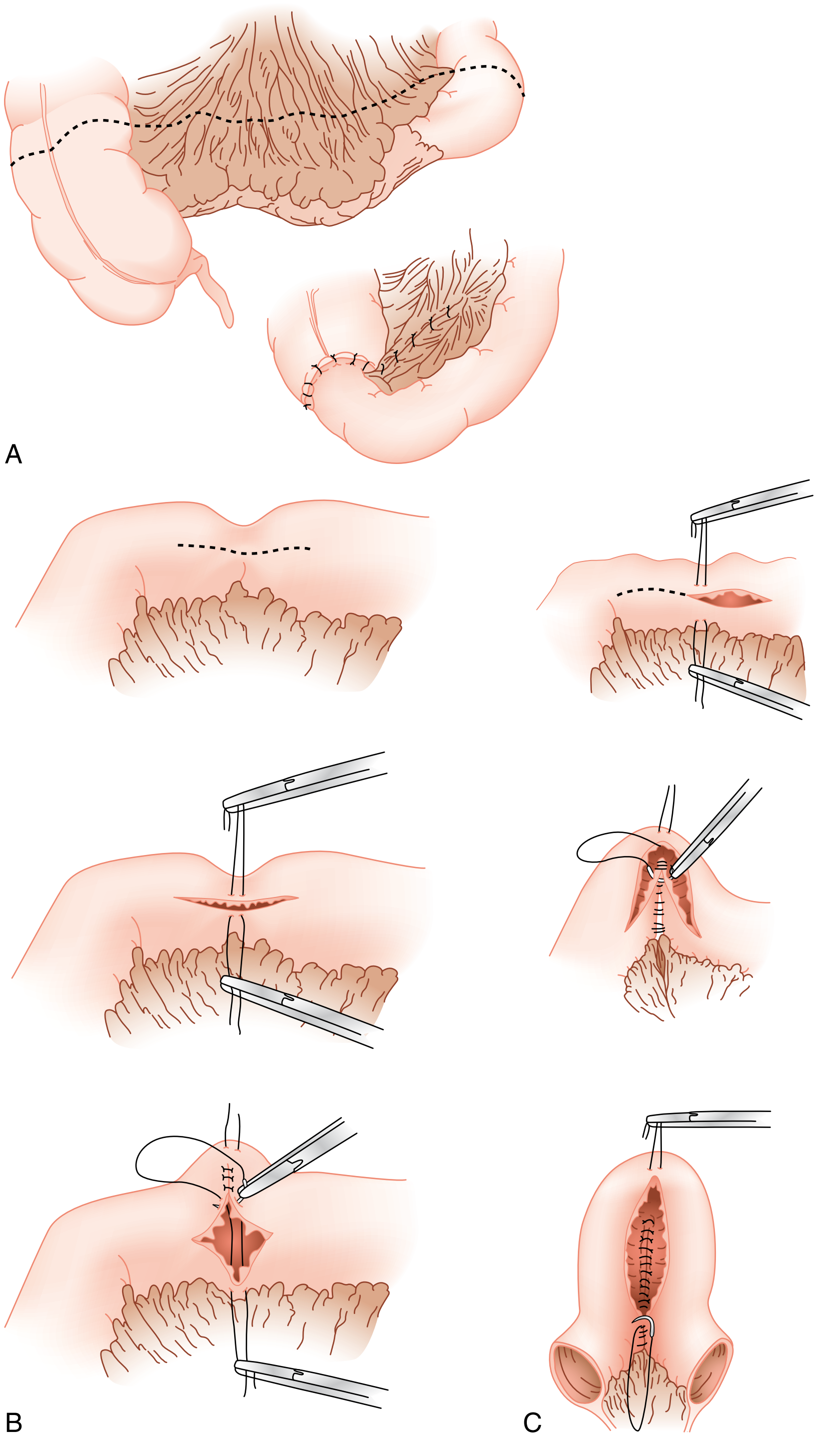

FIGURE 91.9 (A) Ileocecal resection secondary to Crohn disease. Resection of the ileum, ileocecal valve, cecum, and ascending colon for Crohn disease of the ileum. Intestinal continuity is restored by end-to-end anastomosis. (B) Technique of short strictureplasty in the manner of a Heineke-Mikulicz pyloroplasty. (C) For longer diseased segments, strictureplasty may be performed in a manner similar to Finney pyloroplasty. (Adapted from Alexander-Williams J, Haynes IG. Up-to-date management of small-bowel Crohn's disease. In: Mannick JA, ed. *Advances in Surgery*. St. Louis: Mosby; 1987:245-264.)

(see Fig. 91.9B). For longer diseased segments (10–25 cm), a Finney strictureplasty can be performed, which involves folding the diseased segment on itself and creating a common channel of the strictured segment. For longer strictures, the Michelassi strictureplasty can be performed, which involves creating a side-to-side isoperistaltic strictureplasty (see Fig. 91.9C).[25] Strictureplasty is best used in patients with multiple short areas of narrowing present over long segments of intestine, in those who have already had several previous resections of the small intestine, and in patients with chronic fibrous obstruction. This procedure preserves

BOX 91.5 Contraindications to Strictureplasty

- Excessive tension due to rigid and thickened bowel segments
- Perforation of the intestine
- Fistula or abscess formation at the intended strictureplasty site
- Hemorrhagic strictures
- Multiple strictures within a short segment
- Malnutrition or hypoalbuminemia (<2.0 g/dL)
- Suspicion of cancer at the intended strictureplasty site

Adapted from Yamamoto T, Watanabe T. Surgery for luminal Crohn's disease. *World J Gastroenterol.* 2014;20:78-90.

intestine and is associated with complication and recurrence rates comparable to those of resection and anastomosis. Given the concerns for development of carcinoma at chronically strictured segments, full-thickness biopsy with a frozen section of the stricture site has been advocated at the time of surgery to rule out malignant disease before strictureplasty is performed (Box 91.5).

In the past, bypass procedures were commonly used. There are two types of bypass operations: exclusion bypass and simple (continuity) bypass. For certain types of ileocecal disease associated with an abscess or phlegmon densely adherent to the retroperitoneum, the proximal transected end of the ileum is anastomosed to the transverse colon in an end-to-side fashion, with or without construction of a mucous fistula, using the distal transected end of the ileum (exclusion bypass), or an ileotransverse colonic anastomosis is made in a side-to-side fashion (continuity bypass). Currently, bypass with exclusion is most useful for patients with severe gastroduodenal Crohn disease that is not amenable to strictureplasty. Rarely, but remaining a consideration, bypass can be used in older, poor-risk patients; patients who have had several prior resections and cannot afford to lose any more bowel; and those in whom resection would necessitate entering an abscess or endangering a normal structure.

Penetrating disease. Fistula and abscess in patients with Crohn disease are relatively common and usually involve adjacent small bowel, colon, or other surrounding viscera (e.g., bladder). The presence of a radiographically demonstrable enteroenteral fistula with no signs of sepsis or other complications is not in itself an indication for surgery. Furthermore, penetrating disease is particularly sensitive to anticytokine therapy, and a conservative, surgical approach to Crohn disease–related fistula is most appropriate.[26] Enterocutaneous fistulas may develop but are rarely spontaneous and are more likely to follow resection or drainage of intraabdominal abscesses. These fistulas may close spontaneously, and treatment should entail outflow reduction, preventing infection and maximizing nutrition and optimal skin care. If conservative management fails, excision of the fistula tract and primary anastomosis is preferred. Note that preoperative optimization is necessary, as patients with penetrating disease tend to have longer operative times, higher reoperation rates, increased length of stay, and postoperative complications. If the fistula forms between two or more adjacent loops of diseased bowel, the involved segments should be excised. Alternatively, if the fistula involves an adjacent normal organ, such as the bladder or colon, only the segment of the diseased small bowel and fistulous tract should be resected, and the defect in the normal organ should simply be closed. Most patients with ileosigmoid fistulas do not necessarily require resection of the sigmoid because the disease is usually confined to the small bowel. However, if the segment of sigmoid is also found to have Crohn disease, it should be resected along with the segment of diseased small bowel. All patients presenting with more aggressive disease characterized with fistulas and/or abscesses should have treatment tailored and individualized to the patient.

Perforation. Penetrating disease in the form of free perforation into the peritoneal cavity is uncommon in patients with Crohn disease. Typically, penetration manifests with a localized abscess densely adherent to the diseased segment of bowel. Patients with small abscesses (typically less than 3 cm) who are hemodynamically stable and have not been on biologics or have an associated fistula can be treated with antibiotics alone. Abscesses that do not meet these criteria should undergo percutaneous drainage. In fact, early treatment of an abscess is key regardless of percutaneous or surgical drainage in terms of time to resolution. In cases of free perforation, the segment of involved bowel should be resected, and in the presence of minimal contamination, a primary anastomosis can be performed. If generalized peritonitis is present, a safer option may be to create an ostomy until the intraabdominal sepsis is controlled and then have the patient return for restoration of intestinal continuity after a period of 4 to 6 weeks. Abscesses can be treated with percutaneous drainage and antibiotics; however, fistula or uncontrolled sepsis may develop, requiring resection with or without primary anastomosis.

Gastrointestinal bleeding. Although anemia from chronic blood loss is common in patients with Crohn disease, life-threatening gastrointestinal hemorrhage is rare. The incidence of hemorrhage is more common in patients with Crohn disease involving the distal colon rather than the small bowel. As with the other complications, the segment involved should be resected and intestinal continuity restored. In hemodynamically unstable hemorrhage, colectomy with end ileostomy is appropriate. Arteriography may be useful to localize the bleeding before surgery. In cases of bleeding associated with duodenal disease, endoscopic intervention is usually successful. However, in cases of failure, duodenotomy with oversewing of the bleeding ulcerative area is indicated. However, there remains a scarcity of data on the appropriate management of gastroduodenal disease, as medically refractory disease can progress to cancer.[22]

Urologic complications. Genitourinary complications occur in up to one-third of patients with Crohn disease. Such complications include ureteral obstruction and recurrent urinary tract infections (enterovesical fistulas). Ureteral obstruction is usually secondary to ileocolic disease with retroperitoneal inflammatory compression. Surgical treatment of the primary intestinal disease is adequate in most patients. In a few cases of long-standing inflammatory disease, periureteric fibrosis may be present and require ureterolysis with or without ureteral stenting.

Cancer. Patients with long-standing Crohn disease of the small bowel and, in particular, the colon have an increased incidence of cancer. The management of these patients is the same as that for any patient—resection of the cancer with appropriate margins, lymphadenectomy, and perioperative chemotherapy/radiation. Patients with cancer associated with Crohn disease commonly have a worse prognosis than those who do not have Crohn disease, largely because the diagnosis in these patients is often delayed. In addition, a strictureplasty should not be performed if malignant disease is suspected.

Colorectal disease. The same principle applies to patients with Crohn disease limited to the colon as to those with disease to the small bowel; that is, surgical resection should be limited to the main segment involved. Indications for surgery include a lack of response to medical management and complications of Crohn colitis, which include obstruction, hemorrhage, perforation, and toxic megacolon. Depending on the diseased segments, procedures commonly include segmental colectomy with colocolonic anastomosis; total abdominal colectomy with ileorectal anastomosis; total proctocolectomy with ileoanal anastomosis; and in patients with extensive perianal and rectal disease, abdominoperineal resection with end ileostomy. In the case of acute illness, temporizing colectomy with end ileostomy is a consideration. Strictureplasty has limited usefulness in colonic Crohn disease, and concerns of malignant transformation at an area of colonic obstruction should limit its application.

A particularly troubling problem after abdominoperineal resection in patients with Crohn disease is delayed healing of the perineal wound. More than half of perineal wounds are open 6 months after surgery in these patients. Persistent nonhealing wounds require excision with secondary closure. Large cavities or sinuses may be filled by using well-vascularized pedicles of muscle (e.g., gracilis, semimembranosus, rectus abdominis) or omentum or by using an inferior gluteal myocutaneous graft.

Although controversial, continence-preserving operations, such as ileal pouch–anal anastomosis or continent ileostomies (Kock pouch), may be considered in very carefully selected patients with Crohn disease isolated to the colon who undergo thorough counseling about the increased risk of anastomotic failure and wound complication. However, these procedures should never be considered in patients with evidence of terminal ileal or perianal disease, as these patients have a significantly increased rate of recurrence of Crohn disease in the pouch, fistulas to the anastomosis, and peripouch abscesses.

Perianal disease. Diseases involving the perianal region include fissures and fistulas and are common in patients with Crohn disease, particularly those with colonic involvement. The treatment of perianal disease should be nonoperative unless an abscess or complex fistula develops, and even in these cases, surgery should be approached cautiously and limited to addressing the specific problem with minimal tissue loss. Nonsuppurative, chronic fistulization or perianal fissuring is treated with antibiotics, immunosuppressive agents (e.g., AZT or 6-MP), and anti-TNF therapy, which is the most widely supported therapy as it has shown the best results in fistula closure. Additionally, there is some evidence to support the use of cyclosporine, FK-506, or IL-12/23 inhibition treatment for fistula management.[16]

Wide excision of abscesses or fistulas is not indicated, but more conservative interventions, including the liberal placement of drainage catheters and noncutting Setons, are preferable. Definitive fistulotomy is indicated for most patients with superficial, low transsphincteric, and low intersphincteric fistulas, although one must recognize that some degree of anal stenosis may occur as a result of chronic inflammation. High transsphincteric, suprasphincteric, and extrasphincteric fistulas are usually treated with noncutting Setons. Fissures are usually lateral, relatively painless, large, and indolent and often respond to conservative management. Abscesses should be drained, but large excisions of tissue *should not* be performed. Advancement flap closure of perineal fistulas may be required in certain cases. Selective construction of diverting stomas has good results in combination with optimal medical therapy to induce remission of inflammation. Proctectomy is infrequent but required in a subset of patients who have persistent and unremitting disease despite conservative medical and surgical therapy.

Duodenal disease. Crohn disease of the duodenum occurs in less than 5% of patients and occurs most commonly in the duodenal bulb. Operative intervention is uncommon. The primary indication for surgery in these patients is duodenal obstruction that does not respond to medical therapy, with endoscopic balloon dilation and surgery being the mainstays of treatment. Antrectomy with Roux-en-Y bypass and laparoscopic bypass with gastrojejunostomy without resection are surgical options. Strictureplasties for short segments have been performed with success in selected patients and may avoid the marginal ulceration and diarrhea associated with gastrojejunostomy. For disease refractory to medical management, surgical resection should be considered, as the disease can progress to dysplasia and cancer.[22]

Prognosis

Crohn disease is a chronic inflammatory disorder that is not medically or surgically curable; therefore, therapeutic approaches are required to induce and to maintain symptomatic control, to improve quality of life, and to minimize long-term complications. Thanks to improvements in medical management, surgery in these patients is decreasing; however, over half will require at least one operation in their lifetime.[27] Symptomatic recurrence varies from 40% to 80%. Endoscopic recurrence is an effective temporizing procedure; however, eventual recurrence requiring surgical intervention is inevitable. The only clearly modifiable risk factor is smoking cessation. Surgery is generally indicated when the patient fails to respond to medical therapy or develops complications, and multiple studies have shown that patients report significant improvement in quality-of-life scores after surgical intervention. Although postsurgical recurrence is high, algorithms using careful endoscopic surveillance combined with maintenance immunomodulators, anti-TNF antibodies, antiintegrin therapy, and even investigational traditional Chinese medicine all play a role in the prevention of postoperative recurrence of Crohn disease. Although there is currently no cure, advances in medical and surgical therapies have clearly increased quality of life and disease-free progression.

Long-term survival studies suggest that patients with Crohn disease have a death rate approximately two to three times higher than that of the general population. Mortality has been associated with cardiovascular disease, wound complications, sepsis, cancer, thromboembolic complications, and electrolyte disorders.

Typhoid Enteritis

Typhoid fever remains a significant problem in developing countries, most commonly in areas with contaminated water supplies and inadequate waste disposal. Roughly 9 million people worldwide develop typhoid fever, with an estimated 110,000 deaths per year. Children and young adults are most often affected. Improvements in sanitation have decreased the incidence of typhoid fever in industrialized countries. Most cases of typhoid fever in the United States arise in international travelers; however, unrecognized and untreated typhoid fever is a life-threatening illness with significant long-term morbidity.

Typhoid enteritis is an acute systemic infection caused primarily by *Salmonella typhi*. The pathologic events of typhoid fever are initiated in the intestinal tract after oral ingestion of the typhoid bacillus. These organisms penetrate the small bowel mucosa, make their way rapidly to the lymphatics, and then spread systemically. Hyperplasia of the reticuloendothelial system, including lymph nodes, liver, and spleen, is characteristic of typhoid fever. Peyer patches in the small bowel become hyperplastic and may subsequently ulcerate, complicated by hemorrhage or perforation.

The diagnosis of typhoid fever is confirmed by isolating the organism from blood, bone marrow, and stool cultures. In addition, the finding of high titers of agglutinins against O and H antigens (Widal test) was used historically but is nonspecific and is no longer an acceptable clinical method. Assays for the diagnosis of *S. typhi* using PCR analysis are unpredictable and too costly for many endemic areas. Skin biopsies of active lesions, indirect enzyme-linked immunosorbent assay for IgM and IgG antibodies to *S. typhi* polysaccharide, and urine cultures can detect active or prior disease but are not typically used today. Using a combination of tests can achieve sensitivity and specificity as high as 83% and 100%, respectively.

Typhoid fever and uncomplicated typhoid enteritis are treated by antibiotic administration. If a patient presents with clinical symptoms and has been in an endemic area, broad-spectrum empirical antibiotics should be started immediately. Treatment should not be delayed for confirmatory tests because prompt treatment drastically reduces the risk of complications and fatalities. Antibiotic therapy should be narrowed once more information is available. Chloramphenicol was initially the mainstay of treatment in the 1950s, but widespread antibiotic resistance occurred. Currently, the most widely used agents are fluoroquinolones, mainly ciprofloxacin. Alternatively, amoxicillin, trimethoprim-sulfamethoxazole, and third-generation cephalosporins can be used. Vaccination against typhoid has decreased disease burden and is used in endemic areas.

Complications requiring potential surgical intervention include hemorrhage and perforation. The incidence of hemorrhage was reported to be as high as 20%, but with the availability of antibiotics, this figure has decreased. When hemorrhage occurs, transfusion is indicated and usually suffices. Rarely, laparotomy must be performed for uncontrollable, life-threatening hemorrhage. Intestinal perforation through an ulcerated Peyer patch occurs in approximately 2% of cases. Typically, it is a single perforation in the terminal ileum, and simple closure of the perforation is the treatment of choice. Multiple perforations, which occur in about 25% of patients, may require resection with primary anastomosis or exteriorization of the intestinal loop.

Enteritis in the Immunocompromised Host

The acquired immunodeficiency syndrome (AIDS) epidemic, as well as the widespread use of immunosuppressive agents after organ transplantation, has resulted in a number of rare and exotic pathogens infecting the gastrointestinal tract. Almost all patients with AIDS have gastrointestinal symptoms during their illness, the most common of which is diarrhea. A surgeon may be asked to evaluate the immunocompromised patient with abdominal pain, acute abdomen, or gastrointestinal bleeding; a number of protozoal, bacterial, viral, and fungal organisms may be responsible.

Protozoa

Protozoa (e.g., *Cryptosporidium, Isospora,* and *Microsporidium*) are the most frequent class of pathogens causing diarrhea in patients with AIDS. The small bowel is the most common site of infection. Diagnosis may be established by acid-fast staining of the stool or duodenal secretions, and the introduction of specific antigen tests for stool examination has improved diagnostic capabilities. Immunochromatography cards for the rapid detection of protozoal proteins from a small sample of stool are available from several different commercial sources and are more sensitive and specific (>90%) than traditional microscopic examinations. Symptoms are most commonly related to diarrhea, which may be intractable at times. Current treatment regimens in immunocompromised patients have not been entirely effective, but drugs such as prophylactic cotrimoxazole and a highly active antiretroviral therapy appear to elicit a response to human immunodeficiency virus (HIV)–related diarrheal illnesses.

Bacteria

Infections by enteric bacteria are more frequent and more virulent in individuals infected with HIV than in healthy hosts. *Salmonella, Shigella,* and *Campylobacter* are associated with higher rates of bacteremia and antibiotic resistance in the immunocompromised patient. The diagnosis of *Shigella* or *Salmonella* infection may be established by stool cultures. The diagnosis of *Campylobacter* infection is not as easily established because stool cultures are often negative, but PCR techniques evaluating stool and serum have shown promising diagnostic results in patients with negative cultures. These enteric infections are manifested clinically with high fever, abdominal pain, and diarrhea that may be bloody. Abdominal pain may mimic an acute abdomen. Bacteremia and serious infections should be treated by IV administration of antibiotics. Antibiotic resistance has been growing in *Campylobacter* strains, but most commonly can be treated with ciprofloxacin or erythromycin.

Diarrhea caused by *C. difficile* is more common in patients with AIDS because of the increased antibiotic use in this population compared with healthy hosts. Diagnosis is by standard assays of stool for *C. difficile* enterotoxin. Treatment with metronidazole or vancomycin is usually effective.

Mycobacteria

Mycobacterial infection is a frequent cause of intestinal disease in immunocompromised hosts. This can be secondary to *Mycobacterium tuberculosis* or *Mycobacterium avium complex* (MAC), which is an atypical mycobacterium related to the type that causes cervical adenitis (scrofula). The usual route of infection is by swallowed organisms that directly penetrate the intestinal mucosa. The luminal gastrointestinal tract is affected by MAC infection, with massive thickening of the proximal small intestine often noted. Clinically, patients with MAC present with diarrhea, fever, anorexia, and progressive wasting.

The most frequent site of intestinal involvement of *M. tuberculosis* is the distal ileum and cecum, with approximately 90% of patients demonstrating disease at this site. The gross appearance can be ulcerative, hypertrophic, or ulcerohypertrophic. The bowel wall appears thickened, and an inflammatory mass often surrounds the ileocecal region. Acute inflammation is apparent, as are strictures and even fistula formation. The serosal surface is normally covered with multiple tubercles, and mesenteric lymph nodes are frequently enlarged and thickened; on sectioning, caseous necrosis is noted. The mucosa is hyperemic, edematous, and, in some cases, ulcerated. On histologic evaluation, the distinguishing lesion is a granuloma, with caseating granulomas found most commonly in the lymph nodes. Most patients complain of chronic abdominal pain that may be nonspecific, weight loss, fever, and diarrhea.

The diagnosis of mycobacterial infection is made by identification of the organism in tissue by direct visualization with an acid-fast stain, culture of the excised tissue, or PCR assay. Radiographic examinations usually reveal a thickened mucosa with distorted mucosal folds and ulcerations. CT may be useful and shows a thickening of the ileocecal valve and cecum.

The treatment of *M. tuberculosis* is similar in the immunocompromised or nonimmunocompromised host. The organism is usually responsive to multidrug antimicrobial therapy. The therapy for MAC infection is evolving; drugs that have been successfully used in vivo and in vitro include amikacin, ciprofloxacin, cycloserine, and ethionamide. Clarithromycin has also been successfully used in combination with other agents. Surgical intervention may be required for intestinal tuberculosis, particularly *M. tuberculosis*. Obstruction and fistula formation are the leading indications for surgery; however, with current treatment, most fistulas now respond to medical management. Surgery may be necessary for ulcerative complications when free perforation, perforation with abscess, or massive hemorrhage occurs. The treatment is usually resection with anastomosis.

Viruses

CMV is the most common viral cause of diarrhea in immunocompromised patients. Clinical manifestations include intermittent diarrhea accompanied by fever, weight loss, and abdominal pain. The manifestations of enteric CMV infection result from mucosal ischemic ulcerations, which account for the high rate of perforations noted with CMV. As a result of the diffuse ulcerating involvement of the intestine, patients may present with abdominal pain, peritonitis, or hematochezia. Diagnosis of CMV is made by demonstrating viral inclusions. The most characteristic form is an intranuclear inclusion, which is often surrounded by a halo, producing a so-called *owl's eye appearance.* There may also be cytoplasmic inclusions. Cultures for CMV are usually positive when inclusion bodies are present, but these cultures are less sensitive and specific than histopathologic identification. Once CMV infection is diagnosed, treatment is usually effective with ganciclovir. An alternative to ganciclovir is foscarnet, a pyrophosphate analogue that inhibits viral replication. Infections with other less common viruses, including adenovirus, rotavirus, and novel enteric viruses such as astrovirus and picornavirus, have been reported.

Fungi

Fungal infections of the intestinal tract have been recognized in patients with AIDS. Gastrointestinal histoplasmosis occurs in the setting of systemic infection, often in association with pulmonary and hepatic disease. Diagnosis is made by fungal smear and culture of infected tissue or blood. The infection is most commonly treated by the administration of amphotericin B followed by itraconazole. Coccidioidomycosis of the intestinal tract is rare and, like histoplasmosis, occurs in the context of systemic infection.

NEOPLASMS

General Considerations

Despite composing 75% of the length and 90% of the surface area of the gastrointestinal tract, the small bowel develops relatively few primary neoplasms and less than 3% of gastrointestinal malignant neoplasms. Small bowel cancers encompass around 40 different disease entities, with an ever-increasing incidence comprising both malignant (i.e., adenocarcinoma) and benign (i.e., stromal tumors, adenomas) entities. In general, most benign lesions go undiagnosed in a lifetime and are only detected at autopsy, whereas most symptomatic lesions are of a malignant origin. Distribution, epidemiologic risk factors, and survival all depend on the type of small bowel cancer.[28]

The risk factors and associated conditions related to small bowel neoplasms have been described. These include patients with familial adenomatous polyposis (FAP), juvenile polyposis syndrome, hereditary nonpolyposis colorectal cancer, Peutz-Jeghers syndrome, Crohn disease, gluten-sensitive enteropathy (i.e., celiac sprue), prior peptic ulcer disease, cystic fibrosis, and biliary diversion (i.e., previous cholecystectomy). Controversial factors that may contribute to small bowel neoplasms include smoking, heavy alcohol consumption (>80 g/day of ethanol), and consumption of red meat or salt-cured foods.

Although the molecular genetics of small bowel neoplasms have not been entirely characterized, similar to colorectal cancers, mutations of the *KRAS* gene are commonly identified. Allelic losses, particularly involving tumor suppressor genes at chromosome locations 5q (*APC* gene), 17q (*p53* gene), and 18q (*DCC* [deleted in colon cancer] and *DPC4 [SMAD4]* genes), have been noted in some small bowel cancers. Approximately 15% of small intestinal adenocarcinomas have an inactivated DNA mismatch gene repair and display a high level of microsatellite instability (MSI-H). Interestingly, MSI-H is typical of small bowel carcinomas associated with celiac disease, which is potentially linked by an aberrant CpG island methylation. Other genetic mutations of clinical interest include human epidermal growth factor receptor 2 (HER2) and programmed cell death ligand 1 (PD-L1). Microarray analyses demonstrate a high percentage of small bowel tumors expressing both epidermal growth factor receptor and vascular endothelial growth factor (VEGF), which may contribute to carcinogenesis.

Clinical Manifestations

Symptoms associated with small bowel neoplasms are often vague and nonspecific and may include dyspepsia, anorexia, malaise, and dull abdominal pain, often intermittent and colicky. These symptoms may be present for months or years before diagnosis. Most patients with benign neoplasms remain asymptomatic, and the neoplasms are only discovered at autopsy or as incidental findings at laparotomy or upper gastrointestinal radiologic studies. Of the remainder, pain, obstruction, and bleeding are the most frequent complaints. Usually, obstruction is the result of intussusception, and benign, small tumors are the most common cause of this condition in adults. Bleeding is usually occult; hematochezia or hematemesis may occur, although life-threatening hemorrhage is uncommon.

Diagnosis

Because of the insidious nature of many small bowel neoplasms, a high index of suspicion must be present for these neoplasms to be diagnosed. In most series, a correct preoperative diagnosis is made in only 50% of symptomatic patients. Plain films may show dilated loops of small bowel suspicious for an obstruction; however, for the most part, plain films are not helpful in making a diagnosis of small bowel neoplasms. An upper gastrointestinal tract series with small bowel follow-through can sometimes yield an accurate diagnosis with malignant neoplasms of the small intestine but is not as accurate or specific as more advanced imaging modalities. Small bowel capsule endoscopy has a negative predictive value of 90%, but it can fail to detect more proximal tumors. Ultrasonography has not proved effective for preoperative diagnosis of small bowel neoplasms. CT of the abdomen can prove particularly useful in detecting extraluminal tumors, such as malignant gastrointestinal stromal tumors (GISTs), and can provide helpful information about the staging of malignant cancers

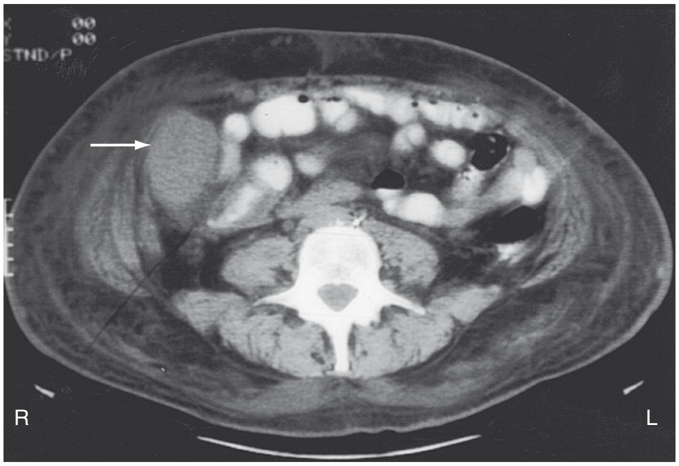

FIGURE 91.10 Small bowel neoplasm. CT scan of abdomen demonstrates a small bowel neoplasm *(arrow)*. (Courtesy Dr. Melvyn H. Schreiber, The University of Texas Medical Branch, Galveston, TX.)

(Fig. 91.10). CTE appears to be a more sensitive technique, with sensitivity of 90% and positive predictive value of 98%, whereas MRE has a sensitivity and specificity of 98% and 97%, respectively.

Flexible endoscopy may be useful, particularly in diagnosing duodenal lesions, and the colonoscope can be advanced into the terminal ileum for visualization and biopsy of ileal neoplasms. Push enteroscopy has not been used routinely to evaluate lesions in the small bowel because this test may take up to 8 hours to perform and may not visualize the entire small bowel. Double-balloon enteroscopy can be a helpful adjunct; however, it should be reserved for cases in which biopsy or preoperative tattoo is required, as it carries a risk of perforation, and for cases where less invasive and more accurate diagnostic tools are unavailable. Angiography is of value in diagnosing and localizing tumors of vascular origin. Despite these sophisticated imaging and diagnostic modalities, diagnosis of a small bowel tumor is often achieved only at the time of surgical exploration.

Benign Neoplasms

The most common benign neoplasms include benign stromal tumors, adenomas, and lipomas. In general, when a benign tumor is identified at operation, resection is indicated because symptoms are likely to develop over time. At operation, a thorough search of the remainder of the small bowel is warranted because multiple tumors are not uncommon.

Stromal Tumors

GISTs are most prevalent in the stomach (60%) and jejunum and ileum (30%) and rarely in duodenum (5%). Stromal tumors arise from the interstitial cell of Cajal, an intestinal pacemaker cell of mesodermal descent. The median age of diagnosis is 65 years of age, with slight male predominance. GISTs can be very large, with a median size of 6 cm at diagnosis; some GISTs can even be larger than 20 cm. With the advances in noninvasive imaging technology, many GISTs are being identified earlier, when they are small and asymptomatic. GISTs can be malignant tumors, and nearly 20% of patients are found to have metastatic disease, most commonly in the liver. Symptoms of GIST include abdominal pain, fullness, bowel obstruction, or tumor hemorrhage resulting in anemia, melena, or hematemesis. The workup of GIST is often initiated with a CT scan. MRI may provide more information for tumors in the rectum, duodenum, and liver metastases. After identification on imaging, CT-guided or endoscopic core-needle biopsy can be used to obtain tissue. Tissue samples undergo immunohistochemical staining for KIT, which is positive in 95% of GISTs. DOG-1 (anoctamin-1) is positive in approximately 88% of GISTs.[29] More than 95% of stromal tumors express CD117, the KIT proto-oncogene protein that is a transmembrane receptor for the stem cell growth factor, and 70% to 90% express CD34, the human progenitor cell antigen. These tumors infrequently stain positive for actin (20%–30%), S100 (2%–4%), and desmin (2%–4%). In gross appearance, stromal tumors are firm, gray-white lesions with a whorled appearance noted on cut surface; microscopic examination demonstrates well-differentiated smooth muscle cells. These tumors may grow intramurally and cause obstruction. Alternatively, the tumors demonstrate intramural and extramural growth, sometimes achieving considerable size and eventually outgrowing their blood supply, resulting in bleeding manifestations.

Surgical resection is necessary for appropriate treatment. GIST malignancy risk and prognosis are stratified based on the number of mitoses per high-power field (hpf) and tumor size. The mitotic index is classified as low (<5 mitoses/50 hpf) or high (>5 mitoses/50 hpf). Although benign tumors generally show a low mitotic index (<5 mitoses/50 hpf), the size of the tumor also must be considered. Tumors larger than 5 cm, regardless of mitotic index, have higher rates of metastasis and recurrence, whereas those with a high mitotic index have a higher risk of metastasis and recurrence regardless of size. Higher-risk GIST lesions may require adjuvant therapy after resection.

Adenomas

Adenomas account for approximately 15% of all benign small bowel tumors and are of three primary types: tubular adenomas, villous adenomas, and Brunner gland adenomas. The majority of adenomas are found in the duodenum near the ampulla of Vater. Most of these lesions are asymptomatic; most occur singly and are found incidentally at autopsy. When symptoms do occur, they are most commonly bleeding and obstruction. Both true and villous adenomas have malignant potential, but villous adenomas have a particular propensity for malignant degeneration and may be relatively large (>3 cm) in diameter.[30] Treatment is determined by location and adenoma type. The majority are able to be removed endoscopically, with piecemeal resection emerging as a viable option. If endoscopic resection is not possible, segmental resection is indicated. Endoscopic resection is heavily favored for duodenal lesions given the potential morbidity (about 40%) associated with duodenal resection by pancreaticoduodenectomy or pancreas-preserving duodenectomy. However, invasive changes or a recurrence after polypectomy necessitates a more definitive approach (e.g., pancreaticoduodenectomy). Endoscopic ultrasound is a useful modality in the preintervention evaluation and may help guide in therapeutic planning, particularly if there are malignant concerns. Duodenal adenomas are associated with colonic polyps, and colonoscopy is necessary for evaluation after detection of a duodenal adenoma.

Familial adenomas typically occur in the presence of FAP syndrome and require a different algorithm. Extracolonic manifestations of FAP have significant consequences. Numerous studies have shown that adenomas in the duodenum can be found in 50% to 90% of cases, and increasing age was identified as an independent risk factor for adenoma development. Although these neoplasms grow slowly, patients with FAP carry a 5% lifetime risk for development of duodenal adenocarcinoma, which represents the leading cause of cancer-related mortality in these patients; therefore, routine lifelong surveillance is a priority. To direct surveillance and treatment, patients are classified by the Spigelman classification (Table 91.8). Screening endoscopy with a forward- and side-viewing endoscope is performed at regular intervals with biopsy of all suspicious, villous, or large (>3 cm) adenomas. The frequency of endoscopic screening ranges from 1 to 5 years, depending on the Spigelman classification (Box 91.6). Random sampling of the duodenum was previously recommended, but now duodenal/ampullary surveillance with lesion management is based on endoscopic findings; however, different guidelines have different recommendations, with optimal surveillance still under investigation.[31] Endoscopic mucosal resection and cold snaring are typically used to remove polyps, with surgical polypectomy as a valid alternative should the lesions not be amenable to endoscopic intervention. Ablative therapy in the form of argon beam coagulation or photodynamic therapy has been attempted for these patients but is not widely used because of suboptimal results. The presence of high-grade dysplasia, invasive cancer, or a Spigelman stage IV classification should be considered for pancreaticoduodenectomy or pancreas-preserving duodenectomy. Adenomas of the remaining small bowel also occur more frequently in patients with FAP but are not as prevalent as duodenal disease in this population of patients.

Brunner gland adenomas represent benign hyperplastic lesions arising from the Brunner glands of the proximal duodenum. These adenomas may produce symptoms mimicking those of peptic ulcer disease. Diagnosis can usually be accomplished by endoscopy and biopsy, and symptomatic lesions in an accessible region can be resected by simple excision, preferably endoscopic, with surgery reserved for those not amenable to endoscopic resection. There is no malignant potential for Brunner gland adenomas, and a radical resection should not be used.

TABLE 91.8 Spigelman Classification for Duodenal Adenomatosis

	POINTS		
PARAMETER	1	2	3
No. of polyps	1–4	5–20	>20
Polyp size (mm)	1–4	5–10	>10
Histology	Tubular	Tubulovillous	Villous
Degree of dysplasia	Mild	Moderate	Severe

Stage 0, 0 points; stage I, 1–4 points; stage II, 5–6 points; stage III, 7–8 points; stage IV, 9–12 points.

Lipomas

Lipomas are most common in the ileum and manifest as single intramural lesions located in the submucosa. They usually occur in the sixth and seventh decades of life and are more frequent in males. Less than half of these tumors are symptomatic and are often found incidentally. They can grow to be large and manifest as obstruction and bleeding from superficial ulcerations. The treatment of choice for symptomatic lesions is excision. Lipomas do not have malignant potential and, therefore, if found incidentally, should be removed only if the resection is simple.

Peutz-Jeghers Syndrome

Hamartomas of the small bowel occur as part of Peutz-Jeghers syndrome, an inherited syndrome of mucocutaneous melanotic pigmentation and gastrointestinal polyps. The pattern of inheritance is autosomal dominant, with a high degree of penetrance. The classic pigmented lesions are small, 1 to 5 mm, as brown or black spots located in the circumoral region of the face, buccal mucosa, forearms, palms, soles, digits, and perianal area. Hamartomas are most commonly found in the jejunum and ileum. However, 50% of patients may also have rectal and colonic lesions, and 25% of patients have gastric lesions. The most common symptom is recurrent colicky abdominal pain, usually the result of intermittent intussusception. Lower abdominal pain associated with a palpable mass has been reported in one-third of patients. Hemorrhage as a result of autoamputation of the polyps occurs, but infrequently, and is most commonly manifested by anemia. Acute life-threatening hemorrhage is uncommon but may occur. Although once considered a purely benign disease, adenomatous changes have been reported in 3% to 6% of hamartomas. Extracolonic cancers are common, occurring in 50% to 90% of patients (small intestine, stomach, pancreas, ovary, lung, uterus, and breast). The most frequent site for cancer is the colon and rectum. The treatment for complications of Peutz-Jeghers syndrome is directed at bowel obstruction or persistent gastrointestinal bleeding. Resection should be limited to the segment of bowel that is producing complications. Because of the widespread nature of intestinal involvement, cure is not possible; therefore, extensive resection is not indicated.

Hemangiomas

Hemangiomas are developmental malformations consisting of submucosal proliferation of blood vessels. They can occur at any level of the gastrointestinal tract; the jejunum is the most commonly affected small bowel segment. Hemangiomas account for 3% to 4% of all benign tumors of the small bowel and are multifocal in 60% of patients. In addition, hemangiomas of the small bowel may occur as part of an inherited disorder known as Osler-Weber-Rendu disease. Hemangiomas may also occur in the lung, liver, and mucous membranes. Patients with Turner syndrome are likely also to have cavernous hemangiomas of the intestine. The most common symptom of small bowel hemangiomas is intestinal bleeding. Angiography and technetium-99m (Tc-99m) red blood cell scanning are the most useful diagnostic studies. If a hemangioma is localized preoperatively, resection of the involved intestinal segment is warranted. Intraoperative transillumination and palpation may help to identify a nonlocalized hemangioma.

Malignant Neoplasms

Population-based analyses have shown that the incidence of malignant neoplasms of the small intestine have increased steadily during the past three decades. A large retrospective study evaluating the Surveillance, Epidemiology, and End Results (SEER) and Medicare database from 1976 to 2016 showed that small bowel carcinoma incidence has more than doubled.[32] This increase has mirrored the increase in diagnosis of small bowel neuroendocrine neoplasms (NENs), which have increased nearly fourfold (3.7–14.6 cases per million population) during the past four decades, whereas changes in the frequency of adenocarcinomas, stromal tumors, and lymphomas are less pronounced. Some theorize that the increase in detection is the result of advancements and increased use of cross-sectional imaging subsequently leading to increased detection of tumors that may have previously gone undiagnosed. Although the incidence of small bowel malignancies has increased, mortality rates have remained relatively stable, particularly for adenocarcinoma and neuroendocrine tumors (NETs).

In contrast to benign lesions, malignant neoplasms almost always produce symptoms, the most common of which are pain and weight loss. Obstruction develops in 15% to 35% of patients and, unlike the intussusception produced by benign lesions, is usually the result of tumor infiltration and adhesions. Diarrhea with tenesmus and passage of large amounts of mucus may occur. Gastrointestinal bleeding, manifested by anemia and guaiac-positive stools or occasionally by melena or hematochezia, occurs to varying degrees with malignant lesions and is more common with GISTs. A palpable mass may be felt in 10% to 20% of patients, and perforations develop in approximately 10%, usually secondary to lymphomas and sarcomas. Although presentation may be similar, each tumor type has a distinct biology that dictates management and prognosis.

Neuroendocrine Neoplasms

Intestinal NENs arise from enterochromaffin cells (Kulchitsky cells), which are considered neural crest cells situated at the base of the crypts of Lieberkühn. These cells are also known as *argentaffin cells* because of their staining by silver compounds. These tumors were first described by Lubarsch in 1888; in 1907, Oberndorfer coined the term *karzinoide* to indicate the carcinoma-like appearance and the presumed lack of malignant potential. However, the term *carcinoid* has become a misnomer, as all NENs have malignant potential. These tumors have been reported in a number of organs, including lungs, bronchi, and the gastrointestinal tract. Most patients with small bowel NENs are in their seventh decade of life, with a median age for gastroenteric NEN of 63 years. The classification of NENs is based predominately on tumor grade and differentiation. NENs are divided into NETs and neuroendocrine carcinomas (NECs). NETs may be benign or of the well-differentiated malignant type and are further subdivided into three groups—low-grade (grade 1, G1), intermediate-grade (grade 2, G2), or high-grade (grade 3, G3) tumors—based on the appearance, mitotic rates, behavior (invasion of other organs, angioinvasion), and Ki-67 proliferative index. On the other hand, NECs are all G3, poorly differentiated malignant tumors. The distinction between a G3 well-differentiated NET and a G3 poorly differentiated NEC can be difficult and may require additional pathologic confirmation or immunohistochemical staining.[33]

NENs are also categorized based on the embryologic site of origin and secretory product. These tumors may derive from the foregut (respiratory tract, thymus), midgut (jejunum, ileum and right colon, stomach, proximal duodenum), and hindgut (distal colon, rectum). Foregut NENs characteristically produce low levels of serotonin (5-hydroxytryptamine) but may secrete 5-hydroxytryptophan or adrenocorticotropic hormone. Midgut NENs are characterized by having high serotonin production. Hindgut NENs rarely produce serotonin but may produce other hormones, such as somatostatin and peptide YY. In adults, the gastrointestinal tract is one of the most common sites for NENs. In the small intestine, NENs are most frequently found within the last 2 feet of the ileum, but many patients have multifocal disease. NENs have a variable malignant potential and are composed of multipotential cells with the ability to secrete numerous humoral agents, the most prominent of which are serotonin and substance P (Table 91.9). In addition to these substances, NENs have been found to secrete corticotropin, histamine, dopamine, neurotensin, prostaglandins, kinins, gastrin, somatostatin, pancreatic polypeptide, calcitonin, and neuron-specific enolase.

The primary importance of NENs is the malignant potential of the tumors themselves. Additionally, carcinoid syndrome, secondary to serotonin or tachykinin production, is characterized by episodic attacks of cutaneous flushing, bronchospasm, diarrhea, and vasomotor collapse. Because of the liver's ability to metabolize these analytes, most patients who present with carcinoid syndrome have hepatic metastases, where the substances are secreted directly into the systemic vasculature, bypassing hepatic metabolism. Similarly, primary tumors that secrete directly into the venous system, bypassing the portal system (e.g., ovary, lung), give rise to carcinoid syndrome without metastasis.

Pathology. About 70% to 80% of NETs are asymptomatic and found incidentally at the time of surgery.[33] The malignant potential (ability to metastasize) is related to location, size, depth of invasion, and growth pattern. Only approximately 9% of appendiceal NENs metastasize, but about 80% to 90% of small bowel NENs are associated with liver metastasis. Similar to other malignancies, larger size is associated with a higher likelihood of metastatic disease.

In gross appearance, these tumors are small, firm, submucosal nodules that are usually yellow on the cut surface (see Fig. 91.11A).

TABLE 91.9 Secretory Products of Neuroendocrine Tumors[a]

AMINES	TACHYKININS	PEPTIDES	OTHER
5-HT	Kallikrein	Pancreatic polypeptide (40%)	Prostaglandins
5-HIAA (88%)	Substance P (32%)	Chromogranins (100%)	
5-HTP	Neuropeptide K (67%)	Neurotensin (19%)	
Histamine		HCG-α (28%)	
Dopamine		HCG-β	
		Motilin (14%)	

[a] Values in parentheses represent percentage frequency.

HCG, Human chorionic gonadotropin; *5-HIAA*, 5-hydroxyindoleacetic acid; *5-HT*, 5-hydroxytryptamine; *5-HTP*, 5-hydroxytryptophan.

Compiled with help of Zandee WT, Kamp K, van Adrichem RC, et al. Effect of hormone secretory syndromes on neuroendocrine tumor prognosis. *Endocr Relat Cancer*. 2017;24(7):R261-R274.

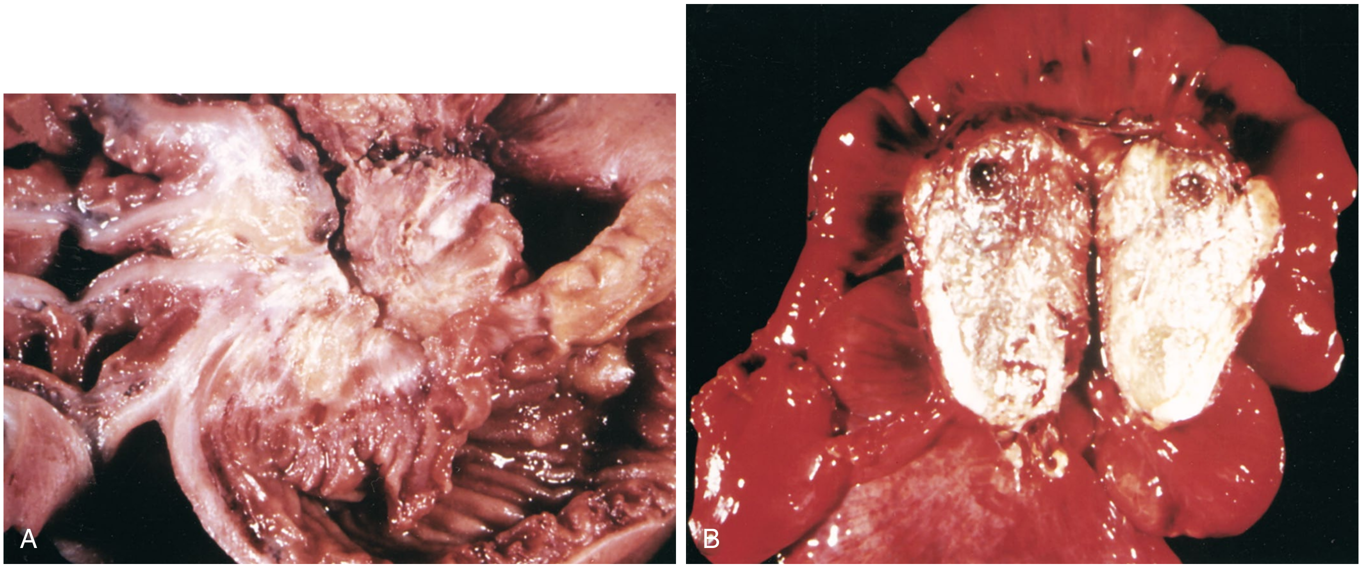

FIGURE 91.11 Gross pathologic characteristics of neuroendocrine tumor (NET). (A) NET of the distal ileum demonstrates the intense desmoplastic reaction and fibrosis of the bowel wall. (B) Mesenteric metastases from a NET of the small bowel. (Adapted from Evers BM, Townsend CM Jr, Thompson JC. Small intestine. In: Schwartz SI, ed. *Principles of Surgery*. 7th ed. New York: McGraw-Hill; 1999:1245.)

They may be as subtle as a small whitish plaque seen on the antimesenteric border of the small intestine (see Fig. 91.11B). Typically, they are associated with a larger mesenteric mass caused by nodal disease and desmoplastic invasion of the mesentery, which is often mistaken for the primary tumor. They tend to grow very slowly, but after invasion of the serosa, the intense desmoplastic reaction produces mesenteric fibrosis, intestinal kinking, and intermittent obstruction. Small bowel NENs are multicentric in 20% to 30% of patients. This tendency toward multicentricity exceeds that of any other malignant neoplasm of the gastrointestinal tract. Another unusual observation is the frequent coexistence of a second primary malignant neoplasm of a different histologic type. This is usually a synchronous adenocarcinoma (most commonly in the large intestine) that can occur in 10% to 20% of patients with NENs. Multiple endocrine neoplasia type 1 is associated with NENs in approximately 10% of cases.

Clinical manifestations. In the absence of carcinoid syndrome, symptoms of patients with NENs of the small bowel are similar to those of patients with small bowel tumors of other histologic types. The most common symptom is abdominal pain, which is variably associated with partial or complete small intestinal obstruction. Obstructive symptoms can be caused by intussusception but usually occur secondary to a local desmoplastic reaction, apparently produced by humoral agents elaborated by the tumor. Diarrhea and weight loss may also occur. The diarrhea is a result of a partial bowel obstruction rather than the secretory diarrhea noted in patients with malignant carcinoid syndrome. As mesenteric and nodal extension progresses, local venous engorgement and, ultimately, ischemia of the affected segment of intestine contribute to most symptoms and complications related to the tumor.

Malignant Carcinoid Syndrome

Malignant carcinoid syndrome is a relatively rare disease, occurring in less than 10% of patients with NENs. The syndrome is usually associated with NENs of the gastrointestinal tract, particularly from the small bowel, but NENs in other locations, such as the bronchus, pancreas, ovary, and testes, have also been described in association with the syndrome. Because of the first-pass metabolism of the vasoactive peptides responsible for carcinoid syndrome, hepatic metastasis or extraabdominal disease is necessary to elicit the syndrome. The classic description of carcinoid syndrome includes vasomotor, cardiac, and gastrointestinal manifestations. A number of humoral factors are produced by NENs, but those considered to contribute to carcinoid syndrome include serotonin, 5-hydroxytryptophan (a precursor of serotonin synthesis), histamine, dopamine, tachykinin, kallikrein, substance P, prostaglandin, and neuropeptide K. Most patients who exhibit malignant carcinoid syndrome have massive hepatic replacement by metastatic disease. However, tumors that bypass the liver, specifically ovarian and retroperitoneal NETs, may produce the syndrome in the absence of liver metastasis.

Common symptoms and signs include cutaneous flushing (80%); diarrhea (76%); hepatomegaly (71%); cardiac lesions, most commonly right-sided heart valvular disease (41%–70%); and asthma (25%). Cutaneous flushing in carcinoid syndrome may be of four varieties:

1. Diffuse erythematous, which is short-lived and normally affects the face, neck, and upper chest
2. Violaceous, which is similar to a diffuse erythematous flush except that the attacks may be longer and patients may develop a permanent cyanotic flush, with watery eyes and injected conjunctivae
3. Prolonged flushes, which may last up to 2 or 3 days and involve the entire body and may be associated with profuse lacrimation, hypotension, and facial edema
4. Bright-red patchy flushing, typically seen with gastric NENs

The diarrhea associated with carcinoid syndrome is episodic (usually occurring after meals), watery, and often explosive. Increased circulating serotonin levels are thought to be the cause of the diarrhea because the serotonin antagonist methysergide effectively controls the symptom. Cardiac lesions usually involve the right side of the heart, but left-sided lesions are present in 15% of patients and can lead to congestive heart disease and symptomatic left-sided heart failure. The three most common cardiac lesions are pulmonary stenosis (90%), tricuspid insufficiency (47%), and tricuspid stenosis (42%). Asthmatic attacks are usually observed during the flushing symptom, and serotonin and bradykinin have been implicated in this. Malabsorption and pellagra (dementia, dermatitis, and diarrhea) are occasionally present and are thought to be caused by excessive diversion of dietary tryptophan.

Diagnosis. The elevation of various humoral factors forms the basis for diagnostic tests in patients with NENs and carcinoid syndrome. NENs produce serotonin, which is then metabolized in the liver and the lung to the pharmacologically inactive 5-hydroxyindoleacetic acid (5-HIAA). Elevated urinary levels of 5-HIAA measured during 24 hours with high-performance liquid chromatography are highly specific although not sensitive. For the last decade, chromogranin A (CgA) has been a well-established marker for carcinoid disease; it is elevated in more than 80% of patients with NENs. CgA alone may be used for the diagnosis of NENs, given its specificity of 95%, but some investigators suggest that other tests should be used in conjunction with CgA for diagnostic purposes because its sensitivity is as low as 60%. A combination of serum CgA measurement with 24-hour urine 5-HIAA is an acceptable diagnostic combination with increased sensitivity. Studies suggest that serum CgA and N-terminal pro-brain natriuretic peptide may also be used in combination for both diagnosis and surveillance because patients with increased N-terminal pro-brain natriuretic peptide and CgA levels show worse overall survival than patients with elevated CgA alone. In terms of surveillance after resection or as a prognostic marker to monitor response to therapy, CgA levels have proven efficacy over urine 5-HIAA levels.

Plasma serotonin, substance P, neurotensin, neurokinin A, and neuropeptide K levels can be measured, but these peptides may not be elevated in all patients. Provocative tests using pentagastrin, calcium, or epinephrine may be used to reproduce the symptoms of NENs. More recently, pentagastrin has been used to differentiate between NENs and chronic atrophic gastritis but is generally not used for the diagnosis of NENs, given the diagnostic reliability of 5-HIAA, CgA, and N-terminal pro-brain natriuretic peptide.

NENs of the small intestine are rarely diagnosed preoperatively. Barium radiographic studies of the small bowel may exhibit multiple filling defects as a result of kinking and fibrosis of the bowel but are not typically used today in the workup of suspected small intestinal NENs. A combination of anatomic and functional imaging techniques is routinely performed to optimize sensitivity and specificity.

Traditionally, CT scanning was the imaging modality of choice for identifying the site of disease and the presence of lymphatic or hematogenous metastases. CT scan findings depend on the size, the degree of mesenteric invasion and desmoplastic reaction, and the presence of regional lymph node invasion. If these entities are not well defined, CT has limited diagnostic capabilities in this disease. However, when CT scanning reveals a solid mass with spiculated borders and radiating surrounding strands that are associated with linear strands within the mesenteric fat and kinking of the bowel, a diagnosis of gastrointestinal NENs can be made fairly confidently. CT angiography may be useful in cases associated with a large mesenteric process to identify encasement and pseudoaneurysm formation, typical of a malignant process in the mesentery. In general, MRI is not used in the diagnosis of gastrointestinal NENs but can be helpful in diagnosing metastatic disease, especially in the liver. Liver metastases are well demonstrated with MRI and usually have low signal intensity on T1-weighted images and high signal intensity on T2-weighted images. After the administration of a gadolinium-based contrast agent, liver metastases enhance peripherally in the hepatic arterial phase and appear as hypointense defects in the portal venous phase. Diffusion-weighted MRI and dynamic contrast-enhanced techniques have become increasingly capable of detecting liver metastases from intestinal NENs.[34]

Octreotide is a synthetic analogue of somatostatin, and indium (^{111}In)-labeled pentetreotide specifically binds to somatostatin receptor subtypes 2 and 5. Functional nuclear imaging studies capitalize on the concept of somatostatin receptor positivity, and these techniques are used to image many NENs, including those with somatostatin-binding sites. Scintigraphic localization has a higher sensitivity than CT for delineating and localizing NENs and is particularly useful in the identification of extraabdominal metastatic disease or in cases in which the primary tumor cannot be identified by CT scan. With this modality of imaging, there is an 84% positive predictive value and 50% negative predictive value. Another imaging modality, ^{18}F-fluorodeoxyglucose positron emission tomography (^{18}FDG PET) scanning, alone has limited capabilities because ^{18}FDG is taken up only in high-grade NENs (e.g., high Ki-67 expression), whereas most NENs have low Ki-67 expression and are not apparent with this imaging modality. However, the addition of newer isotopes, such as ^{18}F-L-dihydroxyphenylalanine (^{18}F-DOPA), has dramatically improved the sensitivity of PET for the diagnosis and surveillance of neuroendocrine malignant neoplasms.

Somatostatin receptor imaging with gadolinium ^{68}Ga–DOTATATE PET/CT is increasingly used for the preoperative staging for patients with NENs. DOTATATE is an amide of 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA) and the octreotide-derived radionuclide tyrosine-3-octreotate (TATE). The latter binds to somatostatin receptors and thus directs the radioactivity into the tumor. ^{68}Ga-DOTATATE PET/CT is a clinically useful imaging technique to localize primary tumors in patients with neuroendocrine metastases of unknown origin as well as to define the existence and extent of metastatic disease. Combining the two modalities may be even more helpful in diagnosing and managing NENs. Studies have demonstrated a 95% detection rate with the use of ^{68}Ga-DOTATATE PET/CT, with a sensitivity of 93.5%. Additionally, it is a shorter study with less radiation. There continues to be investigational studies into different hybrid chelators to further maximize detection, including ^{68}Ga-DOTA-peptides and ^{64}Cu-DOTATATE.[35] The benefits of ^{64}Cu-DOTATATE imaging include better true positive lesion detection, longer shelf life, and longer scanning window when compared with ^{68}Ga-DOTATATE, making it an ideal diagnostic tool. Lastly, the peptide receptor radionuclide therapy agent lutetium-177 (^{177}Lu) is both diagnostic and therapeutic and belongs to a new class of drugs known as *theranostics*. The reason for developing compounds with high affinity for somatostatin receptors 2, 3, and 5 is to improve diagnostic sensitivity. Because resection is the only curative treatment in patients with small intestinal NENs, accurate preoperative imaging is critical to guide surgical management.

Treatment

Surgical therapy. Currently, surgery is the only curative treatment for NENs, regardless of their location. Patients should undergo segmental intestinal resection with regional lymph node excision. Lesions of the terminal ileum are best treated by right hemicolectomy. Small duodenal tumors can be excised endoscopically; however, more extensive lesions may require pancreaticoduodenectomy. Outcomes between laparoscopic and open surgery are comparable. However, guidelines recommend bidigital palpation of the entirety of the small bowel, which is not feasible in a purely laparoscopic case. As such, many guidelines recommend open surgical resection as the standard of care. Alternatively, laparoscopic procedures with hand-assist or an extraction point to run the bowel would allow for palpation of the bowel. Determination of surgical technique should weigh the risks and benefits of both techniques for the individual patient and the extent of their disease.[36]

Caution should be exerted in the anesthetic management of patients with NENs because anesthesia may precipitate a carcinoid crisis characterized by hypotension, bronchospasm, flushing, and tachyarrhythmias. Carcinoid crisis is treated with IV octreotide given as a bolus of 500 to 1000 μg, which may be continued as an infusion at 50 μg/h. In patients with liver lesions, prophylactic perioperative administration of IV octreotide should be considered.

In addition to treating the primary tumor, the abdomen must be thoroughly explored for multicentric lesions. There often is a large desmoplastic reaction causing shortening, folding, and pleating of the small bowel mesentery resulting in intestinal angina and obstruction. In cases in which the mesenteric disease appears to involve a large portion of the mesentery, dissection of the tumor off the mesenteric vessels, with preservation of the blood supply to unaffected bowel, is appropriate, albeit technically demanding. Extensive mobilization of the small bowel mesentery is required to perform a difficult resection. All guidelines emphasize the need to preserve bowel when able and only consider tumors with their desmoid reactions unresectable if they involve vessels at the root of the mesentery.

In patients with NENs and widespread metastatic disease, surgery may still be indicated. In contrast to metastases from other tumors, there is a definite role for surgical debulking, which often provides beneficial symptomatic relief. In patients with limited hepatic involvement, metastasectomy provides the most durable survival benefit compared with other treatment modalities. For patients with liver metastases, surgical resection is an option as long as there are no extrahepatic metastases, liver function is not compromised, and hepatic disease burden is less than 70%. Patient performance status should also be an important consideration in deciding on surgical intervention. Unfortunately, most patients are not candidates for liver resection because of extensive disease at diagnosis. Even with liver metastasectomy, there is still a high recurrence rate of 75%. In these cases, transarterial chemoembolization or radioembolization has been shown to provide liver-directed control of disease. Furthermore, resection of the primary tumor, with or without mesenteric resection, has been shown to improve survival and to slow progression of hepatic metastases in patients with unresectable disease. Although some small studies have evaluated hepatic transplantation for extensive liver metastases from NENs, unacceptably high recurrence rates limit this approach. Overall, because of the complexity of treatment regimens, all surgical resections should be performed at a high-volume center.

TABLE 91.10 **Medical Therapies for Neuroendocrine Tumor Treatment**

Approved Therapeutics	
Somatostatin analogues	Octreotide (Sandostatin; Sandostatin LAR) Lanreotide (Somatuline depot)
Cytotoxic therapies	Streptozotocin (pancreatic NET only)
mTOR inhibitor	Everolimus (Afinitor; gastrointestinal, pancreatic, lung NET)
Tyrosine kinase inhibitors	Sunitinib (Sutent; pancreatic NET only)
Peptide receptor radionuclide therapy	^{177}Lu isotopes conjugated with somatostatin analogues (Lutathera)
Serotonin synthesis inhibitors	Telotristat etiprate (Xermelo)
Used Off-Label	
Pan-receptor somatostatin agonists	Pasireotide (Signifor); approved indication for Cushing disease only
Interferons	Interferon alfa-2b (Intron A)
Cytotoxic therapies	5-Fluorouracil (5-FU) Capecitabine (Xeloda); oral 5-FU Temozolomide (Temodar)
Investigational	
Peptide Receptor Radiotherapy	^{177}Lu-OPS 201 ^{177}Lu-DOTA JR11
Dopamine agonists	Dopastatins
Checkpoint Inhibitor	JS001
Somatostatin Drug Conjugate	PEN-221

mTOR, Mammalian target of rapamycin; *NET,* neuroendocrine tumor.

Compiled with assistance of Lowell B. Anthony, MD, University of Kentucky.

Medical therapy. Medical therapy for patients with malignant carcinoid syndrome is primarily directed toward the relief of symptoms caused by the excess production of humoral factors. Table 91.10 summarizes medical therapies for NEN treatment. Somatostatin analogs (SSAs) are the standard of care for controlling symptoms of patients with functional gastrointestinal NENs, and they control symptoms in more than 70% of patients with carcinoid syndrome. SSAs such as octreotide and lanreotide and their depot formulations (Sandostatin LAR and Somatuline, respectively) relieve symptoms of carcinoid syndrome (e.g., diarrhea, flushing, antisecretory effect) in most patients and delay cancer progression (antiproliferative effect). The antiproliferative effect was demonstrated in two randomized phase III trials. First, the PROMID trial of 85 patients confirmed that tumor burden is an important predictor of survival, and octreotide LAR provided delayed tumor progression compared with placebo.[37] Octreotide LAR is recommended for grade 1 and 2 NENs and is not recommended in grade 3 disease. Second, the landmark controlled study of Lanreotide Antiproliferative Response In NeuroEndocrine Tumors (CLARINET) trial found that lanreotide, an SSA, was associated with prolonged progression-free survival among patients with metastatic grade 1 or 2 enteropancreatic NENs.[38] Octreotide LAR and lanreotide are both appropriate as first-line therapy. The treatment of asymptomatic patients with low-volume and unresectable disease requires a personalized decision regarding observation or initiation of SSAs. However, observation requires close monitoring with diagnostic imaging every 3 to 6 months.[39]

For patients who have disease progression on SSA therapy, several treatment options remain. Everolimus, a mammalian target of rapamycin (mTOR) inhibitor initially developed as an immunosuppressant therapy, is approved for the treatment of nonfunctional gastrointestinal NENs with unresectable, locally advanced or metastatic disease. A randomized controlled trial

(RADIANT-4) demonstrated that with everolimus treatment, progression-free survival improved from 3.9 months to 11 months. Although everolimus can slow tumor progression, significant tumor reduction is rarely obtained. Targeting multiple signaling pathways is a treatment strategy that may provide better tumor control and overcome resistance mechanisms involved with simply targeting a single pathway. There are many ongoing studies investigating combinational therapy, including the addition of mTOR inhibitors, VEGF pathway inhibitors, cytotoxic chemotherapy, immunotherapy, and combination therapy with radiation treatments.[39]

Peptide receptor radionuclides are another class of therapy used in progressive disease. The NETTER-1 randomized control trial demonstrated that treatment with radionuclide ^{177}Lu-DOTATATE had a 79% improvement in progression-free survival when compared with high-dose octreotide. ^{177}Lu-DOTATATE can be used for PET imaging and to determine the distribution and the dosimetry of the tumor. Given the success of peptide receptor radionuclide therapy (PRRT), it continues to gain support for the treatment of NENs and is considered second-line therapy if somatostatin analogues fail. There are investigational studies looking at combination therapies to maximize therapeutic effect. Another second-line therapy is pasireotide, a second-generation SSA developed to address the limitations of the current regimens. Pasireotide has been shown to provide a 25% reduction in diarrhea and 42% reduction in flushing.[39]

Other treatment options include interferon-α, which was used as monotherapy for NENs in 1983. Interferon binds to two different receptors to elicit effects that include cell cycle inhibition at G_1/S, antiangiogenesis effects through downregulation of VEGF, and upregulation of somatostatin receptors. Although some series showed tumor regression in 20% to 40% of patients and tumor stabilization in 40% to 70% of patients, side effects, which included chronic fatigue, pancytopenia, thyroiditis, and systemic lupus erythematosus, were not tolerable. Thus, interferon-α has declined in use. Some series showed that given the upregulation of somatostatin receptors by interferon-α, its combination with SSAs may be efficacious. However, the literature is not consistent in these findings. Prospective randomized controlled trials have demonstrated variable findings, with resultant improved progression-free survival in some studies and no difference observed in other trials. Interferon is less expensive than the SSAs, but the increased incidence of side effects and variable outcomes preclude the widespread use of this drug.[39]

Patients with carcinoid syndrome resistant to SSAs have limited treatment options, which include increasing the dose of SSA or adding a short-acting octreotide and starting antidiarrheals. An extensive workup is needed to rule out other causes of diarrhea, but few treatment options remain. Currently, the serotonin synthesis inhibitor telotristat etiprate is indicated for somatostatin-refractory diarrhea in the setting of carcinoid syndrome. In the TELESTAR trial, telotristat treatment reduced daily bowel movements by 35%.[39] Methysergide is no longer used because of the increased incidence of retroperitoneal fibrosis.

Historically, the only available treatment for metastatic NENs was cytotoxic chemotherapy, most frequently combinations that included streptozotocin, 5-fluorouracil (5-FU), and cyclophosphamide. These treatments resulted in a median survival of around 2 years. Currently, the role of chemotherapy is confined predominantly to patients who have failed all other therapeutic options. The duration of response, however, is short-lived. Temozolomide as monotherapy has acceptable toxicity and provided antitumoral effects in a small series of patients with advanced NENs, and in combination with capecitabine, it was shown to prolong survival in patients with well-differentiated, metastatic NENs who experienced progression with previous therapies. Capecitabine-temozolomide in combination with PRRT studied in patients who had already failed single therapy demonstrated disease control in 38% to 55% of patients with progression-free survival of 7.1 months.[39] The use of cisplatin and etoposide has shown some promise, but only in patients with poorly differentiated NECs.

The treatment of metastatic NENs requires a multidisciplinary approach; combined modalities may be the best option, including surgical debulking, hepatic artery embolization, chemoembolization, or radioembolization and medical therapy. In addition, newer and more targeted therapies are being developed that may be useful in the future.

Prognosis. Although the incidence of NETs has increased, the mortality rate has remained stable. Other small bowel tumors, such as lymphomas and GISTs, have demonstrated improvements in survival that are likely secondary to advances in therapeutic options. This emphasizes the need for further investigations into effective treatments for NETs.[32] Survival in small intestinal NENs depends on the grade and stage of the disease. Resection of a NET localized to its primary site approaches a 100% survival rate. Five-year survival rate in metastatic disease is 35% to 80%. Given their indolent nature and delays in diagnosis, up to 90% of patients present with disease that has already metastasized to the liver. When widespread metastatic disease precludes cure, extensive resection for palliation may be indicated. In fact, long-term palliation often can be obtained because these tumors are relatively slow growing. Many factors have been evaluated to identify patients with NENs who have a poor prognosis. However, there are currently no reliable markers for prognosis beyond grade (including Ki-67 and mitotic rate) and stage. CgA is widely used to assist in the diagnosis of NENs and may indicate more aggressive disease, but it remains controversial in its ability to predict aggressive disease.

Adenocarcinomas

Adenocarcinomas constitute approximately 30% to 45% of the malignant tumors of the small bowel. The median age at diagnosis is in the seventh decade of life, and most series show a slight male predominance. Most of these tumors are located in the duodenum and proximal jejunum (Fig. 91.12A).[40] Those arising in association with Crohn disease or other familial syndromes tend to occur at a somewhat younger age and have an increased risk of developing multiple lesions. Small bowel adenocarcinoma may have important gene mutations (*APC,* β-*CATENIN, EGFR, VEGF-A, KRAS, HER2, TP53*). Familial syndromes associated with small bowel adenocarcinomas include FAP, Lynch syndrome, and Peutz-Jeghers syndrome. Tumors of the duodenum tend to manifest somewhat earlier than those in the jejunum and ileum because of the earlier presentation of symptoms, which are usually jaundice and chronic bleeding. Adenocarcinomas of the jejunum and ileum usually produce more nonspecific symptoms that include vague abdominal pain and weight loss. Intestinal obstruction and chronic bleeding may also occur. Perforation is uncommon. As with adenocarcinomas in other organs, survival of patients with small bowel adenocarcinomas is related to the stage of disease at the time of diagnosis. Unfortunately, diagnosis is often delayed, and the disease is advanced at the time of surgery secondary to a variety of factors (e.g., vagueness of symptoms, absence of

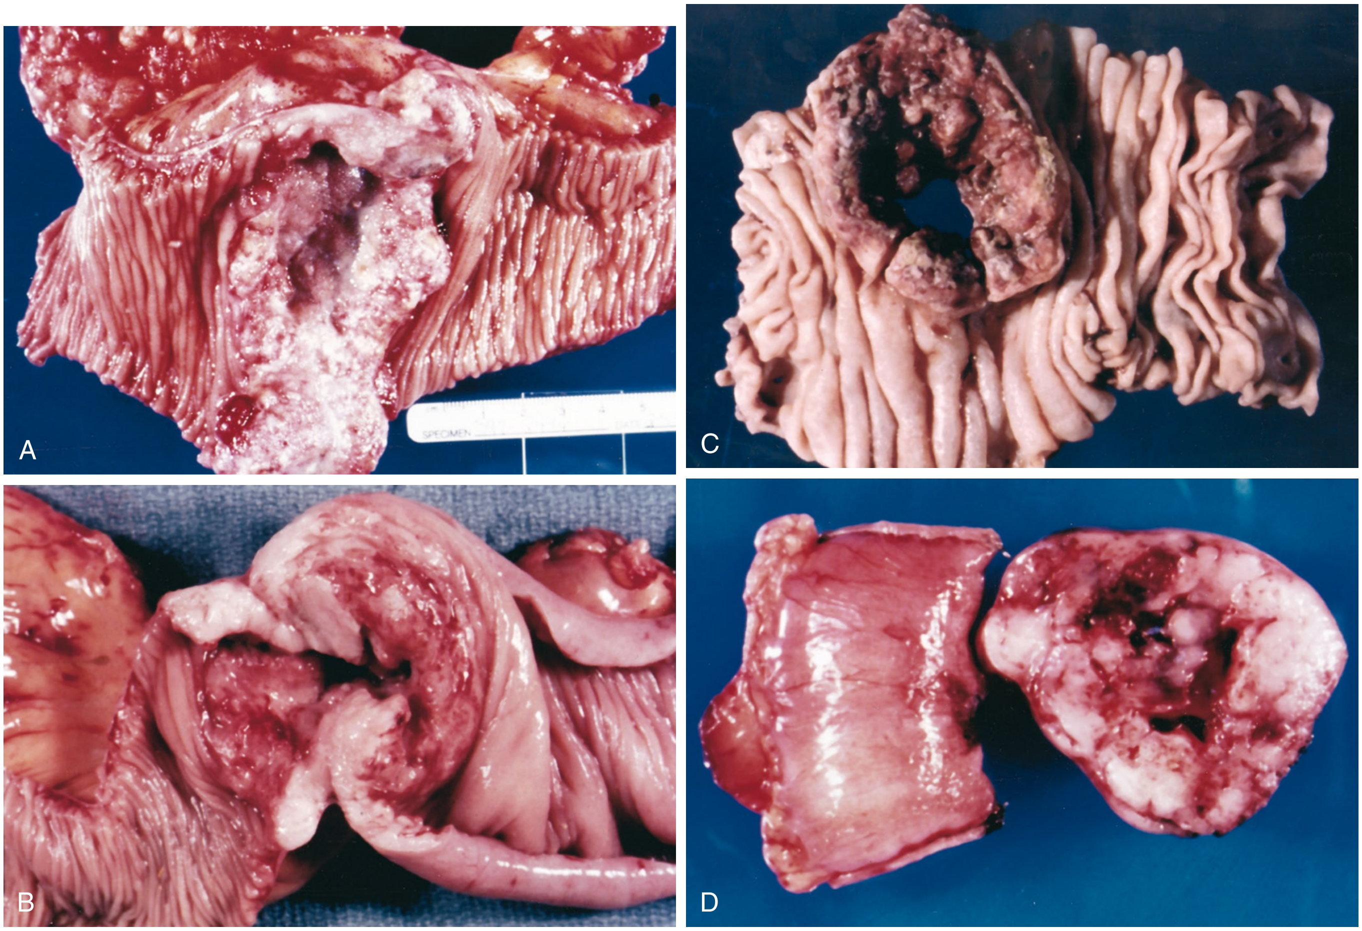

FIGURE 91.12 (A) Jejunal adenocarcinoma. Large circumferential mucinous adenocarcinoma of the jejunum. (B) Lymphoma of the small intestine. Gross photograph of primary lymphoma of the ileum shows replacement of all layers of the bowel wall with tumor. (C) Lymphoma of the small intestine. Small bowel lymphoma manifests as perforation and peritonitis. (D) Small intestine gastrointestinal stroma tumor (GIST). Small bowel GIST with hemorrhagic necrosis. (A–D, Courtesy Dr. Mary R. Schwartz, Baylor College of Medicine, Houston, TX.)

physical findings, lack of clinical suspicion because of the rarity of these lesions). A variety of radiologic and endoscopic techniques such as CT of the abdomen and pelvis, esophagogastroduodenoscopy with endoscopic ultrasound, MRI, video capsule endoscopy, and double-balloon enteroscopy (for biopsy and diagnosis) may be very useful in establishing the diagnosis before surgery.

Treatment of small bowel adenocarcinoma is determined by location and stage. An R0 resection of the primary tumor with locoregional lymph node resection is the only curative treatment. Neoadjuvant chemotherapy is appropriate to consider if there is unresectable disease, such as tumor invasion into adjacent structures. Duodenal resection can be performed for a noninfiltrating tumor if it is located in the first, third, or fourth portion of the duodenum, but this is not recommended if an expected R0 resection (no microscopic tumor at margin) is not possible. Residual microscopic tumor (R1 status) and grossly visible tumor after resection (R2 status) are associated with poor prognosis. Resectable adenocarcinomas in the second portion of the duodenum are treated with pancreaticoduodenectomy. In addition, regional lymphadenectomy of the periduodenal, peripancreatic, and hepatic lymph nodes as well as involved vascular structures is necessary. Jejunal and ileal adenocarcinomas require surgical resection with regional lymphadenectomy and jejunojejunal or ileoileal anastomosis. If the terminal ileum is involved, an ileocecectomy with right hemicolectomy should be performed with ligation of the ileocolic artery and subsequent regional lymphadenectomy.

There is currently no standard adjuvant protocol for small bowel adenocarcinoma, with clinical trials being the optimal route for medical therapy. Most guidelines suggest that patients with poorly differentiated cancers or those who had incomplete lymph node resections (<10 nodes identified) should at least be considered for adjuvant chemotherapy. Adjuvant regimens are often dictated by location, although studies have suggested that fluoropyrimidine and oxaliplatin may increase overall survival in patients with advanced disease. A prospective international phase III trial (BALLAD study) comparing observation with adjuvant chemotherapy in patients with an R0 resection is currently ongoing. This trial proposes that adjuvant chemotherapy will result in an improvement in disease-free survival and overall survival compared with observation alone after potentially curative surgery for patients with stage I, II, and III small bowel adenocarcinoma. Guidelines currently recommend adjuvant therapy with agents such as FOLFOX (oxaliplatin, 5-FU, and leucovorin), capecitabine plus oxaliplatin, 5-FU/leucovorin, and capecitabine. FOLFIRI (irinotecan, 5-FU, and leucovorin) can also be used as a second-line therapy for advanced and metastatic disease. Unresectable metastatic disease may require surgical intervention for uncontrolled bleeding, bowel obstruction, or perforation.

The prognosis of small bowel adenocarcinoma is poor, probably because of the delayed presentation and presence of advanced disease at diagnosis. Five-year survival rates for localized disease are much higher at 85% compared with stage IV disease, with a 5-year survival of 42%. Those with peritoneal carcinomatosis have a median overall survival of only about 6 months. Lymph node invasion is the main prognostic factor for local small bowel adenocarcinoma; moreover, the number of lymph nodes assessed and the number of positive lymph nodes are of prognostic value. Guidelines recommend obtaining at least eight regional lymph nodes during surgical resection with the possibility that greater lymph node resection may improve survival.[40]

Lymphoma

Malignant lymphomas involve the small bowel primarily or as a manifestation of systemic disease. Lymphomas constitute 20% of small bowel malignant tumors in the adult; in children younger than 10 years, they are the most common intestinal neoplasm. Lymphomas are commonly found in the ileum, where there is the greatest concentration of gut-associated lymphoid tissue. An increased risk for development of primary small bowel lymphomas was reported in patients with celiac disease and immunodeficient states (e.g., AIDS). Grossly, their appearance is variable, but they have a tendency to grow to large sizes (see Fig. 91.12B). Symptoms of small bowel lymphoma include pain, weight loss, nausea, vomiting, and change in bowel habits. Patients may also present with perforation or obstruction (see Fig. 91.12C). Fever is uncommon and suggests systemic involvement.

The treatment of small bowel lymphoma remains controversial. Traditionally, a combination of surgery, chemotherapy, and radiation therapy was used for all small bowel tumors. However, in the absence of symptoms, small bowel lymphomas are often chemoresponsive and do not require surgery. This can typically be predicted by cell type because B-cell lymphomas are more chemosensitive than T-cell lymphomas and have high remission rates with or without surgery. T-cell lymphomas are traditionally more resistant to therapy and will progress to symptoms of obstruction or perforation if not resected. Regardless of cell type, resection is indicated at any onset of symptoms because progression to life-threatening hemorrhage or perforation portends a dismal prognosis. Survival also depends on the type of lymphoma and extent of disease, but it is also largely dependent on response to systemic therapy rather than by the success of surgical resection.[41]

Gastrointestinal Stromal Tumors

Malignant GISTs arise from mesenchymal tissue, with the small bowel being the second most common location behind the stomach (see Fig. 91.12D). These tumors are more common in the jejunum and ileum and typically are diagnosed in the fifth and sixth decades of life. The most common indications for surgery include bleeding and obstruction, although free perforation may occur as a result of hemorrhagic necrosis in large tumor masses. Typically, GISTs tend to invade locally and to spread by direct extension into adjacent tissues and hematogenously to the liver, lungs, and bone; lymphatic metastases are unusual. The most useful indicators of survival and the risk for metastasis include the size of the tumor at presentation, mitotic index, and evidence of tumor invasion into the lamina propria.[29]

Treatment of GISTs continues to evolve and represents one of the first breakthroughs in signal transduction manipulation. The treatment regimen is based on localized versus metastatic disease. Surgical management includes complete resection for localized GISTs, with extreme care to avoid rupture of the tumor capsule, which results in one of the highest risk factors for disease recurrence. If capsule rupture occurs, these patients should receive adjuvant therapy regardless of the extent of the tumor before surgery. It is advisable to perform an en bloc resection to include adjacent organs for prevention of tumor capsule rupture. A laparoscopic approach in patients with large tumors is discouraged if it places the patient at risk for tumor rupture. Radiologic criteria for unresectability include large tumors with nonrecoverable infiltration of surrounding organs, which would cause significant comorbidity, and can include infiltration of the celiac trunk, superior mesenteric artery, or portal vein. Lymphadenectomy is unnecessary, given the low frequency of lymph node metastasis. The management of small GISTs (<2 cm) is controversial. Where surgical resection has classically been recommended for GISTS found on endoscopy, some now suggest that if there are no high-risk features, endoscopic surveillance may be appropriate. For similarly small GISTs identified incidentally in a surgical specimen, no further treatment is typically required. Before the development of tyrosine kinase inhibitors, adjuvant strategies for GISTs were lacking, and recurrence rates after resection were as high as 70%. However, the development of imatinib mesylate (Gleevec) has significantly altered previous treatment strategies. Imatinib mesylate is a tyrosine kinase inhibitor that blocks the unregulated mutant c-*kit* tyrosine kinase and inhibits the BCR-ABL and PDGF tyrosine kinases. Multiple randomized trials have confirmed its efficacy as a first-line agent in the treatment of GIST. Current guidelines suggest that patients with high-risk disease should receive 3 years of adjuvant treatment with imatinib, but it is not recommended for low-risk patients after an R0 resection. Neoadjuvant imatinib should be considered for patients requiring extensive surgery to allow for tumor shrinkage before resection.[29]

Relapse-risk assessment for a primary GIST is critical, as it provides prognostic information as well as estimates of the potential benefits of medical therapy. There are a multitude of risk stratification systems, including the National Institutes of Health (NIH) GIST consensus criteria, the American Forces Institute of Pathology criteria, the Joensuu risk criteria, prognostic nomograms, and mutational analysis. The modified NIH risk stratification system separates tumors into four groups ranging from very low risk to high risk based on tumor size, mitotic rate, and tumor site. In addition to staging information, several mutations are found to have implications on prognosis. For example, deletions affecting CD117 exons 9, 11, 13, or 17 and D842V PDGFR-α mutations have a higher risk of recurrence within the first 3 to 4 years after surgery. In fact, adjuvant imatinib therapy is not recommended in patients with D842V PDGFR-α mutations, given its known resistance to this agent.

Imatinib is also a first-line treatment for unresectable and metastatic GISTs with characteristic tumor biology. Genotyping is standard of care for patients with advanced or metastatic GIST. Standard-dose therapy (400 mg daily) is recommended. Unfortunately, there is a growing resistance to imatinib in metastatic GISTs. Tumors with CD117 mutations in exons 9, 13, or 14 should be treated with sunitinib, whereas ponatinib is useful for the treatment of tumors with exon 17 mutations.[29]

New molecular-targeted therapies may provide better treatments for patients with genetic mutations and GISTs. In phase III clinical trials evaluating imatinib dosing in patients with metastatic GIST, there was no objective response in patients who carry the D842V PDGFR-α mutation. Other medications are available as second- and third-line therapy, including dasatinib, an oral tyrosine kinase inhibitor of c-*kit*, PDGFR, ABL (Abelson murine leukemia viral oncogene homologue), and the proto-oncogene *Src* with a distinct binding affinity for c-*kit* and PDGFR. Regorafenib is a second-generation tyrosine kinase inhibitor that targets c-*kit, RET, BRAF,* VEGFR, PDGFR, and fibroblast growth factor receptor. Nilotinib is a second-generation tyrosine kinase inhibitor active in chronic myeloid leukemia and has an inhibitory effect on c-*kit* and PDGF. Sorafenib is a VEGF, c-*kit,* PDGFR, and *BRAF* inhibitor. All these agents may be useful in tumors resistant to imatinib but have shown variable results.

Metastatic Neoplasms

Metastases to the small intestine usually arise from other intraabdominal organs, including the uterine, cervix, ovaries, kidneys, stomach, colon, and pancreas. Small intestinal involvement is by direct extension or implantation of tumor cells. Metastases from extraabdominal tumors are rare but may be found in patients with adenocarcinoma of the breast and carcinoma of the lung. Cutaneous melanoma is the most common extraabdominal source to involve the small intestine and should always be a consideration when presented with a patient with advanced melanoma and gastrointestinal symptoms. Common symptoms of metastatic disease include anorexia, weight loss, anemia, bleeding, and partial bowel obstruction. Treatment is often palliative to relieve symptoms or, occasionally, a bypass if the metastatic tumor is extensive and not amenable to resection. Nonoperative palliation of malignant bowel obstruction includes endoscopic or radiologic placement of self-expandable metal stents, especially in patients with very poor performance status who may not tolerate a surgical procedure. Gastrostomy and jejunostomy tubes also may be placed to provide decompression when other palliative methods are not possible.

DIVERTICULAR DISEASE

Diverticular disease of the small intestine is relatively common. It may manifest as true or false diverticula. A true diverticulum contains all layers of the intestinal wall and is usually congenital. False diverticula consist of mucosa and submucosa protruding through a defect in the muscle coat and are usually acquired defects. Small bowel diverticula may occur in any portion of the small intestine. Duodenal diverticula are the most common acquired diverticula of the small bowel, and Meckel diverticulum is the most common true congenital diverticulum of the small bowel.

Duodenal Diverticula

Incidence and Cause

First described by Chomel, a French pathologist, in 1710, diverticula of the duodenum are relatively common, representing the second most common site for diverticulum formation after the colon, representing 60% to 79% of all small bowel diverticula.[42] The incidence of duodenal diverticula varies, depending on the age of the patient and method of diagnosis. Upper gastrointestinal radiographic studies may show pooling of contrast in the diverticula but are not commonly used for diagnosis, given only a 1% to 5% identification rate. Endoscopic retrograde cholangiopancreatography has an increased ability to identify diverticula. Diverticula are classified as congenital or acquired, true or false, and intraluminal or extraluminal. Extraluminal duodenal diverticula are considerably more common than intraluminal diverticula, are acquired, and consist of mucosal or submucosal outpouchings herniated through a muscle defect in the bowel wall. Intraluminal duodenal diverticula (also known as *windsock diverticula*) are congenital and occur as a single saccular structure that is connected to the entire circumference or part of the wall of the duodenum to create a duodenal web. Incomplete recanalization of the duodenum during fetal development leads to intraluminal diverticula, which are exceedingly rare. In general, extraluminal diverticula usually occur within the second portion of the duodenum (62%) and less commonly in the third (30%) and fourth (8%) portions. They rarely occur in the first part of the duodenum (<1%). When they occur in the second portion, most (88%) are noted on the medial wall around the ampulla (i.e., periampullary), 8% are seen posteriorly, and 4% occur on the lateral wall.

Clinical Manifestations

Importantly, the overwhelming majority of duodenal diverticula are asymptomatic and were previously noted incidentally by an upper gastrointestinal series for an unrelated problem. These studies have become less commonly used with the increased use of CT. CT can identify large diverticula by the presence of a masslike structure interposed between the duodenum and pancreatic head, containing air, air-fluid levels, fluid contrast material, or debris. However, CT has been shown to identify only 7% of known diverticula. Arguably, this is a reflection of both the technology and the ability to identify diverticula from surrounding tissue. Upper gastrointestinal endoscopy identifies approximately 75% of duodenal diverticula, and the use of a side-viewing scope further increases the success rate. Magnetic resonance cholangiopancreatography is particularly helpful to demonstrate the relationship of the diverticulum to the biliary and pancreatic ducts and associated pathologic changes in the biliary system and pancreas. Hemorrhage in duodenal diverticula is less common than jejunal and ileal diverticula. It can be diagnosed via triple-phase CT imaging, Tc-99m-labeled red blood cell scan, or endoscopy for duodenal and very proximal jejunal lesions; however, surgery should not be delayed to obtain imaging in the event of hemorrhage in a hemodynamically unstable patient. Less than 5% of duodenal diverticula will require surgery because of a complication from the diverticulum itself. Major complications of duodenal diverticula include obstruction of the biliary or pancreatic ducts that may contribute to cholangitis and pancreatitis, hemorrhage, perforation, and, rarely, blind loop syndrome. Iatrogenic injuries, most commonly acquired during endoscopic instrumentation of an asymptomatic diverticulum, can result in perforation or hemorrhage.

Only diverticula associated with the ampulla of Vater are significantly related to complications of cholangitis and pancreatitis. In these patients, the ampulla usually enters the duodenum at the superior margin of the diverticulum rather than through the diverticulum itself. Perivaterian diverticulum, defined as within 3 cm of the ampulla of Vater, may distort the common bile duct as it enters the duodenum, resulting in partial obstruction and stasis. However, other causes of biliary obstruction should be investigated before determining a diverticulum to be the causative entity. In addition, hemorrhage can be caused by inflammation, leading to erosion of a branch of the superior mesenteric artery. Perforation of duodenal diverticula has been described but is rare. Finally, stasis of intestinal contents within a distended diverticulum can result in bacterial overgrowth, malabsorption, steatorrhea, diarrhea, and megaloblastic anemia, essentially producing a blind loop syndrome. Symptoms related to duodenal diverticula in the absence of any other demonstrable disease usually are nonspecific epigastric complaints that can be treated conservatively and may actually prove to be the result of another problem not related to the diverticulum itself.

Treatment

Most duodenal diverticula are asymptomatic and benign; when they are found incidentally, no intervention is indicated. For symptomatic duodenal diverticula, treatment consists of removal of the diverticulum, which can be accomplished endoscopically or surgically. Appropriate classification of these diverticula guides management. All intraluminal duodenal diverticula typically require treatment, as recurrence of symptoms is certain. Curative treatment consists of removal of the intraluminal diverticulum by laparotomy and duodenotomy or by endoscopic resection. A large (>3 cm) or obstructing intraluminal duodenal diverticulum does not preclude endoscopic resection, but an endoscopic approach in the setting of massive hemorrhage or perforation with intraabdominal contamination secondary to intestinal contents is discouraged. These entities are relatively rare and often require a multidisciplinary approach to determine the best treatment strategy.

Extraluminal duodenal diverticula should be resected in the setting of symptomatic disease or need for urgent surgery, such as free perforation or hemorrhage. Several operative procedures have been described for treatment of the symptomatic extraluminal duodenal diverticula. The most common and effective treatment is diverticulectomy, which is most easily accomplished by performing a wide Kocher maneuver that exposes the duodenum. The diverticulum is then excised, and the duodenum is closed in a transverse or longitudinal fashion, whichever produces the least amount of luminal obstruction. Careful identification of the ampulla is essential to prevent injury to the common bile duct and pancreatic duct. For diverticula embedded deep within the head of the pancreas, a duodenotomy is performed, with invagination of the diverticulum into the lumen, which is then excised, and the wall is closed. An alternative method that has been described for duodenal diverticula associated with the ampulla of Vater is an extended sphincteroplasty through the common wall of the ampulla in the diverticulum. Laparoscopic duodenal diverticulectomy is safe and effective in patients with symptomatic and noncomplicated (i.e., not perforated or bleeding) diverticula. An endoscopic stapler is most commonly used to traverse and to resect the diverticulum at its base, and an omental patch reinforcement can be placed over the staple line.

The treatment of a perforated diverticulum may require procedures similar to those described for patients with massive trauma-related defects of the duodenal wall. The perforated diverticulum should be excised and the duodenum closed in a manner that limits luminal obstruction. This can include the use of a serosal patch from a jejunal loop. If the surrounding inflammation is severe, it may be necessary to divert the enteric flow away from the site of the perforation with a gastrojejunostomy or duodenojejunostomy. Interruption of duodenal continuity proximal to the perforated diverticulum may be accomplished by pyloric closure with suture or a row of staples in conjunction with a diversion procedure. If the diverticulum is posterior and perforates into the substance of the pancreas, operative repair may be difficult and dangerous. Wide drainage with duodenal diversion may be all that is feasible in such cases. Great care should be taken if the perforation is adjacent to the ampulla of Vater. Surgical jejunostomy should also be a consideration for all patients with acute perforation to ensure nutrition repletion. Lastly, stable patients with a contained perforation, without active enteric leak, may be able to be managed nonoperatively in the acute setting. However, such patients should be monitored closely and considered for future intervention to prevent recurrence.

Jejunal and Ileal Diverticula

Incidence and Cause

Diverticula of the small bowel are much less common than duodenal diverticula, with 20% to 25% found in the jejunum and approximately 5% in the ileum. These are false diverticula, occurring mainly in an older age group (after the sixth decade of life). These diverticula are multiple, usually protrude from the mesenteric border of the bowel, and may be overlooked at surgery because they are embedded within the small bowel mesentery (Fig. 91.13A). The cause of jejunoileal diverticulosis is thought to be a motor dysfunction of the smooth muscle or the myenteric plexus, resulting in disordered contractions of the small bowel, generating increased intraluminal pressure and herniation of the mucosa and submucosa through the weakest portion of the bowel (i.e., the mesenteric side).

Clinical Manifestations

Jejunoileal diverticula are usually found incidentally at laparotomy or during an upper gastrointestinal study (see Fig. 91.13B); the great majority remain asymptomatic. Acute complications, such as intestinal obstruction, hemorrhage, and perforation, can occur but are rare. Chronic symptoms include vague chronic abdominal pain, malabsorption, functional pseudoobstruction, and chronic low-grade gastrointestinal hemorrhage. Acute complications are diverticulitis with or without abscess or perforation, gastrointestinal hemorrhage, and intestinal obstruction. Stasis of intestinal flow with bacterial overgrowth (blind loop syndrome), caused by the jejunal dyskinesia, may lead to deconjugation of bile salts and uptake of vitamin B_{12} by the bacterial flora, resulting in steatorrhea and megaloblastic anemia, with or without neuropathy.

Treatment

For incidentally noted, asymptomatic jejunoileal diverticula, no treatment is required. Treatment of complications of obstruction, bleeding, and perforation is usually by intestinal resection and end-to-end anastomosis. Patients presenting with malabsorption secondary to blind loop syndrome and bacterial overgrowth in the diverticulum can typically use antibiotics for symptom resolution. Obstruction may be caused by enteroliths that form in a jejunal diverticulum and are subsequently dislodged and obstruct the distal intestine. This condition may be treated by enterotomy and removal of the enterolith, or sometimes the enterolith can be milked distally into the cecum. When the enterolith causes obstruction at the level of the diverticulum, bowel resection is necessary. When a perforation of a jejunoileal diverticulum is encountered, resection with reanastomosis is required because lesser procedures, such as simple closure, excision, and invagination, are associated with greater mortality and morbidity rates. Laparoscopic bowel resection with reanastomosis is a safe option

(B) Contrasted radiograph demonstrating jejunal diverticula. Multiple jejunal diverticula demonstrated by a barium contrast upper gastrointestinal study. (C) Persistent omphalomesenteric remnant. Omphalomesenteric remnant persisting as a fibrous cord from the ileum to the umbilicus. (D) Meckel diverticulum. Common presentation of a Meckel diverticulum projecting from the antimesenteric border of the ileum. (E) Contrasted radiograph of Meckel diverticulum. Barium radiograph demonstrates an asymptomatic Meckel diverticulum *(arrow)*. (F) Nuclear imaging of Meckel diverticulum. A Tc-99m-pertechnetate scintigram from a child demonstrates a Meckel diverticulum clearly differentiated from the stomach and bladder. (A, Adapted from Evers BM, Townsend CM Jr, Thompson JC. Small intestine. In: Schwartz SI, ed. *Principles of Surgery*. 7th ed. New York: McGraw-Hill; 1999:1248. B, E, F, Courtesy Dr. Melvyn H. Schreiber, The University of Texas Medical Branch, Galveston, TX.)

in minimally contaminated surgical fields. In extreme cases, such as diffuse peritonitis, enterostomies may be required if judgment dictates that reanastomosis is not feasible.

Meckel Diverticulum

Incidence and Cause

Meckel diverticulum is the most commonly encountered congenital anomaly of the small intestine, occurring in about 2% of the population. It was reported initially in 1598 by Hildanus and then described in detail by Johann Meckel in 1809. Meckel diverticulum is located on the antimesenteric border of the ileum 45 to 60 cm proximal to the ileocecal valve and results from incomplete closure of the omphalomesenteric, or vitelline, duct. Meckel diverticulum may exist in different forms, ranging from a small bump that may be easily missed to a long projection that communicates with the umbilicus by a persistent fibrous cord (see Fig. 91.13C) or, much less commonly, a patent fistula. The usual manifestation is a relatively wide-mouthed diverticulum measuring about 3 to 6 cm in length (see Fig. 91.13D). Cells lining the vitelline duct are pluripotent; therefore, about half contain heterotopic tissue. The most common ectopic tissue identified is gastric mucosa, followed by pancreatic mucosa and, in rare cases, colonic mucosa.

Clinical Manifestations

Most Meckel diverticula are benign and are incidentally discovered during autopsy, laparotomy, or barium studies (see Fig. 91.13E). The most common clinical presentation of Meckel diverticulum is gastrointestinal bleeding; hemorrhage is the most common symptomatic presentation in children 2 years of age or younger. This complication may manifest as acute massive hemorrhage, anemia secondary to chronic bleeding, or a self-limited recurrent episodic event. The usual source of the bleeding is a chronic acid-induced ulcer in the ileum adjacent to a Meckel diverticulum that contains gastric mucosa.

Another common presenting symptom of Meckel diverticulum is intestinal obstruction. Obstruction may result from a volvulus of the small bowel that surrounds the diverticulum and is associated with a fibrotic band attached to the abdominal wall, intussusception, or, rarely, incarceration of the diverticulum in an inguinal hernia (Littre hernia). Volvulus is usually an acute event and, if allowed to progress, may result in strangulation of the involved bowel. In intussusception, a broad-based diverticulum invaginates and then is carried forward by peristalsis. This may be ileoileal or ileocolic and manifest as acute obstruction associated with an urge to defecate, early vomiting, and occasionally passage of the classic currant jelly stool. A palpable mass may be present. Although reduction of an intussusception secondary to Meckel diverticulum can sometimes be performed by air enema, the patient should still undergo resection of the diverticulum to negate subsequent recurrence of the condition.

Meckel diverticulitis is more common in adult patients. Meckel diverticulitis, which is clinically indistinguishable from appendicitis, should be considered in the differential diagnosis of a patient with right lower quadrant pain. Progression of the diverticulitis may lead to perforation and peritonitis. When the appendix is found to be normal during exploration for suspected appendicitis, the distal ileum should be inspected for the presence of an inflamed Meckel diverticulum.

Neoplasms can also occur in 0.5% to 3.2% of Meckel diverticulum, with NET the most common malignant neoplasm (33%–44%). Other histologic types include leiomyosarcoma (18%–25%); adenocarcinoma (12%–16%), which generally originates from the gastric mucosa; GIST (12%); and, less frequently, lymphoma and pancreatic malignancies.[43]

Diagnostic Studies

The diagnosis of Meckel diverticulum may be difficult. Plain abdominal radiography, CT, and ultrasonography are rarely helpful. In children, the single most accurate diagnostic test for Meckel diverticula is with sodium Tc-99m-pertechnetate scintigraphy. The Tc-99m-pertechnetate is preferentially taken up by the mucus-secreting cells of gastric mucosa and ectopic gastric tissue in the diverticulum (see Fig. 91.13F). The diagnostic sensitivity of this scan has been reported as high as 85%, with a specificity of 95% and an accuracy of 90% in the pediatric age group.

In adults, however, the sensitivity of Tc-99m-pertechnetate scan falls to 63% because of the smaller presence of gastric mucosa in the diverticulum compared with that noted in the pediatric age group. The sensitivity and specificity can be improved by the use of pharmacologic agents. Cimetidine may be used to increase the sensitivity of scintigraphy by decreasing the peptic secretion while not affecting radionuclide uptake, which may be caused by the release of pertechnetate from the diverticular lumen. Therefore, cimetidine treatment results in higher radionuclide concentrations in the wall of the diverticulum. False-negative results can occur because of absent gastric mucosal cells, inflammatory changes causing edema or necrosis, presence of outlet obstruction of the diverticulum, or anemia. In false-negative cases, barium contrast imaging, mesenteric arteriography, or double-balloon endoscopy can be helpful. In patients with acute hemorrhage, angiography is sometimes useful. Nevertheless, surgical intervention should not be delayed to obtain imaging for a patient with signs and symptoms of hemorrhage and hemodynamic instability.

Treatment

The treatment of a symptomatic Meckel diverticulum requires prompt surgical intervention with diverticulectomy or segmental resection of ileum containing the diverticulum. Segmental small bowel resection is required for treatment of patients with hemorrhage because the bleeding site is usually adjacent to the diverticulum. Diverticulectomy for nonbleeding Meckel diverticula can be performed with a hand-sewn technique or stapling across the base of the diverticulum in a diagonal or transverse line to minimize the risk for subsequent stenosis. Retrospective studies have demonstrated equivalent outcomes in laparoscopic resection as compared with open resection of Meckel diverticulum.

Although the treatment of a complicated or symptomatic Meckel diverticulum is straightforward, the optimal treatment of an asymptomatic diverticulum found incidentally is still debated. It is generally recommended that asymptomatic diverticula found in children during laparotomy should be resected. The treatment of Meckel diverticula encountered in the adult patient, however, remains controversial. A landmark paper by Soltero and Bill[44] formed the basis of the surgical management of asymptomatic Meckel diverticula in adults for many years. In this study, the likelihood of a Meckel diverticulum becoming symptomatic in the adult patient was estimated to be 2% or less, and given that the morbidity rates from incidental removal were 12% at the time, the recommendation was to not remove the incidental Meckel diverticulum. Recent studies have argued for surgical resection because of their propensity for harboring malignancies.[43] The factors associated with a higher risk of complications, and warranting consideration of resection, include age younger than 50 years, male sex, diverticulum length >2 cm, and ectopic tissue or palpable abnormalities. Taken together, the decision for surgical resection of Meckel diverticulum needs to be made on a personalized basis, weighing the risk and benefits of malignancy, age, and complications. Future prospective trials are needed to clarify this controversy.

MISCELLANEOUS PROBLEMS

Small Bowel Ulcerations

Ulcerations of the small bowel are relatively uncommon and may be attributed to Crohn disease, typhoid fever, tuberculosis, lymphoma, and gastrinoma (Table 91.11). Drug-induced ulcerations can occur and were, in the past, attributed to enteric-coated potassium chloride tablets and corticosteroids. In addition, ulcerations of the small intestine in which no causative agent can be identified have been described. Currently, many different drugs are linked to small bowel injury, including certain NSAIDs, biologic therapies, immunosuppressive medications, and blood pressure medications (i.e., olmesartan). NSAID-induced ulcers occur more commonly in the ileum, with single or multiple ulcerations noted. Complications necessitating operative intervention include bleeding, perforation, and obstruction. In addition to ulcerations, NSAIDs are known to induce an enteropathy characterized by increased intestinal permeability leading to protein loss and hypoalbuminemia, malabsorption, and anemia. Treatment of complications from small bowel ulcerations is segmental resection and intestinal reanastomosis.[45]

Ingested Foreign Bodies

Ingested foreign bodies, which can lead to subsequent perforation or obstruction of the gastrointestinal tract, are swallowed, usually accidentally, by children or adults. These include glass and metal fragments, pins, needles, toothpicks, fish bones, coins, whistles, toys, and broken razor blades (Fig. 91.14). Intentional ingestion of foreign bodies is sometimes seen in the prison population and those who have a psychiatric illness. For most patients, treatment is observation to permit safe passage of these objects through the intestinal tract. If the object is radiopaque, progress can be followed by serial abdominal films. Cathartic agents are contraindicated. Sharp pointed objects such as needles, razor blades, or fish bones may penetrate the bowel wall. If abdominal pain, tenderness, fever, or leukocytosis occurs, immediate surgical intervention with removal of the offending object(s) is indicated. Similarly, if obstruction occurs, surgery should be performed to remove the object(s).

TABLE 91.11 Small Intestinal Gastrointestinal Tumor Classification

	STAGE					
	I	IIA	IIB	IIIA	IIIB	IV
Primary tumor size[a]	T1 or T2	T3	T4	Any T		
Regional lymph node metastasis[b]	N0			N1	N2	Any N
Distant metastasis[c]	M0					M1

[a] **T1,** Tumor invades the lamina propria or submucosa; **T2,** Tumor invades the muscularis propria; **T3,** Tumor invades into the subserosa or extends into nonperitonealized perimuscular tissue (mesentery or retroperitoneum) without serosal penetration; **T4,** Tumor perforates the visceral peritoneum or directly invades other organs/structures (other loops of small bowel, mesentery of adjacent bowel, abdominal wall, invasion of pancreas or bile duct [for duodenum]).

[b] **N0,** No regional lymph node metastasis; **N1,** One or two regional lymph node metastasis; **N2,** Three or more regional lymph node metastasis.

[c] **M0,** No distant metastasis; **M1,** Distant metastasis.

Small Bowel Fistulas

Despite improvements in surgical nutrition and critical care, mortality from enterocutaneous fistulas remains high at 10% in recent reports. Improvements in outcome focus on prevention and, when fistulas occur, prompt recognition and intervention. Multidisciplinary care is critical for improving fistula outcomes. Enterocutaneous fistulas are most commonly iatrogenic after surgical intervention (e.g., anastomotic leakage, injury of the bowel or blood supply, erosion by suction catheters, laceration of the bowel by wire mesh or retention sutures). Additional causes include predisposing conditions such as Crohn disease, malignant disease, radiation enteritis, diverticulitis, intraabdominal sepsis, or trauma.

Clinical Manifestations

Recognition of enterocutaneous fistulas is usually not difficult. The typical clinical presentation is that of a febrile postoperative patient with an erythematous wound. When a few skin sutures are

TABLE 91.12 Causes of Small Intestine Ulceration

CAUSE	EXAMPLES
Infections	Tuberculosis, syphilis, cytomegalovirus, typhoid, parasites, *Strongyloides* hyperinfection, *Campylobacter, Yersinia*
Inflammatory	Crohn disease, systemic lupus erythematosus, celiac disease, ulcerative enteritis
Ischemia	Mesenteric arterial insufficiency or venous thrombosis
Idiopathic	Primary ulcer, Behçet syndrome
Drug induced	Potassium, indomethacin, phenylbutazone, salicylates, antimetabolites
Radiation	Therapeutic, accidental
Vascular	Vasculitis, giant cell arteritis, amyloidosis (ischemic lesion), angiocentric lymphoma
Metabolic	Uremia
Hyperacidity	Zollinger-Ellison syndrome, Meckel diverticulum, stomal ulceration
Neoplastic	Lymphoma, adenocarcinoma, melanoma
Toxic	Acute jejunitis (β-toxin–producing *Clostridium perfringens*), arsenic
Mucosal lesions	Lymphocytic enterocolitis

Adapted from Rai R, Bayless TM. Isolated and diffuse ulcers of the small intestine. In: Feldman M, Scharschmidt BF, Sleisenger MH, eds. *Gastrointestinal and Liver Disease: Pathophysiology, Diagnosis, Management*. Philadelphia: WB Saunders; 1998:1771-1778.

removed, a purulent or bloody discharge is noted; leakage of enteric contents then occurs, sometimes immediately but often within 1 or 2 days. Small bowel fistulas can also be manifested with generalized peritonitis, although this is less common. Recently, the popularization of damage control laparotomy and staged management of the open abdomen has led to a more virulent form of small bowel fistula referred to as an *enteroatmospheric fistula*. These patients typically present with an open segment of intestine exposed through a large fascial defect, without a surrounding epidermal margin.

Enterocutaneous fistulas are classified according to their location and volume of daily output (Tables 91.12 and 91.13). These factors dictate treatment and morbidity and mortality rates. Proximal fistulas are associated with higher output, greater fluid and electrolyte loss, and greater loss of digestive capacity. Distal fistulas tend to have lower output, making them easier to manage and more likely to close spontaneously. Multiple factors prevent the spontaneous closure of fistulas, including retained **F**oreign body, **R**adiation enteritis, **I**nflammatory bowel disease or infection, **E**pithelialization of the fistula tract, **N**eoplasm, and **D**istal obstruction (FRIENDS). Once a fistula is identified, management should focus on prompt IV fluid resuscitation and consideration of potential factors that could prevent spontaneous closure. Successful management of patients with intestinal fistulas requires a coordinated staged approach that can be defined in three phases: (1) stabilization, (2) staging and supportive care, and (3) definitive management.

TABLE 91.13 Factors Predictive of Nonoperative Fistula Closure

FAVORABLE	UNFAVORABLE
Surgical etiology	Ileal, jejunal, nonsurgical etiology
Appendicitis or diverticulitis	Inflammatory bowel disease, cancer, radiation
Transferrin >200 mg/dL	Transferrin <200 mg/dL
No evidence of bowel obstruction, discontinuity, infection, inflammation	Distal small bowel obstruction, bowel is in discontinuity, adjacent infection, adjacent inflammation
Length >2 cm, end fistula	Length <2 cm, lateral or multiple fistulas
Output <200 mL/24 hours	Output >500 mL/24 hours
No sepsis, balanced electrolytes	Sepsis, electrolyte disturbances
Initial referral to tertiary care center and subspecialty care	Delay getting to tertiary care center and subspecialty care

Treatment

Stabilization. Historically, malnutrition and fluid losses were the leading causes of death in patients with small bowel fistula. However, with better nutritional supplementation and critical care support, sepsis has become the most common cause of death in affected patients. Nevertheless, the fluid losses and volume depletion associated with small bowel fistula cannot be marginalized. Therefore, prompt fluid resuscitation and electrolyte replacement should occur on recognition of a fistula. Sepsis control is critical, and in the early period, CT scanning may be invaluable in identifying undrained abscesses, complete distal obstructions, or generalized intraabdominal sepsis with peritonitis. Numerous treatment options are available for enterocutaneous fistulas (Box 91.7). All infections should be adequately drained percutaneously or operatively, if necessary, along with appropriate antibiotic administration. Once sepsis is controlled and the patient is resuscitated, effluent control with skin protection and adequate nutrition are necessary. Fistula output can be controlled by intubation of the fistula tract with a drain. Protection of the skin around the fistulous opening is important to prevent excoriation and destruction of the skin. This can be accomplished by using a Stomahesive product with applications of zinc oxide, aluminum paste, or karaya powder. The suction catheter can be brought out through the end of the Stomahesive appliance, which is cut to just fit the fistulous opening. This will allow collection and accurate measurement of the output. The use of TPN has been an important advance in the management of patients with high-output enterocutaneous fistulas and significantly decreases the incidence of malnutrition. TPN is particularly valuable in the stabilization period to help minimize high-output fistula losses and for immediate nutritional repletion while the fistula is being delineated. However, if the patient can meet calorie goals without the use of TPN, especially when a high-output fistula is not present, enteral feeding is preferable and recommended.

BOX 91.7 Treatment Strategy in Patients With an Enterocutaneous Fistula

Sepsis Control

- Radiologic drainage of abscess
- Relaparotomy on demand, minimally invasive if possible
- Consider other infectious foci: intravenous line, urinary tract infection, pulmonary

Optimization of Nutritional Status

- Rehydration and electrolyte supplementation
- Enteral nutrition is preferred
- Parenteral nutrition to meet calorie requirements, small bowel ECF
- Allow 500 mL/day clear liquids orally

Wound Care

- Gauzes for low-output ECF
- Collect ECF fluids with bag (wound manager, fistula bag), paste to protect the skin
- Drainage of excessive ECF fluid with sump suction
- Proton pump inhibitors

Anatomy of ECF

- Macroscopic
- Biochemical analysis of ECF fluid (bilirubin/amylase)
- Methylene blue
- Preoperatively: fistulography or contrast CT; length of intestine and localization of origin of ECF, stenosis, obstruction, and fluid collection

Timing of Surgery

- Clinically stable (above)
- Psychologically willing to undergo surgery
- Albumin >25 g/L
- Period of convalescence >6 weeks

Surgical Strategy

- One-stage procedure
- Careful adhesiolysis
- Wedge excision of intestinal resection
- Limit number of anastomoses to minimum
- Cover sutures with healthy, viable tissue
- Keep away from compromised area

ECF, Enterocutaneous fistula.

Adapted from Visschers RG, van Gemert WG, Winkens B, et al. Guided treatment improves outcome of patients with enterocutaneous fistulas. *World J Surg.* 2012;36:2341-2348.

Staging and supportive care. When sepsis has been controlled and nutritional therapy has been instituted, the fistula must be adequately staged. The combined use of fluoroscopic contrast studies, fistulography if necessary, and CT, along with the patient's clinical behavior, will characterize the anatomy and underlying pathology of the fistula. Some have advocated conservative management for up to 3 months to allow spontaneous closure. However, others have shown that after sepsis is controlled, more than 90% of small intestinal fistulas that closed did so within 1 month. Less than 10% of the fistulas closed after 2 months, and none closed spontaneously after 3 months. In one large retrospective study, the majority of enterocutaneous fistulas closed spontaneously (54%), whereas 18% needed definitive surgery at a later time. Operative mortality was 9.8%, and recurrence rate was 8%. Uncomplicated proximal fistulas have higher spontaneous closure rates, with duodenal fistulas closing within 2 to 4 weeks. Therefore, a reasonable management plan would be to follow a 6-week period of convalescence, at which time, if closure has not been obtained, surgical management should be considered if the preoperative albumin level is above 25 g/L. However, knowledge that spontaneous closure is unlikely should not prompt immediate reexploration at 8 weeks. In general, a period of 3 to 6 months is beneficial to allow the profound inflammatory response associated with intraabdominal sepsis to subside completely and for the adhesion formation to stabilize. This period will provide a better opportunity for safe and successful operative intervention. Furthermore, as is the case with enteroatmospheric small bowel fistulas, it may take several months to stabilize the complex abdominal wound associated with the fistula.

Several adjuncts have been proposed to help assist in spontaneous fistula closure and management of the associated abdominal wound, although none are supported by vigorous level I data. Studies suggest that bowel rest with TPN therapy improves fistula closure rates and time to closure in patients with high-output fistulas. Low-output fistulas can successfully be managed with enteral therapy while avoiding the known complications of parenteral therapy. Dysmotility agents such as loperamide and codeine can also assist with attempts at enteral therapy. Furthermore, newer techniques, such as fistuloclysis, in which the distal limb of a proximal fistula is intubated and enteral therapy is delivered to the distal bowel, have proved effective. Several randomized trials have evaluated the role of octreotide in the management of fistulas. Although octreotide has been shown to decrease fistula output, which can be useful in the presence of a high-output fistula, it has not convincingly provided an improvement in spontaneous closure rates. Vacuum devices are valuable in the setting of enteroatmospheric fistulas to help contract the open abdominal wound around the associated fistula. Care should be given to avoid direct contact with visceral contents, as this can cause new fistulas. Skin grafting up to the fistula has also been used in cases associated with an open abdomen, with a graft success rate of up to 80% in some series. Importantly, patients who could not be discharged before definitive repair also have higher mortality risk.

Definitive management. If the fistula persists despite adequately addressing the patient's nutritional, fluid, and wound care needs, reoperative intervention will ultimately be necessary for some patients. Surgery is most easily accomplished by entering the previous abdominal wound, with great care taken to avoid further damage to adherent bowel. The preferred operation is fistula tract excision and segmental resection of the involved segment of intestine and reanastomosis. Simple closure of the fistula after removal of the fistula tract almost always results in fistula recurrence. If an unexpected abscess is encountered or if the bowel wall is rigid and distended over a long distance, thus making primary anastomosis unsafe, exteriorization of both ends of the intestine should be accomplished. Various bypass procedures have also been described as part of a staged approach in which exclusion of the segment containing the fistula is accomplished in the first reoperation, and then another operation is required for resection of the involved segment and fistula tract. Although this may be necessary in extreme circumstances, this is certainly not the preferred surgical management. Basic surgical considerations include attempting a one-stage procedure, careful adhesiolysis, addressing compromised tissues with wedge excision or intestinal resection, covering sutures with viable tissues, and avoiding friable areas that are not directly involved with the fistula.

In summary, enterocutaneous fistulas occur most commonly as a result of a previous operative procedure. Once identified, a three-phase approach of stabilization, staging, and supportive care and, in some cases, definitive surgical intervention is necessary. Most of these fistulas heal spontaneously within 6 weeks. If closure is not achieved after 6 weeks, surgery is indicated.

Pneumatosis Intestinalis

Pneumatosis intestinalis is an uncommon condition manifesting as multiple gas-filled cysts of the gastrointestinal tract. The cysts may be located in the subserosa, submucosa, and, rarely, muscularis layer and vary in size from microscopic to several centimeters in diameter. They can occur anywhere along the gastrointestinal tract, from the esophagus to the rectum; however, they are most common in the jejunum, followed by the ileocecal region and colon. Extraintestinal structures such as mesentery, peritoneum, and the falciform ligament may also be involved. There is an equal incidence in males and females, and the condition usually occurs in the fourth to seventh decades of life. Pneumatosis in neonates is usually associated with necrotizing enterocolitis. The cause of pneumatosis intestinalis has not been completely delineated. A number of theories have been proposed; mechanical, mucosal damage, bacterial, and pulmonary hypotheses seem to be the most plausible.

There are two forms of pneumatosis intestinalis. Primary pneumatosis (15%) is a benign idiopathic condition that is not associated with any other conditions or symptoms and is found incidentally. The majority of pneumatosis intestinalis cases (85%) are "secondary" and can be associated with a multitude of other local and systemic factors such as chronic obstructive pulmonary disease, autoimmune diseases, malignancies, obstructive pathologies, infections, and trauma.

Upon gross inspection, the cysts resemble cystic lymphangiomas or hydatid cysts. On histologic section, the involved portion has a honeycomb appearance. The cysts are thin walled and break easily. Spontaneous rupture gives rise to pneumoperitoneum. Symptoms are nonspecific and, in pneumatosis associated with other disorders, may be those of the associated disease. Symptoms in primary pneumatosis intestinalis are rare, but when present, usually include diarrhea, abdominal pain, abdominal distention, nausea, vomiting, weight loss, and mucus in stools. Hematochezia and constipation have also been described. Pneumatosis intestinalis represents one of the few cases of sterile pneumoperitoneum and should be considered in the patient with free abdominal air but no evidence of peritonitis. However, pneumatosis intestinalis is an ominous sign when associated with peritonitis, mesenteric gas, or portovenous gas, as this is most concerning for life-threatening small bowel ischemia.

The diagnosis is usually made radiographically by plain abdominal or CT studies. On plain films, pneumatosis intestinalis appears as radiolucent areas within the bowel wall, which must be differentiated from luminal intestinal gas (Fig. 91.15A). The radiolucency may be linear or curvilinear or appear as grapelike clusters or tiny bubbles. CT is the gold standard for diagnosis and can help elucidate any causative etiology (see Fig. 91.15B). Visualization of intestinal cysts has also been described by ultrasound.

No treatment is necessary unless one of the complications supervenes, such as small bowel ischemia, rectal bleeding, cyst-induced volvulus, or tension pneumoperitoneum. Prognosis in most patients is that of the underlying disease, but in most studies the presence of peritonitis is a strongly negative predictive factor. The important point is to recognize that pneumatosis intestinalis is a radiographic finding and not a diagnosis. Treatment should be directed at the underlying cause of the pneumatosis, and surgical intervention should be predicated on the clinical course of the patient.[46]

Blind Loop Syndrome

Blind loop syndrome is a rare condition manifested by diarrhea, steatorrhea, megaloblastic anemia, weight loss, abdominal pain, and deficiencies of the fat-soluble vitamins as well as neurologic disorders. The underlying cause of this syndrome is bacterial

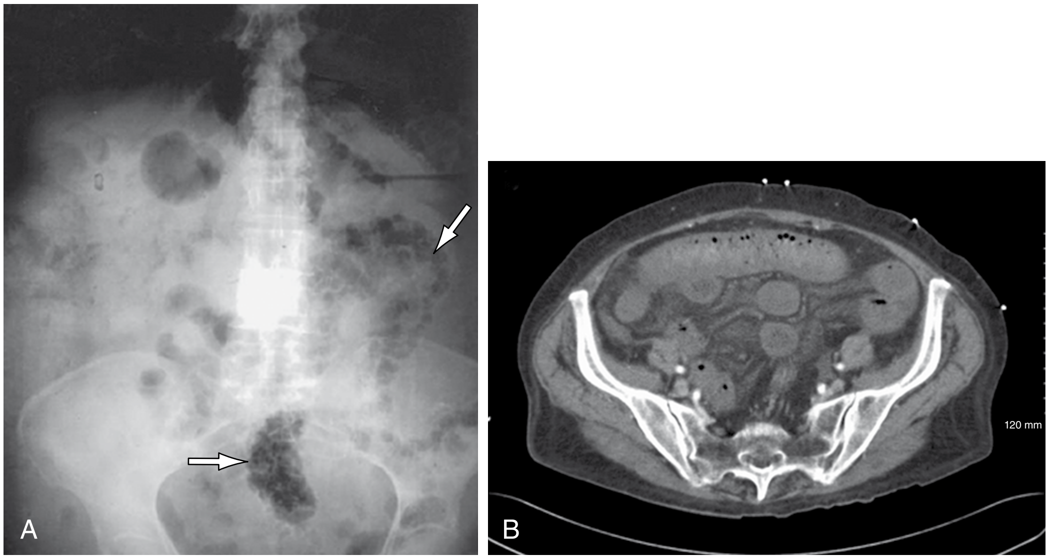

FIGURE 91.15 Pneumatosis intestinalis. (A) Plain abdominal film demonstrates pneumatosis intestinalis *(arrows)*. (B) CT findings consistent with curvilinear radiolucency appearing as tiny bubbles in the antimesenteric border of the bowel consistent with pneumatosis intestinalis. (A, Courtesy Dr. Melvyn H. Schreiber, The University of Texas Medical Branch, Galveston, TX. B, Courtesy Dr. Kristin Long, University of Kentucky Medical Center, Lexington, KY.)

overgrowth in stagnant areas of the small bowel produced by stricture, stenosis, fistulas, or diverticula (e.g., jejunoileal or Meckel diverticulum). Under normal circumstances, the upper gastrointestinal tract contains fewer than 10^3 bacteria/mL, mostly gram-positive aerobes and facultative anaerobes. However, with stasis, the number of bacteria increases, with excessive proliferation of aerobic and anaerobic bacteria; *Bacteroides,* anaerobic lactobacilli, coliforms, and enterococci are likely to be present in varying numbers. The bacteria compete for dietary vitamin B_{12}, producing a systemic deficiency of vitamin B_{12} and megaloblastic anemia.

The syndrome can be confirmed by a series of laboratory investigations. Bacterial overgrowth can be diagnosed with cultures obtained through an intestinal tube or by indirect tests such as carbohydrate breath tests, which detect substrates produced by bacteria, such as hydrogen from lactulose. Historically, after bacterial overgrowth and steatorrhea were confirmed, the Schilling test (^{57}Co-labeled vitamin B_{12} absorption) would be performed, which would reveal a pattern of urinary excretion of vitamin B_{12} resembling that of pernicious anemia (a urinary loss of 0%–6% of vitamin B_{12} compared with the normal of 7%–25%). In patients with blind loop syndrome, vitamin B_{12} excretion is not altered by the addition of intrinsic factor, but a course of a broad-spectrum antibiotic (e.g., tetracycline) should return vitamin B_{12} absorption to normal. Although previously in common use, the Shilling test is no longer used today.

Treatment of patients with blind loop syndrome includes parenteral vitamin B_{12} therapy and broad-spectrum antibiotics. Tetracyclines have been the mainstay of treatment, but studies have shown that rifaximin and metronidazole demonstrate less resistance and are also effective. For most patients, a single course of therapy (7–10 days) is sufficient, and the patient may remain symptom free for months. Prokinetic agents have been used without real success. Surgical correction of the condition causing stagnation and blind loop syndrome produces a permanent cure and is indicated for patients who require multiple rounds of antibiotics or are receiving continuous therapy.

Radiation Enteritis

Radiation therapy is generally used as adjuvant therapy for various abdominal and pelvic cancers. In addition to tumor cells, however, other rapidly dividing cells in normal tissues may be affected by radiation. Surrounding normal tissue, such as the small intestinal epithelium, may sustain severe, acute, and chronic deleterious effects. Radiation injury to the small bowel can be subdivided into acute and chronic forms. Acute radiation-induced small bowel disease usually manifests with colicky abdominal pain, bloating, loss of appetite, nausea, diarrhea, and fecal urgency during or shortly after a course of radiotherapy. Most patients notice symptoms during the third week of treatment, and these resolve 2 to 6 weeks after completion of radiation. Symptoms consistent with chronic radiation injury typically develop between 18 months and 6 years after a completed course of radiotherapy, but symptoms can be present up to 30 years after the treatment course.

The amount of radiation appears to correlate with the probability for the development of radiation enteritis. Serious late complications are unusual if the total radiation dosage is less than 4000 cGy; morbidity risk increases with dosages exceeding 5000 cGy. Other factors, including previous abdominal surgeries, preexisting vascular disease, hypertension, diabetes, and adjuvant treatment with certain chemotherapeutic agents (such as 5-FU, doxorubicin, dactinomycin, and MTX), contribute to the development of enteritis after radiation treatments. A previous history of laparotomy increases the risk for enteritis, presumably because of adhesions that fix portions of the small bowel into the irradiated field. Radiation damage leads to symptoms of diarrhea, abdominal pain, and malabsorption. The late effects of radiation injury are the result of damage to small submucosal blood vessels, with a progressive obliterative arteritis and submucosal fibrosis; these events eventually result in thrombosis and vascular insufficiency. This injury may produce necrosis and perforation of the involved intestine, but more commonly leads to stricture formation with symptoms of obstruction or small bowel fistulas.

Multiple strategies are used to reduce radiation injury to the small bowel (Box 91.8). Radiation enteritis may be minimized by adjusting ports and dosages of radiation to deliver optimal treatment specifically to the tumor and not to surrounding tissues. Placement of radiopaque markers, such as titanium clips, at the time of the original operation facilitates better targeting of the radiation treatment. A reduction in field size, multiple field arrangements, conformal radiotherapy techniques, and intensity-modulated radiotherapy can reduce toxicity related to radiotherapy. Methods designed to exclude the small bowel from the irradiated field include reperitonealization, omental transposition, and placement of absorbable mesh slings.

Various pharmacologic interventions have also been described to reduce the side effects of radiation enteritis. Angiotensin-converting enzyme inhibitors and statins significantly reduce acute gastrointestinal symptoms during radical pelvic radiotherapy. Sucralfate, a highly sulfated polyanionic disaccharide thought to stimulate epithelial healing and thereby form a protective barrier over damaged mucosal surfaces, may help in the treatment of bleeding from radiation proctitis, but no evidence exists supporting its use in the prevention of radiation-induced small bowel disease. Superoxide dismutase, a free radical scavenger, has been used successfully to reduce complications. Other compounds that have been evaluated include glutathione, antioxidants (e.g., vitamin A, vitamin E, beta-carotene), histamine antagonists, and the combination of pentoxifylline and tocopherols, a class of chemical compounds with vitamin E activity. There is currently a double-blind randomized controlled trial investigating the use of probiotics as a radioprotective agent for the gut. Amifostine (WR-2721), a sulfhydryl compound that is converted intracellularly to an active metabolite, WR-1065, which in turn binds to free radicals,

BOX 91.8 Prevention of Radiation-Induced Small Bowel Disease

Clinical Guidance

Use of modern imaging and radiotherapy techniques to minimize radiation exposure to normal tissues

Consideration of circadian rhythm effects and use of evening radiotherapy sessions

Continuation of angiotensin-converting enzyme inhibitors and statins and consideration of their introduction if appropriate

Consideration of the use of probiotics

Consideration of surgical techniques to minimize radiation exposure to the small bowel if appropriate and surgical team is experienced and competent at the procedure involved

Adapted from Stacey R, Green JT. Radiation-induced small bowel disease: latest developments and clinical guidance. *Ther Adv Chronic Dis.* 2014;5:15-29.

has also been used to protect the cell from radiation injury. Glutamine has been found to offer little benefit, even when it is used before or during radiation therapy.

The treatment of acute radiation enteritis is directed at controlling symptoms. Antispasmodics and analgesics may alleviate abdominal pain and cramping, and diarrhea usually responds to opiates or other antidiarrheal agents. The use of corticosteroids for acute radiation enteritis is of uncertain value. Dietary manipulation, including oral elemental diets, has also been advocated to ameliorate the acute effects of radiation enteritis; however, results are conflicting. Antibiotics are frequently used in the setting of bacterial overgrowth. Bile acid malabsorption, thought to be partially responsible for diarrheal symptoms in some patients with radiation-induced small bowel disease, responds well to cholestyramine, but it is not well tolerated, and many patients voluntarily discontinue use.

Approximately 30% of patients with radiation enteritis will require operative intervention.[47] Indications for operation include obstruction, fistula formation, perforation, and bleeding, with obstruction being the most common presentation. Operative procedures include a bypass or resection with reanastomosis. Previously, bypass was strongly advocated for as a safer procedure and reduces the risk of anastomotic leaks. However, recent studies have demonstrated resection with reanastomosis is safe if an appropriate resection of diseased bowel is performed. In patients presenting with obstruction, extensive lysis of adhesions should be avoided. Obstruction caused by rigid, fixed intestinal loops in the pelvis is best bypassed. If resection and reanastomosis are planned, at least one end of the anastomosis should be from intestine outside the irradiated field. Macroscopic inspection may not be accurate in evaluating the full extent of radiation damage. Frozen section and laser Doppler flowmetry techniques have been used to assist resection and anastomosis. Perforation of the intestine should be treated with resection and anastomosis. When reanastomosis is thought to be unsafe, the ends should be exteriorized.

Short Bowel Syndrome

Short bowel syndrome results from a total small bowel length that is inadequate to support nutrition. Short bowel syndrome occurs mostly from massive intestinal resection (i.e., midgut volvulus, mesenteric occlusion, traumatic disruption of the superior mesenteric vessels) or multiple sequential resections (i.e., patients with Crohn disease). In neonates, the most common causes of short bowel syndrome are bowel resection secondary to necrotizing enterocolitis and intestinal malformations. The clinical hallmarks of short bowel syndrome include diarrhea, fluid and electrolyte deficiency, and malnutrition. Other complications include an increased incidence of gallstones caused by disruption of the enterohepatic circulation and of nephrolithiasis from hyperoxaluria. Specific nutrient deficiencies must be prevented, and levels must be monitored closely; these nutrients include iron, magnesium, zinc, copper, and vitamins. The likelihood that a patient with short bowel syndrome will be permanently dependent on TPN is thought to be primarily influenced by the length, location, and health of the remaining intestine. In patients with short bowel syndrome, postabsorptive levels of plasma citrulline, a nonprotein amino acid produced by intestinal mucosa, may provide an indicator to differentiate transient from permanent intestinal failure.

The bowel has a remarkable capacity to adapt after small bowel resection; in many cases, this process of intestinal adaptation, termed *adaptive hyperplasia,* effectively prevents severe complications that result from the markedly decreased surface area available for absorption and digestion. However, any adaptive mechanism can be overwhelmed, and adaptation can be inadequate if too much small bowel is lost. Although there is considerable individual variation, resection of up to 70% of the small bowel usually can be tolerated if the terminal ileum and ileocecal valve are preserved. Length alone, however, is not the only determining factor of complications related to small bowel resection. For example, if the distal two-thirds of the ileum, including the ileocecal valve, is resected, significant abnormalities of absorption of bile salts and vitamin B_{12} may occur, resulting in diarrhea and anemia, although only 25% of the total length of the small bowel has been removed. Proximal bowel resection is tolerated better than distal resection because the ileum can adapt and increase its absorptive capacity more efficiently than the jejunum.

Treatment

The most important issue to remember about short bowel syndrome is prevention. In patients with Crohn disease, limiting bowel resections to only segments with a particular complication should be performed. In addition, during surgery for problems related to intestinal ischemia, the smallest possible resection should be performed, and if necessary, second-look operations should be carried out to allow the ischemic bowel to demarcate, thus potentially preventing unnecessary extensive resection of the bowel.

After massive small bowel resection, the treatment course may be divided into early and late phases. In its early phase, treatment is primarily directed at the control of diarrhea, replacement of fluid and electrolytes, and prompt institution of TPN in patients who cannot safely tolerate enteral feedings. Volume losses may exceed 5 L/day, and vigorous monitoring of intake and output with adequate replacement must be carried out. Diarrhea in this early phase can be caused by a multitude of sources. For example, hypergastrinemia and gastric hypersecretion occur after massive small bowel resection and can significantly contribute to diarrhea after a massive small bowel resection. Acid hypersecretion can be managed by H_2 receptor antagonists or proton pump inhibitors, such as omeprazole. Diarrhea may also be caused by ileal resection, resulting in disruption of the enterohepatic circulation and excessive amounts of bile salts entering the colon. Cholestyramine may be beneficial when diarrhea is related to the cathartic effects of unabsorbed bile salts in the colon. In addition, the judicious use of agents that inhibit gut motility (e.g., codeine, diphenoxylate) may be helpful. The long-acting SSA octreotide also appears to reduce the amount of diarrhea during the early phase of short bowel syndrome; however, it has an inhibitory effect on gut adaptation and is not generally recommended, particularly early during the gut adaptation period.

As soon as the patient has recovered from the acute phase, enteral nutrition should be started. Controversy exists about the optimal diet for these patients. Many different restrictive diets have been trialed, including purely elemental diets, high-carbohydrate, high-protein, and low-fat, without universal success. It is recommended to tailor the diet to the patient with consideration of their remaining anatomy, as different resections will have different absorptive deficits.[48] For example, in patients who retained their colon, a high-carbohydrate and low-fat diet is beneficial, whereas for patients without their colon (i.e., end jejunostomy), a low-fat diet is not beneficial. Guidelines suggest a focus on maintaining a patient's compensatory hyperphagia with at least a 50% increase in their estimated caloric needs split into small meals throughout the day. Vitamins, especially fat-soluble vitamins, as well as calcium, magnesium, and zinc supplementation should be provided. The roles of hormones administered systemically and glutamine administered enterally have been evaluated. The hormones neurotensin, growth hormone, bombesin, and glucagon-like peptide-2 (GLP-2) have demonstrated marked mucosal growth in a variety of experimental studies and have been shown to prevent gut atrophy associated with TPN in experimental studies; combination therapy appears more efficacious than single-agent administration. Randomized controlled trials showed that teduglutide, a GLP-2 analogue that is resistant to degradation by the proteolytic enzyme dipeptidyl peptidase 4 and therefore has a longer half-life than natural GLP-2, is well tolerated and led to the restoration of intestinal functional and structural integrity through significant intestinotrophic and proabsorptive effects. It is the first targeted therapeutic agent to gain approval for use in short bowel syndrome in both pediatric and adult patients with intestinal failure.

Two other hormones, not derived from the gut, that have been evaluated extensively in various experimental and limited clinical trials include growth hormone. Although trials demonstrated the use of growth hormone may show some benefit in terms of body weight, lean body mass, and absorptive capacity, it is no longer recommended for use in this population because of side effects and poor long-term efficacy.

The first step in terms of surgical intervention is to restore digestive continuity, which can be accomplished by the reversal of a proximal stoma to reduce rates of dehydration. A number of surgical strategies have been attempted in patients who are chronically TPN dependent, with limited success; these include procedures to delay intestinal transit time, methods to increase absorptive area, and small bowel transplantation. Methods to delay intestinal transit time include the construction of various valves and sphincters, with inconsistent results reported. Antiperistaltic segments of small intestine have been constructed to slow the transit, thus allowing additional contact time for nutrient and fluid absorption. Moderate successes have been described with this technique. Other procedures, including colonic interposition, recirculating loops of small bowel, and retrograde electrical pacing, have been tried but were found to be unsuccessful in humans and were largely abandoned. Surgical procedures to increase absorptive area include the intestinal tapering and lengthening procedure (e.g., Bianchi procedure), which improves intestinal function by correcting the dilation and ineffective peristalsis of the remaining intestine and by doubling the intestinal length while preserving the mucosal surface area. Serial transverse enteroplasty creates staple lines parallel to the mesenteric blood supply on alternating sides to create a channel of intestine that is both longer and smaller in diameter. This technique also increases the surface area of bowel for nutritional absorption. Although beneficial in selected patients, potential complications can include necrosis of divided segments because of poor vasculature, stenosis from smaller caliber of bowel, and anastomotic leaks.

Intestinal transplantation remains the standard of care for patients for whom intestinal rehabilitation attempts have failed and who are at risk of life-threatening complications of TPN; these include impending liver failure, thrombosis of more than two major access veins, frequent severe line infections, and dehydration. Patient survival after intestinal transplantation has significantly improved with the use of the immunosuppressive agents alemtuzumab and tacrolimus and transplantation at a high volume center (≥10 grafts per year). The 5-year survival rates for isolated intestinal transplantation are over 65%. The challenges of small bowel transplantation continue to require better immunosuppression and earlier detection of rejection.

Vascular Compression of the Duodenum

Vascular compression of the duodenum, also known as *superior mesenteric artery syndrome* or *Wilkie syndrome,* is a rare condition characterized by compression of the third portion of the duodenum by the superior mesenteric artery as it passes over this portion of the duodenum. Symptoms include profound nausea and vomiting, abdominal distention, weight loss, and postprandial epigastric pain, which varies from intermittent to constant, depending on the severity of the duodenal obstruction. Weight loss usually occurs before the onset of symptoms and contributes to the syndrome.

This syndrome is most commonly seen in young asthenic individuals, with females more commonly affected than males. Predisposing factors for vascular compression of the duodenum, aside from weight loss, include supine immobilization, scoliosis, and placement of a body cast, sometimes called the *cast syndrome*. An association between vascular compression of the duodenum and peptic ulcer has been observed. Vascular compression of the duodenum has been reported in association with anorexia nervosa and after proctocolectomy and J-pouch anal anastomosis, resection of an arteriovenous malformation of the cervical cord, abdominal aortic aneurysm repair, and orthopedic procedures, usually spinal surgery.

Diagnosis of this condition is made by a barium upper gastrointestinal series, which demonstrates abrupt or near-total cessation of flow of barium from the duodenum to the jejunum. CT imaging is used to establish the angle of the superior mesenteric artery coming off the aorta. Conservative measures should be tried initially and have been increasingly successful as definitive treatment. The main component of conservative management is nutrition. Operative management may include duodenojejunostomy, gastrojejunostomy to bypass the obstructing segment, or duodenal derotation (Strong procedure).

ANATOMY

The average pancreas weighs around 100 g and, in the adult, measures 14 to 20 cm in length. It lies in the retroperitoneum just anterior to the first lumbar vertebra and is anatomically divided into five sections, the head, uncinate, neck, body, and tail. The head lies to the right of midline within the C loop of the duodenum, immediately anterior to the vena cava at the confluence of the renal veins. The uncinate process extends from the head of the pancreas behind the superior mesenteric vein (SMV) and terminates adjacent to the superior mesenteric artery (SMA). The neck is the short segment of pancreas that immediately overlies the SMV. The body and tail of the pancreas then extend across the midline, anterior to Gerota fascia and slightly cephalad, terminating within the splenic hilum (Fig. 92.1).

Arterial Blood Supply

The pancreas is supplied by a complex arterial network arising from the celiac trunk and SMA. It can be divided into two main regions: the head and the body/tail of the pancreas. There can be several arterial variations, with the conventional anatomy being the most common. The gastroduodenal artery (GDA) provides the main arterial supply to the pancreatic head. The tributaries of the gastroduodenal artery, the anterior and posterior superior pancreatoduodenal arteries, supply the respective aspects of the pancreatic head. They branch and form arcades with tributaries of the SMA (the anterior and posterior inferior pancreatoduodenal arteries). These arterial arcades are located in the soft tissue of the pancreatoduodenal groove, at the bottom of the natural crevice between the duodenal wall and the anterior or posterior pancreatic surface, respectively. The inferior pancreaticoduodenal artery arises from SMA and also divides into anterior and posterior branches as it runs superiorly within the pancreaticoduodenal groove. It is often visible as a plexus of arterial vessels in the mediocaudal aspect of the pancreatic head.

The splenic artery provides the blood supply to the body and tail of the pancreas. It has several main branches (dorsal, inferior, and greater pancreatic arteries), which form an anastomosing network around the pancreatic body and tail up to the neck of the pancreas. At the neck, communicating anastomoses between the splenic and pancreatoduodenal arterial systems commonly occur. The greater pancreatic artery, a large tributary of the splenic artery, penetrates the pancreas and provides branches that run parallel to the main pancreatic duct (MPD) and form anastomoses with the other tributaries of the splenic artery. The interlobular and intralobular arteries extend as branches of the greater pancreatic artery.

Venous Drainage

The venous drainage parallels the arterial supply, with blood flow from the head of the pancreas draining into the anterior and posterior pancreaticoduodenal veins. The posterior superior pancreaticoduodenal vein enters the SMV laterally at the superior border of the neck of the pancreas. The anterior superior pancreaticoduodenal vein enters the right gastroepiploic vein just before its confluence with the SMV at the inferior border of the pancreas. The

anterior and posterior inferior pancreaticoduodenal veins enter the SMV along the inferior border of the uncinate process. The remaining body and tail are drained through the splenic venous system.

Lymphatic Drainage

Understanding the lymphatic drainage of the pancreas is paramount to performing an appropriate oncologic resection. The pancreas can be thought of as having four quadrants of primary drainage. The tissue in the left side of the gland drains to lymph nodes in the splenic hilum or gastrosplenic omentum via lymphatics along the superior and inferior border of the pancreas. Small lymph nodes are present along this drainage pathway. Tissue in the right side of the gland drains superiorly to gastroduodenal lymph nodes and inferiorly to infrapancreatic lymph nodes. Again, small lymph nodes are present along these lymphatic channels. These four pathways form a “ring” around the border of the pancreas. A secondary drainage pathway occurs via retropancreatic lymph nodes located anterior to the aorta between the celiac and SMA. These lymph nodes can receive drainage either directly from the pancreatic tissue (first-order lymph nodes) or from the “ring” (second order).[1] A schematic of this drainage is shown in Fig. 92.2.

Innervation

The pancreas is innervated by both the sympathetic (through splanchnic nerves) and parasympathetic (via the vagus nerve) nervous systems. The sympathetic nerve fibers originate from the neural bodies in the thoracic region of the spinal cord and connect with neurons in the abdominal plexus (e.g., the celiac node). The postganglionic fibers from these neurons follow the arterial routes to the pancreas. Meanwhile, the parasympathetic vagal efferent nerves end at nodes within the pancreatic tissue, where their postganglionic fibers extend to the acinar cells, islets of Langerhans, and pancreatic ducts.

To alleviate pain associated with pancreatic cancer that infiltrates the celiac plexus, a local anesthetic (e.g., xylocaine) is administered directly via celiac node infiltration during endoscopic ultrasound (EUS).

Embryology

The exocrine pancreas begins development during the fourth week of gestation. Pluripotent pancreatic epithelial stem cells give rise to exocrine and endocrine cell lines as well as the intricate pancreatic ductal network. Initially, dorsal and ventral buds appear from the primitive duodenal endoderm (Fig. 92.3A). The dorsal bud typically appears first and ultimately develops into the superior head, neck, body, and tail of the mature pancreas. The ventral bud develops as part of the hepatic diverticulum and maintains communication with the biliary tree throughout development. The ventral bud will become the inferior part of the head and uncinate process of the gland. Between the fourth and eighth weeks of gestation, the ventral bud rotates posteriorly in a clockwise fashion to fuse with the dorsal bud (see Fig. 92.3B). At approximately 8 weeks of gestation, the dorsal and ventral buds are fused (see Fig. 92.3C).

The initiation of pancreas bud formation and differentiation of the ventral bud from the hepatic-biliary fates is dependent on the expression of pancreatic duodenal homeobox 1 (PDX1) protein and pancreas-specific transcription factor 1 (PTF1). In the absence of PDX1 expression in mice, pancreatic agenesis occurs, indicating its importance in the early phases of organogenesis. PTF1 expression is first detectable shortly after PDX1 in cells of the early endoderm, which will become the dorsal and ventral pancreas. By lineage analysis, 95% of acinar cells express PTF1. In PTF1 null mice, acini do not form. The notch signaling pathway

is also critical to duct and acinar differentiation. In the absence of notch signaling, embryonic cells commit to endocrine lineage, suggesting that notch signaling is vital to exocrine differentiation. In addition to PDX1, PTF1, and notch signaling, complex interactions between mesenchymal growth factors, such as transforming growth factor-β (TGF-β), and other signaling pathways, including hedgehog and Wnt, seem to play critical roles in pancreas development.[2] The precise interactions that lead to normal organogenesis continue to be defined. Table 92.1 summarizes the factors and pathways that affect pancreas development.[2]

Pancreas Divisum

During normal organogenesis, the primitive ducts of both the dorsal and ventral buds contribute to the mature ductal system of

TABLE 92.1 Molecular Factors and Pathways Associated With Pancreatic Organogenesis

GENE	RELEVANCE
PDX1	Critical role in exocrine differentiation; knockout mice develop primitive pancreatic buds but agenesis of the organ
PTF1	Coexpression with *PDX1* determines progenitor cells to pancreatic fate
Notch signaling pathway	Suppresses endocrine differentiation, promoting exocrine development via induction of *Hes1* transcription factor; prolonged notch expression prevents acinar formation via *RBP-Jκ* binding of *Ptf1a*
Hedgehog	Inhibition of hedgehog in *PDX1*-positive cells leads to initiation of endoderm differentiation into pancreas lineage
Wnt	Complex Wnt signaling is important in all aspects of pancreas development; lack of Wnt signaling results in varying levels of pancreatic agenesis
Neurogenin 3	Repressed by notch signaling, drives endocrine lineage differentiation.
Arx and *Pax-4*	*Arx* expression favors α/PP cell differentiation, whereas *Pax-4* expression favors β versus δ cell differentiation, depending on length of exposure.

the pancreas. These ducts fuse together such that the proximal aspect of the dorsal duct forms the duct of Santorini, whereas the distal aspect combines with the duct of the ventral bud to form the duct of Wirsung. The duct of Wirsung is generally the major exocrine drainage pathway of the pancreas, joins the common bile duct at the ampulla of Vater, and enters the duodenum through the major papilla. The duct of Santorini may drain through a minor papilla that is more proximal in the duodenum. Failure of the dorsal and ventral ducts to fuse during embryogenesis leads to pancreas divisum, the most common congenital anomaly of the pancreas. This condition is identified by a ventral pancreatic duct and common bile duct that enter the duodenum through a major papilla, whereas a dorsal pancreatic duct enters through a minor papilla that is slightly proximal (Fig. 92.4). Because most pancreatic exocrine secretions exit through the dorsal duct, pancreas divisum can lead to a condition of partial obstruction caused by a small minor papilla, leading to chronic backpressure in the duct. This relative outflow obstruction has been implicated in the development of relapsing acute or chronic pancreatitis. Although 10% of the population is affected by pancreas divisum, only rarely do affected individuals develop pancreatitis.

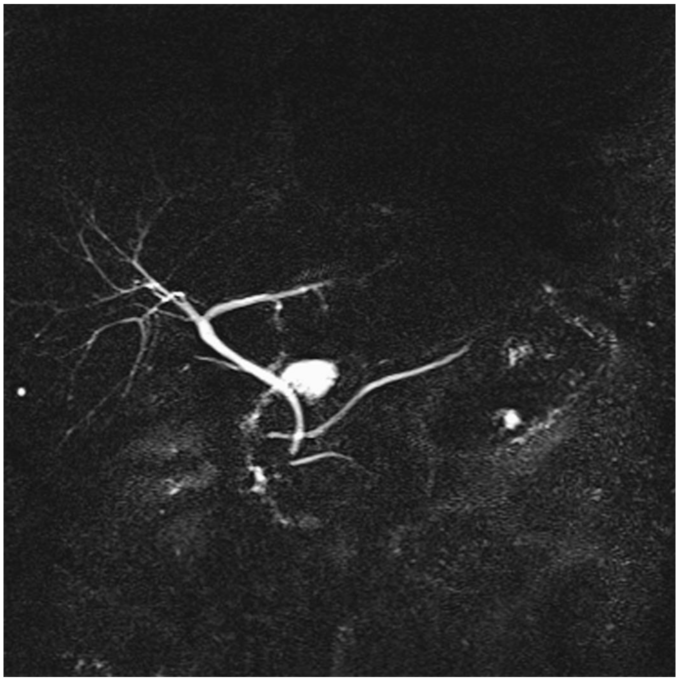

FIGURE 92.4 MRCP showing pancreas divisum, with the dorsal pancreatic duct draining through the minor papilla and the ventral pancreatic duct joining the biliary tree draining through the major papilla. *MRCP*, Magnetic resonance cholangiopancreatography.

Annular Pancreas

Annular pancreas results from aberrant migration of the ventral pancreas bud, which leads to circumferential or near-circumferential pancreas tissue surrounding the second portion of the duodenum. This abnormality may be associated with other congenital defects, including Down syndrome, malrotation, intestinal atresia, and cardiac malformations. At a molecular level, formation of annular pancreas may result from reduced hedgehog signaling.[3] If symptoms of obstruction occur, surgical bypass through duodenojejunostomy is performed instead of dividing the pancreatic tissue because this annular pancreas has a pancreatic duct, and its division will likely lead to pancreatic fistula formation.

Ectopic Pancreas

Ectopic pancreas may arise anywhere along the primitive foregut but is most common in the stomach, duodenum, and Meckel diverticulum. Clinically, ectopic nodules may result in bowel obstruction caused by intussusception, bleeding, or ulceration. They can sometimes be found incidentally as firm yellow nodules that arise from the submucosa. Although there have been rare case reports of adenocarcinoma arising in ectopic pancreas tissue, resection is not necessary unless symptoms occur.

PHYSIOLOGY

The human pancreas is a complex gland with endocrine and exocrine functions. It is mainly composed of acinar cells (85% of the gland) and islet cells (2%) embedded in a complex extracellular matrix, which composes 10% of the gland. The remaining 3% to 4% of the gland is composed of the epithelial duct system and blood vessels.

Major Components of Pancreatic Juice

The main function of the exocrine pancreas is to provide most of the enzymes needed for alimentary digestion. The cells responsible for the synthesis and secretion of these enzymes are grouped into an acinus. These acinar cells have a characteristic pyramidal shape, with a wide basophilic basal portion in contact with vessels and nerves and a narrow acidophilic apical portion that opens onto a duct where enzymes can be released. Acinar cells synthesize many enzymes that digest food proteins, such as trypsin, chymotrypsin, carboxypeptidase, and elastase. Under physiologic conditions, acinar cells synthesize these proteases as inactive proenzymes that are stored as intracellular zymogen granules. With stimulation of the pancreas, these proenzymes are secreted into the pancreatic duct and, eventually, the duodenal lumen. The duodenal mucosa expresses enterokinase on its brush boarder, which catalyzes the enzymatic activation of trypsin from trypsinogen.[4] Trypsin also plays an important role in protein digestion by propagating pancreatic enzyme activation through autoactivation of trypsinogen and other proenzymes, such as chymotrypsinogen, procarboxypeptidase, and proelastase. Fig. 92.5 summarizes the mechanisms of pancreatic exocrine secretion.

In addition to protease production, acinar cells also produce pancreatic amylase and lipase, also known as *glycerol ester hydrolase,* as active enzymes. With the exception of cellulose, pancreatic amylase hydrolyzes major polysaccharides into small oligosaccharides, which can be further digested by the oligosaccharidases present in the duodenal and jejunal epithelium. Pancreatic lipase hydrolyzes ingested fats into free fatty acids and 2-monoglycerides. In addition to pancreatic lipase, acinar cells produce other enzymes that digest fat, but they are secreted as proenzymes, like the proteases previously mentioned. These include colipase, cholesterol ester hydrolase, and phospholipase A2. The main function of colipase is to stabilize the activity of pancreatic lipase in the presence of bile salts. Pancreatic acinar cells also secrete deoxyribonuclease and ribonuclease, enzymes required for the hydrolysis of DNA and RNA, respectively.

Pancreatic enzymes are inactive inside acinar cells because they are synthesized and stored as inactive enzymes. In addition to this autoprotective mechanism, acinar cells synthesize pancreatic secretory trypsin inhibitor, which also protects acinar cells from autodigestion because it counteracts premature activation of trypsinogen inside acinar cells. Pancreatic secretory trypsin inhibitor is encoded by the serine protease inhibitor Kazal type 1 *(SPINK1)* gene. *SPINK1* gene mutations are associated with the development of chronic pancreatitis, especially in childhood.

The primary function of pancreatic duct cells is to provide the water and electrolytes required to dilute and deliver the enzymes synthesized by acinar cells. Although the concentrations of sodium and potassium are similar to their respective concentrations in plasma, the concentrations of bicarbonate and chloride vary significantly according to the secretion phase.

The mechanism responsible for the secretion of bicarbonate was first described in 1988 on the basis of in vitro studies. According to this model, extracellular CO_2 diffuses across the basolateral membrane of ductal cells. Once CO_2 is inside pancreatic duct cells, it is hydrated by intracellular carbonic anhydrase; as a result of this reaction, HCO_3^- and H^+ are generated. The apical membrane of pancreatic duct cells contains an anion exchanger that secretes intracellular HCO_3^- into the lumen of the cell and favors the exchange of luminal Cl^- inside the ductal epithelium. Studies have shown that this exchanger interacts with the cystic fibrosis transmembrane conductance regulator (CFTR); mutations in the *CFTR* gene have been linked to chronic pancreatitis. This may correlate with the inability of patients with cystic fibrosis to secrete water and bicarbonate. Although the nature of this exchanger has not been completely elucidated, it is possible that this anion exchanger is an SLC26 family member. This family

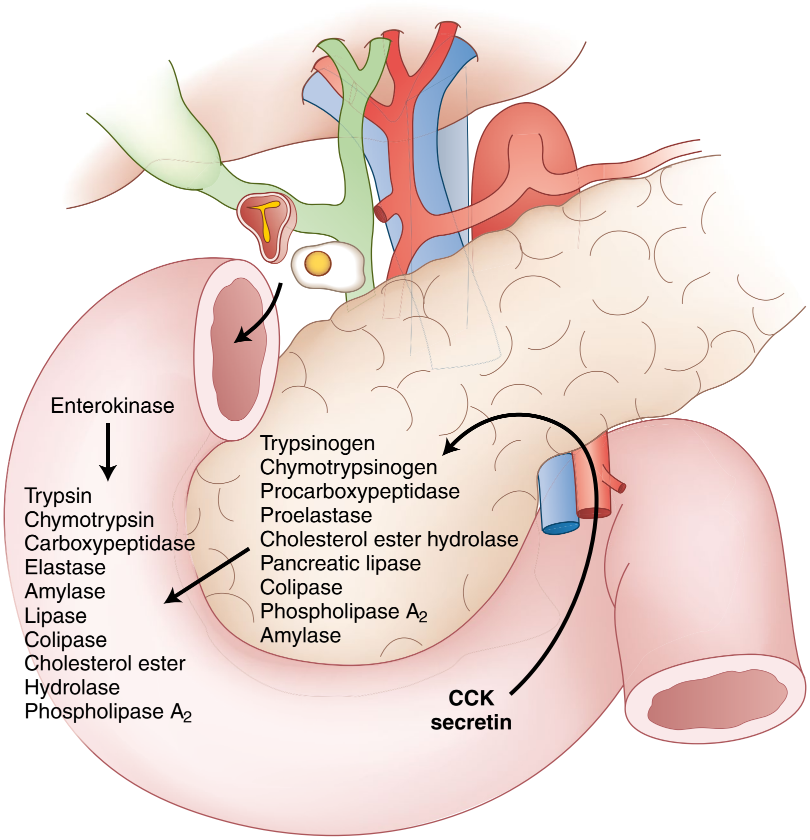

FIGURE 92.5 Physiology of the secretion of pancreatic enzymes. The presence of peptides and fatty acids from food triggers the release of cholecystokinin *(CCK).* CCK induces the release of pancreatic enzymes into the duodenal lumen. Conversely, S cells located in the duodenum release secretin in response to the acidification of the duodenum. Secretin induces the secretion of HCO_3^- from pancreatic cells into the duodenum.

contains different anion exchangers that transport monovalent and divalent anions, such as Cl^- and HCO_3^-. Some of these exchangers are known to interact with CFTR. Thus, HCO_3^- level in the pancreatic juice varies inversely to the Cl^- level. Secretin hormone is the major stimulator of the HCO_3^- secretion. Cholecystokinin (CCK) weakly stimulates HCO_3^- secretion and also synergizes with the effect of secretin.

In addition to HCO_3^- CO_2 hydration also generates H^+ ions, which are secreted by Na^+ and H^+ exchangers present in the basolateral membrane of ductal cells. These exchangers belong to the *SLC9* gene family. The main function of these exchangers is to maintain the intracellular pH within a physiologic range. In addition, the basolateral membrane of duct cells contains multiple Na^+,K^+-ATPases that provide the primary force that drives HCO_3^- secretion; the Na^+,K^+-ATPase maintains the Na^+ gradient used to extrude H^+ as well. Finally, K^+ channels present in the basolateral membrane of acinar cells maintain the membrane potential to allow recirculation of K^+ ions brought by the Na^+,K^+ pump inside the cell. Fig. 92.6 illustrates HCO_3^- secretion inside pancreatic duct cells. The level of Na^+ and K^+ in pancreatic juice remains relatively constant, without much variation with the secretory rate.

Once the HCO_3^- secreted by pancreatic duct cells reaches the duodenal lumen, it neutralizes the hydrochloric acid secreted by gastric parietal cells. Pancreatic enzymes are inactivated at a low pH; therefore, pancreatic bicarbonate provides an optimal pH for pancreatic enzyme function. The optimal pH for the function of chymotrypsin and trypsin is 8.0 to 9.0; for amylase, the optimal pH is 7.0; and for lipase, it is 7.0 to 9.0.

Phases and Regulation of Pancreatic Secretion

Pancreatic exocrine secretion occurs during the interdigestive state and after the ingestion of food, which is also known as the *digestive state.* The same phases of secretion that have been identified in the stomach during the digestive state have also been described in pancreatic secretion. The first phase is the cephalic phase, in which the pancreas is stimulated by the vagus nerve in response to the sight, smell, or taste of food. This phase is generally mediated by the release of acetylcholine at the terminal endings of postganglionic fibers. The main effect of acetylcholine is to induce acinar cell secretion of enzymes. This phase accounts for 20% to 25% of the daily secretion of pancreatic juice. Every day, 1.5 to 2 L of pancreatic juice is released into the duodenum.

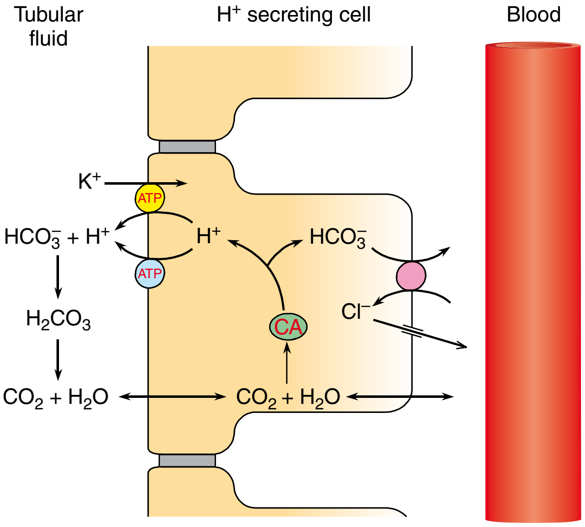

FIGURE 92.6 Concentration, dilution, and acidification of urine. Cellular mechanism for secretion of H^+ and reabsorption of HCO_3^- by intercalated cells of the late distal tubule and collecting ducts. (From Khurana I, Khurana A, Kowlgi NG. *Textbook of Medical Physiology.* 4th ed. Elsevier; 2025: Fig. 6.3.)

The second phase of pancreatic secretion is known as the *gastric phase.* It is mediated by vagovagal reflexes triggered by gastric distention after the ingestion of food. These reflexes induce acinar cell secretion. It accounts for 10% of the pancreatic juice produced daily.

The most important phase of pancreatic secretion is the intestinal phase, which accounts for 65% to 70% of the total secretion of pancreatic juice. It is mediated by secretin and CCK. Acidification of the duodenal lumen induces the release of secretin by S cells. Secretin was the first polypeptide hormone identified and was first discovered more than 100 years ago. It is the most important mediator of the secretion of water, bicarbonate, and other electrolytes into the duodenum. Secretin receptors are located in the basolateral membrane of all pancreatic duct cells but cannot be identified in other pancreatic components, such as islet cells, blood vessels, or extracellular matrix. The most important effect of secretin stimulation is an increase of intracellular cyclic adenosine monophosphate, which activates the HCO_3^--Cl^- anion exchanger in the apical membrane of pancreatic duct cells. It also increases the activity of the enzyme carbonic anhydrase, the excretion of H^+ outside the duct cell, and the activity of the CFTR.

The presence of lipid, protein, and carbohydrates inside the duodenum induces the secretion of CCK-releasing factor and monitor peptide. Both peptides induce release of CCK by I cells present in the duodenal mucosa. Whereas secretin is the main mediator of the secretion of water and bicarbonate in the intestinal phase, CCK is the main mediator of the secretion of pancreatic enzymes. CCK exerts a number of effects:

1. CCK travels through the bloodstream and induces the release of pancreatic enzymes by acinar cells.
2. CCK induces local duodenal vagovagal reflexes that cause the release of acetylcholine, vasoactive intestinal peptide, and gastrin-releasing peptide, which promotes the release of pancreatic enzymes.
3. CCK induces the relaxation of the sphincter of Oddi. Also, CCK potentiates the effects of secretin, and vice versa.

ACUTE PANCREATITIS

The incidence of acute pancreatitis (AP) has increased during the past 20 years. AP is responsible for more than 300,000 hospital admissions annually in the United States. Most patients develop a mild and self-limited course; however, 10% to 20% of patients have a rapidly progressive inflammatory response associated with prolonged length of hospital stay and significant morbidity and mortality. Patients with mild pancreatitis have a mortality rate of less than 1%, but in severe pancreatitis, this increases up to 10% to 50%.[5] The highest mortality rates in this group of patients are those who present with multiple organ dysfunction syndrome. Mortality in pancreatitis has a bimodal distribution. In the first 2 weeks (early phase), it is a result of multiple organ dysfunction caused by the intense inflammatory cascade triggered by pancreatic inflammation. Mortality after 2 weeks (late phase) is often caused by septic complications.[4]

Pathophysiology

The exact mechanism whereby predisposing factors such as ethanol and gallstones produce pancreatitis is not completely known. Most researchers believe that AP is the final result of abnormal pancreatic enzyme activation inside acinar cells. Immunolocalization studies have shown that after 15 minutes of pancreatic injury, both zymogen granules and lysosomes colocalize inside the acinar cells. The fact that zymogen and lysosome colocalization occurs before amylase level elevation, pancreatic edema, and other markers of pancreatitis are evident suggests that colocalization is an early step in the pathophysiologic process and not a consequence of pancreatitis. Studies also suggest that lysosomal enzyme cathepsin B activates trypsin in these colocalization organelles. In vitro and in vivo studies have elucidated an intricate model of acinar cell death induced by premature activation of trypsin. In this model, once cathepsin B in lysosomes and trypsinogen in zymogen granules are brought in contact by colocalization induced by pancreatitis-inciting stimuli, activated trypsin then induces leak of colocalized organelles, releasing cathepsin B into the cytosol. It is the cytosolic cathepsin B that then induces apoptosis or necrosis, leading to acinar cell death. Thus, acinar cell death and, to a degree, the inflammatory response seen in AP can be prevented if acinar cells are pretreated with cathepsin B inhibitors. In vivo studies have also shown that cathepsin B knockout mice have a significant decrease in the severity of pancreatitis.[6]

Intraacinar pancreatic enzyme activation induces autodigestion of normal pancreatic parenchyma. In response to this initial insult, acinar cells release proinflammatory cytokines, such as tumor necrosis factor-α (TNF-α) and interleukin (IL)-1, IL-2, and IL-6, and antiinflammatory mediators, such as IL-10 and IL-1 receptor antagonist. These mediators do not initiate pancreatic injury but propagate the response locally and systemically. As a result of TNF-α, IL-1, and IL-6, neutrophils and macrophages are recruited into the pancreatic parenchyma and cause the release of more TNF-α, IL-1, and IL-6; reactive oxygen metabolites; prostaglandins; platelet-activating factor; and leukotrienes.[7] The local inflammatory response further aggravates the pancreatitis because it increases vascular permeability and damages the microcirculation of the pancreas. In severe cases, the inflammatory response causes pancreatic necrosis and hemorrhage in the pancreas or retroperitoneum. In addition, some of the inflammatory mediators released by neutrophils aggravate the pancreatic injury because they cause pancreatic enzyme activation. The dead, necrotic pancreatic tissue can become infected. The pathophysiology is from translocation of gut bacteria into the portal system, which seeds the pancreas. Accordingly, antibiotics should be selected for gram negatives and GI flora, with Imipenem considered the most effective because of its favorable pharmacokinetic pancreatic tissue perfusion. Long-lasting functional impairments, such as exocrine and endocrine deficiencies, can result from necrosis of pancreatic tissue.

In addition to the local pancreatic inflammation and destruction, there can be a massive release of inflammatory mediators to the systemic circulation. Systemic consequences such as sepsis, renal failure, and acute lung injury contribute to the high mortality in this group. A summary of the inflammatory cascade seen in AP is shown in Fig. 92.7.

Death

FIGURE 92.7 Pathophysiology of severe acute pancreatitis. The local injury induces the release of tumor necrosis factor-α *(TNF-α)* and interleukin-1 *(IL-1)*. Both cytokines produce further pancreatic injury and amplify the inflammatory response by inducing the release of other inflammatory mediators, which cause distant organ injury. This abnormal inflammatory response is responsible for the mortality seen during the early phase of acute pancreatitis. *ERCP,* Endoscopic retrograde cholangiopancreatography; *PAF,* platelet-activating factor.

Risk Factors

Gallstones and ethanol abuse account for 70% to 80% of AP cases.[8] In pediatric patients, abdominal blunt trauma and systemic diseases are the two most common conditions that lead to pancreatitis. Autoimmune and drug-induced pancreatitis should be a differential diagnosis in patients with rheumatologic conditions such as systemic lupus erythematosus and Sjögren syndrome.

Biliary or Gallstone Pancreatitis

Gallstone pancreatitis is the most common cause of AP in the West. It accounts for 40% of US cases. The overall incidence of AP in patients with symptomatic gallstone disease is 3% to 8%. It is seen more frequently in females between 50 and 70 years of age. The exact mechanism that triggers pancreatic injury has not been completely understood, but two theories have been proposed.[9] In the obstructive theory, pancreatic injury is the result of excessive pressure inside the pancreatic duct. This increased intraductal pressure is the result of continuous secretion of pancreatic juice in the presence of pancreatic duct obstruction. Animal studies suggest that high intraductal pressure initiates pancreatitis through a mechanism dependent on calcineurin signaling.[10] The second, or reflux, theory proposes that stones become impacted in the ampulla of Vater and form a common channel that allows bile salt reflux into the pancreas. Animal models have shown that bile salts cause direct acinar cell necrosis because they increase the concentration of calcium in the cytoplasm; however, this has never been proven in humans.[4]

Alcohol-Induced Injury

Excessive ethanol consumption is the second most common cause of AP worldwide. It accounts for 35% of cases and is more prevalent in young males (30–45 years of age) than in females. However, only 5% to 10% of patients who drink alcohol develop AP. Factors that contribute to ethanol-induced pancreatitis include heavy ethanol abuse (>100 g/day for at least 5 years), smoking, and genetic predisposition. Compared with nonsmokers, the relative risk of alcohol-induced pancreatitis in smokers is 4.9.[11]

Alcohol has a number of deleterious effects on the pancreas, and its mechanism of injury is likely multifaceted. It has been shown to (1) trigger proinflammatory pathways via upregulation of nuclear factor κB (NF-κB), TNF-α, and IL-1; (2) cause inappropriate basolateral exocytosis of pancreatic zymogens; (3) result in increased autophagy, possibly as a result of dysregulation of cathepsin L and B; (4) cause increased oxidative stress, leading to mitochondrial dysfunction; (5) cause activation of pancreatic stellate cells (PSCs), leading to increased secretion of matrix metalloproteases; (6) cause impaired pancreatic cell repair as a result of dysregulation in developmental factors PDX1, PTF1a, and Notch; and (7) result in a shift in cell death from apoptosis to necrosis by decreasing caspase 3/8 activity and through loss of adenosine triphosphate (ATP) production via mitochondrial depolarization.[12]

Anatomic Obstruction

Abnormal flow of pancreatic juice into the duodenum can result in pancreatic injury. AP has been described in patients with pancreatic tumors, parasites, and congenital defects.

Pancreas divisum is an anatomic variation present in 10% of the population. Its association with AP is controversial. Patients with this variation have a 5% to 10% lifetime risk for development of AP caused by relative outflow obstruction through the minor papilla. Endoscopic retrograde cholangiopancreatography (ERCP) with minor papillotomy and stenting may be beneficial for such patients.

Infrequent anatomic obstructions that have been associated with AP include *Ascaris lumbricoides* infection and annular pancreas. Although pancreatic cancer can also cause ductal obstruction and should be considered in the differential diagnosis, patients with pancreatic cancer usually do not develop AP.

Endoscopic Retrograde Cholangiopancreatography–Induced Pancreatitis

AP is the most common complication after ERCP, occurring in up to 5% of patients. However, the incidence of this complication after ERCP can be as high as 15% in high-risk patients. Post-ERCP pancreatitis is more common in female patients, young individuals, and patients with prior history of ERCP-induced pancreatitis. AP occurs more frequently in patients who have undergone therapeutic procedures compared with diagnostic procedures. It is also more common in patients who have had multiple attempts of cannulation, sphincter of Oddi dysfunction, and abnormal visualization of the secondary pancreatic ducts after injection of contrast material. The clinical course is mild in 90% to 95% of patients. ERCP-induced pancreatitis is one of the rare opportunities where primary prevention of development of AP may be possible. First, ERCP should only be performed when absolutely necessary. With improvement in other diagnostic modalities, including magnetic resonance cholangiopancreatography (MRCP), the use of diagnostic ERCP with its associated complications, including ERCP-induced pancreatitis, has decreased. Among pharmacologic agents to prevent ERCP-induced pancreatitis, use of indomethacin has gained the most traction. Technique-related and interventional strategies that have been shown to reduce the risk of post-ERCP pancreatitis include use of pancreatic stents and use of minimal pressure while performing ERCP.

Drug-Induced Pancreatitis

Up to 2% of AP cases are caused by medications. The most common agents include sulfonamides, metronidazole, erythromycin, tetracyclines, didanosine, thiazides, furosemide, 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins), azathioprine, 6-mercaptopurine, 5-aminosalicylic acid, sulfasalazine, valproic acid, and human immunodeficiency virus antiretroviral agents.

Metabolic Factors

Hypertriglyceridemia and hypercalcemia can also lead to pancreatic damage. Direct pancreatic injury can be induced by triglyceride metabolites. It is more common in patients with type I, II, or V hyperlipidemia. It should be suspected in patients with a triglyceride level higher than 1000 mg/dL. A triglyceride level higher than 2000 mg/dL confirms the diagnosis. Hypertriglyceridemia secondary to hypothyroidism, diabetes mellitus, and alcohol does not typically induce AP.

Hypercalcemia is postulated to induce pancreatic injury through the activation of trypsinogen to trypsin and intraductal precipitation of calcium, leading to ductal obstruction and subsequent attacks of pancreatitis. Approximately 1.5% to 13% of patients with primary hyperparathyroidism develop AP.

Miscellaneous Conditions

Blunt and penetrating abdominal trauma can be associated with AP in 0.2% and 1% of cases, respectively. Prolonged intraoperative hypotension and excessive pancreatic manipulation during abdominal surgery can also result in AP. Pancreatic ischemia in association with acute pancreatic inflammation can develop after splenic artery embolization. Other rare causes include scorpion venom stings and perforated duodenal ulcers.

Clinical Manifestations

The cardinal symptom of AP is epigastric or periumbilical pain that radiates to the back. Up to 90% of patients have nausea or vomiting that typically does not relieve the pain. The nature of the pain is constant; therefore, if the pain disappears or decreases, another diagnosis should be considered.

Dehydration, poor skin turgor, tachycardia, hypotension, and dry mucous membranes are commonly seen in patients with AP. Severely dehydrated and older patients may also develop mental status changes.

The physical examination findings of the abdomen vary according to the severity of the disease. With mild pancreatitis, the physical examination findings of the abdomen may be normal or reveal only mild epigastric tenderness. Significant abdominal distention associated with generalized rebound and abdominal rigidity is present in severe pancreatitis. The nature of the pain described by the patient may not correlate with the physical examination findings or the degree of pancreatic inflammation.

Rare findings include flank and periumbilical ecchymosis (Grey Turner and Cullen signs, respectively). Both are indicative of retroperitoneal bleeding associated with severe pancreatitis. Patients with concomitant choledocholithiasis or significant edema in the head of the pancreas that compresses the intrapancreatic portion of the common bile duct can present with jaundice. Dullness to percussion and decreased breathing sounds in the left or, less commonly, in the right hemithorax suggest pleural effusion secondary to AP.

Diagnosis

The diagnosis of AP requires two of the following three features to be present according to the Revised Atlanta Classification (RAC): (1) abdominal pain consistent with AP (acute onset of a persistent, severe epigastric pain, often radiating to the back), (2) a threefold or higher elevation of serum amylase or lipase levels above the upper laboratory limit of normal, or (3) characteristics findings of pancreatitis by imaging.[13] The serum half-life of amylase (10 hours) is shorter than that of lipase (6.9–13.7 hours), and it therefore normalizes faster (3–5 vs. 8–14 days, respectively). In patients who do not present to the emergency department within the first 24 to 48 hours after the onset of symptoms, determination of lipase levels is a more sensitive indicator to establish the diagnosis. Lipase is also a more specific marker of AP because serum amylase levels can be elevated in a number of conditions, such as peptic ulcer disease, parotitis, cholecystitis, mesenteric ischemia, renal failure salpingitis, and macroamylasemia.

Patients with AP are typically hyperglycemic; they can also have leukocytosis and abnormal elevation of liver enzyme levels. Increased levels of hemoglobin and hematocrit suggest hypovolemia in the vascular space resulting from “third-spacing,” or the leakage of fluid into the retroperitoneum. The elevation of alanine aminotransferase levels in the serum in the context of AP confirmed by high pancreatic enzyme levels has a positive predictive value of 95% in the diagnosis of acute biliary pancreatitis.[9]

Imaging Studies

Imaging studies are not required for diagnosis but may be helpful in determining need for intervention in severe AP or elucidating an elusive etiology. Although simple abdominal radiographs are not useful for diagnosis of pancreatitis, they can help rule out other conditions, such as perforated ulcer disease. Nonspecific findings in patients with AP include air-fluid levels suggestive of ileus, cutoff colon sign as a result of colonic spasm at the splenic flexure, pleural effusions, and widening of the duodenal C loop caused by severe pancreatic head edema. Additionally, pancreatic calcifications can be indicative of underlying chronic pancreatitis.

The usefulness of ultrasound for diagnosis of pancreatitis is limited by intraabdominal fat and increased intestinal gas as a result of ileus. Nevertheless, this test should always be ordered in patients with AP because of its high sensitivity (95%) in diagnosing gallstones. Combined elevations of liver transaminase, elevated pancreatic enzyme levels, and the presence of gallstones on ultrasound have an even higher sensitivity (97%) and specificity (100%) for diagnosing acute biliary pancreatitis.

Contrast-enhanced computed tomography (CT) is currently the best modality for evaluation of the pancreas, especially if the study is performed with a multidetector CT scanner. Indications for CT include diagnostic uncertainty, confirmation of severity based on clinical predictors, failure to respond to conservative treatment, or clinical deterioration. The most valuable contrast phase in which to evaluate the pancreatic parenchyma is the portal venous phase (65–70 seconds after injection of contrast material), which allows evaluation of the viability of the pancreatic parenchyma, amount of peripancreatic inflammation, and presence of intraabdominal free air or fluid collections. Noncontrast CT scanning may also be of value in the setting of renal failure by identifying fluid collections or extraluminal air.

Abdominal magnetic resonance imaging (MRI) is also useful to evaluate the extent of necrosis, inflammation, and presence of free fluid. However, its applicability is limited by the higher cost, lower availability, and the fact that patients requiring imaging are more likely to be critically ill and in intensive care units. Although MRCP is not indicated in the acute setting of AP, it has an important role in the evaluation of patients with unexplained or recurrent pancreatitis because it allows complete noninvasive visualization of the biliary and pancreatic duct anatomy. For difficult-to-view pancreatic ducts, IV administration of secretin before imaging can cause a transient distention of the pancreatic duct by stimulating pancreatic juice secretion. Any pain associated with the timing of secretin stimulation should be noted because it may help in confirming an uncertain etiology of epigastric pain. For example, secretin-stimulated MRCP is useful in patients with AP and no evidence of a predisposing condition to rule out pancreas divisum, intraductal papillary mucinous neoplasm (IPMN), or a small tumor in the pancreatic duct.

In the setting of gallstone pancreatitis, EUS may play an important role in the evaluation of persistent choledocholithiasis. Several studies have shown that routine ERCP for suspected gallstone pancreatitis reveals no evidence of persistent obstruction in most cases and may actually worsen symptoms because of manipulation of the gland. EUS has been proven to be sensitive for identifying choledocholithiasis; it allows examination of the biliary tree and pancreas with no risk of worsening of the pancreatitis. In patients in whom persistent choledocholithiasis is confirmed by EUS, ERCP can be used selectively as a therapeutic measure.

Assessment of Severity of Disease

Several risk scores have been developed to predict outcome. The earliest scoring system designed to evaluate the severity of AP was introduced by Ranson and colleagues in 1974. It predicts the severity of the disease on the basis of 11 parameters obtained at the time of admission or 48 hours later. The mortality rate of AP directly correlates with the number of parameters that are positive. Severe pancreatitis is diagnosed if three or more of the Ranson criteria are fulfilled. The Ranson score has a low positive predictive value (50%) and high negative predictive value (90%). Therefore, it is mainly used to rule out severe pancreatitis or to predict the risk of mortality. The main disadvantage is that it does not predict the severity of disease at the time of the admission because six parameters are assessed only after 48 hours of admission. The original scoring symptom designed to predict the severity of the disease and its modification for acute biliary pancreatitis are shown in Boxes 92.1 and 92.2.

AP severity can also be addressed by the Acute Physiology and Chronic Health Evaluation (APACHE II) score. Based on the patient’s age, previous health status, and 12 routine physiologic measurements, APACHE II provides a general measure of the severity of disease. An APACHE II score of 8 or higher defines severe pancreatitis. The main advantage is that it can be used on admission and repeated at any time. However, it is complex, not specific for AP, and based on the patient’s age, which easily upgrades the AP severity score. Additionally, the required 12 variables are not routinely obtained in patients who are not critically ill. APACHE II has a positive predictive value of 43% and a negative predictive value of 89%.

The Bedside Index for Severity in Acute Pancreatitis (BISAP) score, created in 2008, gauges the risk of death from AP using five

BOX 92.1 Ranson Prognostic Criteria for Nongallstone Pancreatitis

At presentation

- Age >55 years
- Blood glucose level >200 mg/dL
- White blood cell count >16,000 cells/mm^3
- Lactate dehydrogenase level >350 IU/L
- Aspartate aminotransferase level >250 IU/L

After 48 hours of admission

- Hematocrit[a]: decrease >10%
- Serum calcium level <8 mg/dL
- Base deficit >4 mEq/L
- Blood urea nitrogen level: increase >5 mg/dL
- Fluid requirement >6 L
- PaO_2 <60 mm Hg

Ranson score ≥3 defines severe pancreatitis.

[a] Compared with admission value.

BOX 92.2 Ranson Prognostic Criteria for Gallstone Pancreatitis

At presentation

- Age >70 years
- Blood glucose level >220 mg/dL
- White blood cell count >18,000 cells/mm^3
- Lactate dehydrogenase level >400 IU/L
- Aspartate aminotransferase level >250 IU/L

After 48 hours of admission

- Hematocrit[a]: decrease >10%
- Serum calcium level <8 mg/dL
- Base deficit >5 mEq/L
- Blood urea nitrogen level: increase >2 mg/dL
- Fluid requirement >4 L
- PaO_2: Not available

Ranson score ≥3 defines severe pancreatitis.

[a] Compared with admission value.

criteria: elevated blood urea nitrogen (BUN) levels, altered mental state, systemic inflammatory response syndrome (SIRS), age over 60, and pleural effusion within 24 hours of admission. The lowest score is associated with <1% mortality risk, and the highest is associated with over 20% mortality risk. High BISAP scores also correlate with increased risks of organ failure and pancreatic necrosis. Its widespread use stems from its straightforwardness and easy computation.

C-reactive protein (CRP) is an inflammatory marker that peaks 48 to 72 hours after the onset of pancreatitis and correlates with the severity of the disease. A CRP level of 150 mg/mL or higher defines severe pancreatitis. The major limitation is that it cannot be used on admission; the sensitivity of the assay decreases if CRP levels are measured within 48 hours after the onset of symptoms. In addition to CRP, a number of studies have shown other biochemical markers (e.g., serum levels of procalcitonin, IL-6, IL-1, elastase) that correlate with the severity of the disease. However, their main limitation is their cost, and they are not widely available.

Using imaging characteristics, Balthazar and associates have established the CT severity index. This index correlates CT findings with the patient's outcome. The CT severity index is shown in Table 92.2.

TABLE 92.2 Computed Tomography Severity Index (CTSI) for Acute Pancreatitis

FEATURE	POINTS
Pancreatic Inflammation	
Normal pancreas	0
Focal or diffuse pancreatic enlargement	1
Intrinsic pancreatic alterations with peripancreatic fat inflammatory changes	2
Single fluid collection or phlegmon	3
Two or more fluid collections or gas in or adjacent to the pancreas	4
Pancreatic Necrosis	
None	0
≤30%	2
30%–50%	4
>50%	6

CTSI 0–3, mortality 3%, morbidity 8%; CTSI 4–6, mortality 6%, morbidity 35%; CTSI 7–10, mortality 17%, morbidity 92%.

Although many prognostic indices have been developed to predict severity of disease, most are hindered by complexity, need for imaging, or inability to be calculated at admission. This has led to multiple professional societies recommending the use of the SIRS scoring system (Box 92.3) as a fast, inexpensive, and reliable replacement.[14,15] Having a persistent SIRS throughout hospital admission, having a transient SIRS, or never meeting SIRS criteria has been associated with mortality rates of 25%, 8%, and 0%, respectively.

In 1992, the International Symposium on Acute Pancreatitis defined *severe pancreatitis* as the presence of local pancreatic complications (necrosis, abscess, or pseudocyst) or any evidence of organ failure. Severe pancreatitis is diagnosed if there is any evidence of organ failure or a local pancreatic complication (Box 92.4). In 2012, the International Symposium on Acute Pancreatitis updated its three-tiered grading schema of pancreatitis severity. Mild pancreatitis has no organ dysfunction or local/systemic complications, moderate pancreatitis can have organ failure lasting less than 48 hours and/or local/systemic complications, and severe pancreatitis is characterized by organ failure lasting beyond 48 hours. With increasing severity comes increased rates of morbidity and mortality.[8]

Treatment

Regardless of the cause or the severity of the disease, the cornerstones of treating AP are aggressive fluid resuscitation with isotonic crystalloid solution to restore tissue perfusion, early nutrition to counteract the catabolic state and decrease the rate of infectious complications, and pain control.

BOX 92.3 Definition of Systemic Inflammatory Response Syndrome (SIRS)

Two or more of the following conditions must be met:

- Temperature >38.3°C (100.9°F) or <36.0°C (96.8°F)
- Heart rate of >90 beats/minute
- Respiratory rate of >20 breaths/minute or $PaCO_2$ of <32 mm Hg
- White blood cell count of >12,000 cells/mL, <4000 cells/mL, or >10% immature (band) forms

From Annane D, Bellissant E, Cavaillon JM. Septic shock. *Lancet.* 2005;365:63-78.

BOX 92.4 Atlanta Criteria for Acute Pancreatitis

Organ Failure, as Defined By

Shock (systolic blood pressure <90 mm Hg)
Pulmonary insufficiency (PaO_2 <60 mm Hg)
Renal failure (creatinine level >2 mg/dL after fluid resuscitation)
Gastrointestinal bleeding (>500 mL/24 hour)

Systemic Complications

Disseminated intravascular coagulation (platelet count ≤100,000)
Fibrinogen <1 g/L
Fibrin split products >80 μg/dL
Metabolic disturbance (calcium level ≤7.5 mg/dL)

Local Complications

Necrosis
Abscess
Pseudocyst
Severe pancreatitis is defined by the presence of any evidence of organ failure or a local complication.

IV fluid replacement is necessary to compensate for a reduced oral intake as well as for losses resulting from vomiting or creation of a third space in the abdominal cavity (intraabdominal or retroperitoneal). Hypovolemia is recognized as an unfavorable prognostic factor, and its treatment is essential. Although the nature of the fluid that should be used for initial resuscitation is still being debated, some evidence suggests that lactated Ringer (LR) may be best for initial resuscitation because of an association between an apparent antiinflammatory effect and decreased odds of developing SIRS at 24 hours compared with normal saline.[16] The American College of Gastroenterology (ACG) Acute Pancreatitis Task Force on Quality guideline cites a meta-analysis reporting decreased odds of developing SIRS with LR compared with normal saline when used for the initial resuscitation in AP (OR 0.38 [95% CI 0.15–0.98]).[17]

The rate of fluid administration should be individualized and adjusted on the basis of age, comorbidities, vital signs, mental status, skin turgor, and urine output, titrating to specific measures of perfusion. In 2022, findings of the WATERFALL trial challenged the concept of aggressive fluid resuscitation.[18] In this international, multicenter randomized controlled trial (RCT), adults with AP were randomly assigned to receive either aggressive (bolus 20 mL/kg, maintenance 3 mL/kg) or moderate (bolus 10 mL/kg or no bolus with normovolemia, maintenance 1.5 mL/kg) resuscitation with LR solution. The primary outcome was development of moderately severe or severe pancreatitis during the hospitalization, and the main safety outcome was fluid overload. The study was stopped early because fluid overload occurred in 21% of patients in the aggressive treatment compared with just 6% in the moderate group. There was no statistically significant difference in the primary outcomes; however, there was a trend toward fewer complications with the moderate strategy. Patients who do not respond to initial fluid resuscitation or have significant renal, cardiac, or respiratory comorbidities often require invasive monitoring with central venous access and a Foley catheter.

In addition to fluid resuscitation, patients with AP require continuous pulse oximetry because one of the most common systemic complications of AP is hypoxemia caused by the acute lung injury associated with this disease. Patients should receive supplementary oxygen to maintain arterial saturation above 95%.

It is also essential to provide effective analgesia. Narcotics are usually preferred, especially morphine. One of the physiologic effects described after systemic administration of morphine is an increase in tone in the sphincter of Oddi; however, there is no evidence that narcotics exert a negative impact on the outcome of patients with AP.

Nutritional support is vital in the treatment of AP. The intense inflammatory response in moderate and severe AP incites a catabolic state with subsequent higher caloric requirements. The main options to provide this nutritional support are enteral feeding and total parenteral nutrition (TPN). Evidence overwhelmingly supports enteral feeding over TPN because it reduces the risk of death, organ failure, and systemic infections, especially for severe AP. The mechanisms by which enteral nutrition improves outcomes are likely related to replenishing caloric losses, increasing splanchnic blood flow to preserve the integrity of the bowel mucosa, and stimulating intestinal motility. Current recommendations advise starting enteral feeding within 24 to 72 hours.[19,20] Evidence supporting immediate enteral feeding upon admission was provided in a recent RCT by a Spanish group. In this trial, 131 patients with mild-moderate AP were given a low-fat, solid diet immediately after admission, regardless of symptoms or laboratory parameters, or conventional feeding with progressive diet as clinical and laboratory parameters improved. The results indicated that immediate feeding is safe and feasible, with significantly decreased complications (4.2% vs. 18.3%) and shorter length of stay (LOS) (3.4 d vs. 8.8 d) at 50% of the cost.[21]

If patients are unable to tolerate oral intake within 72 hours, nasoentera—via either nasogastric or nasojejunal tubes—should be initiated. For those who are unable to undergo enteral feeding because of conditions like paralytic ileus or obstruction, TPN can be considered within 72 hours. Although TPN provides most nutritional requirements, it is associated with mucosal atrophy, decreased intestinal blood flow, increased risk of bacterial overgrowth in the small bowel, antegrade colonization with colonic bacteria, and increased bacterial translocation. In addition, patients with TPN have more central line infections and metabolic complications (e.g., hyperglycemia, electrolyte imbalance).

Given the significant increase in mortality associated with septic complications in severe pancreatitis, a number of physicians advocated the use of prophylactic antibiotics in the 1970s. Recent meta-analyses and systematic reviews that have evaluated multiple RCTs have proven that prophylactic antibiotics do not decrease the frequency of surgical intervention, infected necrosis, or mortality in patients with severe pancreatitis. In addition, they are associated with gram-positive cocci infection, such as by *Staphylococcus aureus,* and *Candida* infection, which is seen in 5% to 15% of patients. Current recommendations are to only administer antibiotics if a preexisting infection is present on presentation or radiographic imaging suggests infected peripancreatic fluid collections (e.g., gas within collection or rim enhancement).

Special Considerations

Endoscopic retrograde cholangiopancreatography. Early ERCP, with or without sphincterotomy, was initially advocated to reduce the severity of biliary pancreatitis because the obstructive theory of AP states that pancreatic injury is the result of pancreatic duct obstruction by gallstones. However, multiple randomized trials have evaluated the use and efficacy of early ERCP in the management of acute biliary pancreatitis. The results of these trials do not support the use of early ERCP in the management of acute biliary pancreatitis, regardless of the severity. Routine use of ERCP is not indicated for patients with mild pancreatitis because the bile duct obstruction is usually transient and resolves within 48 hours after the onset of symptoms. Based on a meta-analysis of these clinical trials as well as two major society guidelines based on these clinical trials, ERCP is only indicated for patients who develop cholangitis and those with persistent bile duct obstruction demonstrated by other imaging modalities, such as EUS.[14,22] Finally, in older patients with poor performance status or severe comorbidities that preclude surgery, ERCP with sphincterotomy is a safe alternative to prevent recurrent biliary pancreatitis.

Laparoscopic cholecystectomy. In the absence of definitive treatment, 30% of patients with acute biliary pancreatitis will have recurrent disease. With the exception of older patients and those with poor performance status, laparoscopic cholecystectomy is indicated for all patients with mild acute biliary pancreatitis. Studies have shown that early laparoscopic cholecystectomy, defined as laparoscopic cholecystectomy during the initial admission to the hospital, is a safe procedure that decreases recurrence of the disease.[8] Choledocholithiasis can be excluded by intraoperative cholangiography, EUS, or MRCP. For patients with severe pancreatitis, early surgery may increase the morbidity and length of stay. Current recommendations suggest conservative treatment for at least 6 weeks before laparoscopic cholecystectomy is attempted in this setting. This approach has significantly decreased morbidity.[9]

Complications

Sterile and Infected Peripancreatic Fluid Collections

Discussion regarding appropriate management of pancreatic and peripancreatic fluid collections requires an understanding of the current classification of these entities, as defined in Table 92.3. Fluid collections are divided into acute (present for less than 4 weeks) and chronic (lasting past 4 weeks) and either simple or complex in nature. Acute peripancreatic fluid collections are simple in nature and, after 4 weeks, are referred to as a pseudocyst. Fluid collections associated with necrotizing pancreatitis are referred to as an *acute necrotic collection* (ANC) before 4 weeks and as *walled-off pancreatic necrosis* (WOPN) after that period. The presence of acute peripancreatic fluid collections during an episode of AP has been described in 30% to 57% of patients. In contrast to pseudocysts and cystic neoplasias of the pancreas, fluid collections are not surrounded or encased by epithelium or fibrotic capsule. Treatment is supportive because most fluid collections will be spontaneously reabsorbed by the peritoneum. All of these fluid collections may become infected. The usual signs and symptoms of infection (e.g., fever, elevated white blood cell count, and abdominal pain) may also be present without an infection in AP due to a robust SIRS response in many of these patients, making diagnosis of infection difficult. Evidence of gas within a fluid collection on imaging without prior instrumentation is diagnostic. Acute decompensation or failure to improve after 10 to 14 days may suggest infection, and consideration should be given to CT-guided fluid sampling. Drainage (percutaneous or endoscopic) and IV administration of antibiotics should be instituted if infection is present. Antibiotics known to penetrate pancreatic necrosis include carbapenems, quinolones, metronidazole, and high-dose cephalosporins.

Pancreatic Necrosis and Infected Necrosis

Necrosis is the presence of nonviable pancreatic parenchyma or peripancreatic fat and can manifest as a focal area or diffuse involvement of the gland. Contrast-enhanced CT is the most reliable technique to diagnose ANC, which is typically seen as areas of low attenuation (<40–50 HU) after the IV injection of contrast material. Normal parenchyma usually has a density of 100 to 150 HU. Up to 20% of patients with AP develop ANCs. It is important to identify and provide proper treatment of these complications because most patients who develop multiorgan failure have necrotizing pancreatitis; pancreatic necrosis has been documented in up to 80% of the autopsies of patients who died after an episode of AP.[6]

The main complication of ANC is infection. The risk is directly related to the amount of necrosis; in patients with pancreatic necrosis involving less than 30% of the gland, the risk of infection is 22%. The risk is 37% for patients with pancreatic necrosis that involves 30% to 50% of the gland and up to 46% if more than 70% of the gland is affected.[4] This complication is associated with bacterial translocation, usually involving enteric flora, such as gram-negative rods (e.g., *Escherichia coli, Klebsiella,* and *Pseudomonas* spp.) and *Enterococcus* spp.

An infected necrotic collection should be suspected in patients with prolonged fever, elevated white blood cell count, or progressive clinical deterioration. It should also be suspected if the patient develops sepsis, SIRS, and/or organ failure later in the course of the disease (>7 days after the onset of the AP). Evidence of gas

TABLE 92.3 Atlanta Classification of Morphological Features of Acute Pancreatitis

SUBTYPE	≤4 WEEKS	>4 WEEKS
Interstitial edematous[a]	**Acute Peripancreatic Fluid Collection (APFC)** • Homogeneous collection with fluid density • No definable wall or capsule • Confined to pancreatic fascial planes • No intrapancreatic extension	**Pseudocyst** • Homogeneous fluid • Encapsulated, round or oval • No nonliquid component • Well-defined wall
Necrotizing[b]	**Acute Necrotic Collection (ANC)** • Heterogeneous with nonliquid densities • No definable wall or capsule • Located intra-/extra-pancreatic	**Walled-Off Necrosis (WON)** • Mixed liquid and nonliquid content • Encapsulated with well-defined wall • Varying loculations • Located intra-/extra-pancreatic

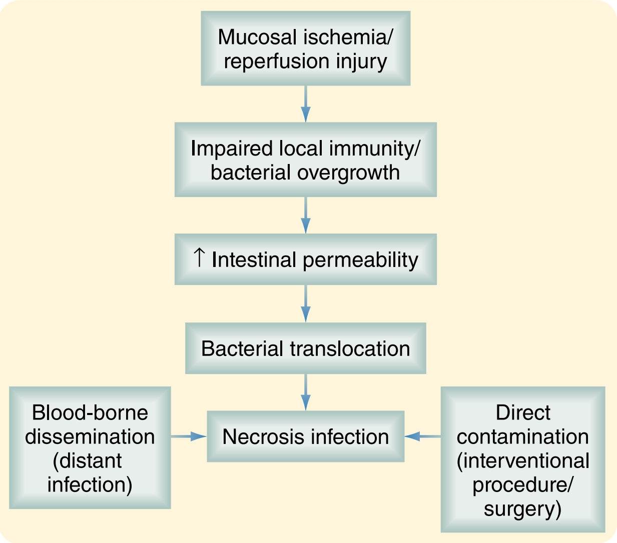
[a] Interstitial edematous pancreatitis: characterized by inflammation and enlargement of the pancreas and surrounding tissues without any evidence of necrosis on imaging.

[b] Necrotizing pancreatitis: nonviable pancreatic tissue and/or peripancreatic fat necrosis, often seen as areas lacking contrast enhancement on CT.

within the pancreatic necrosis seen on a CT scan confirms the diagnosis but is a rare finding. If infected necrosis is suspected, fine-needle aspiration (FNA) may be performed if the diagnosis is equivocal; from the aspirate, a positive Gram stain or culture establishes the diagnosis. Although positive cultures are confirmatory, a review has demonstrated that despite negative preoperative cultures, 42% of patients with so-called persistent unwellness will have infected necrosis.[23] Fig. 92.8 illustrates the pathophysiologic process of pancreatic necrosis infection.

With decades of experience in treatment of pancreatic necrosis, few general concepts have emerged. First, all sterile necrotic collections do not need to be intervened upon. Indications for intervening in sterile necrotizing pancreatitis include persistent pain, failure to improve clinically with conservative management, and/or symptomatic biliary or enteric obstruction. Intervention for these indications should be delayed as much as possible to allow development of walled-off necrosis (WON). Second, clinical suspicion of or documented infected necrotic collection with clinical deterioration is a clear indication for intervention. Even in this situation, the intervention should be delayed as much as possible to allow the collection to become walled off.

Once infection has been demonstrated, IV antibiotics should be given. Because of their penetration into the pancreas and spectrum coverage, carbapenems are the first option for treatment. Alternative therapy includes quinolones, metronidazole, third-generation cephalosporins, and piperacillin. Historically, the definitive treatment of infected pancreatic necrosis is surgical debridement with necrosectomy, closed continuous irrigation, or open packing (Fig. 92.9). The overall mortality rate after open necrosectomy has been as high as 25% to 30%[12] because of the severe nature of the disease as well as the high complication rate of an open debridement. Outcomes are time dependent; patients who undergo surgery in the first 14 days have a mortality rate of 75%, and those who undergo surgery between 15 and 29 days and after 30 days have mortality rates of 45% and 8%, respectively.[24] As a result of the elevated morbidity and mortality rates with open debridement, percutaneous, endoscopic, and laparoscopic techniques with an anterior or retroperitoneal approach have been employed as alternatives.



Mucosal ischemia/ reperfusion injury
Impaired local immunity/ bacterial overgrowth
↑ Intestinal permeability
Bacterial translocation
Blood-borne dissemination (distant infection)
Necrosis infection
Direct contamination (interventional procedure/ surgery)

FIGURE 92.8 Pathophysiology of pancreatic necrosis infection. The acute inflammatory injury that occurs during the first 48 to 72 hours causes mucosal ischemia and reperfusion injury. Both effects favor bacterial overgrowth because they alter local immunity. Mucosal ischemia also produces an increase in the permeability of intestinal cells, which is initiated 72 hours after the acute episode but typically peaks 1 week later. These transient episodes of bacteremia are associated with pancreatic necrosis infection. Less frequently, distant sources of infection, such as pneumonia and vascular or urinary tract infection associated with central lines and catheters, are associated with bacteremia and pancreatic necrosis. Finally, local contamination after surgery or interventional procedures, such as endoscopic retrograde cholangiopancreatography, is responsible for necrosis infection.

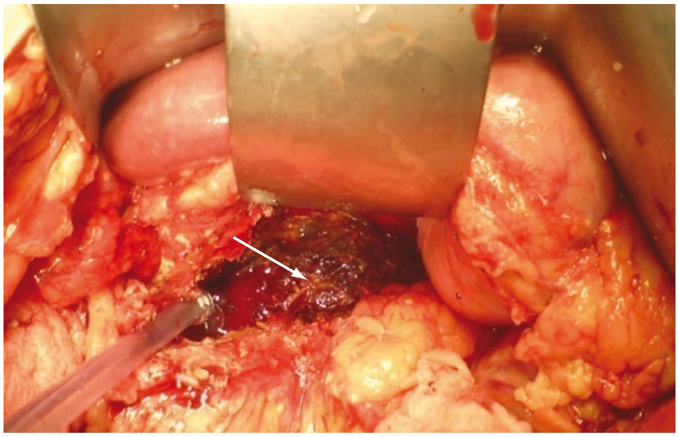


FIGURE 92.9 Infected pancreatic necrosis. This 45-year-old male had severe ethanol-induced pancreatitis. Four weeks after the initial episode, the patient developed fever (39.5°C [103°F]), hypotension, and leukocytosis (19,000 cells/mm^3). The computed tomography scan documented pancreatic necrosis involving 35% of the gland. After fine-needle aspiration, Gram staining documented the presence of gram-negative rods. The exploratory laparotomy indicated pancreatic necrosis involving mainly the body of the gland *(arrow)*. The patient was treated with necrosectomy, closed drainage, and intravenous meropenem. Final culture documented the presence of *Escherichia coli*. The patient was discharged home 56 days after the initial episode.

In 2010, the Dutch Pancreatitis Study Group performed a randomized trial evaluating open necrosectomy versus a “step-up approach” consisting of percutaneous drainage followed by minimally invasive video-assisted retroperitoneal debridement for necrotizing and infected necrotizing pancreatitis. The results showed that long-term end-point complications (e.g., exocrine and endocrine insufficiency) and mortality rates were better in the group using the step-up approach compared with the group undergoing early open necrosectomy.[14] A companion study to this was published in 2018 wherein endoscopic management was compared with the step-up approach. Although the endoscopic approach was nonsuperior to the minimally invasive surgical approach regarding mortality and most secondary end points, it was associated with fewer pancreatic fistulae, reduced cumulative hospital length of stay, and lower cost.[25]

Recent findings have led to a significant change in the approach to treating infected necrotizing pancreatitis, now favoring the use of antibiotics alone with delayed drainage over the previously standard practice of combining antibiotics with immediate drainage for infections that develop after AP. This change is supported by evidence from the Postponed or Immediate Drainage of Infected Necrotizing Pancreatitis (POINTER) trial, an RCT conducted in the Netherlands that evaluated the outcomes of immediate versus delayed drainage in patients with infected necrotizing pancreatitis diagnosed within 35 days from the initial symptoms of AP. The study, which included 104 patients with documented infection, found no difference in complications and mortality rates between the two groups, but it did find that the group that underwent immediate drainage had an average of 4.4 interventions, in contrast to just 2.6 interventions in the delayed-drainage group. Notably, 37% (19 out of 52) of patients in the delayed-drainage group avoided the need for drainage altogether, and their hospital stays were 15% shorter.[26]

Currently, an endoscopic drainage with a large-bore stent and possible endoscopic debridement with or without percutaneous drainage can avoid an operation in most patients. If the endoscopic and/or percutaneous management fails, a minimally invasive operation will usually be more straightforward, and the results will be improved. Occasionally, when there is a large amount of necrosum, the surgical approach may be preferred to the endoscopic approach, which would require several repeat procedures to clear the debris. These points highlight the complexity of treating this disease and the importance that patients be managed at high-volume centers and discussed at multidisciplinary conferences with all relevant expert physicians present. Regardless of which route is taken, physiologic and nutritional support of the patient will have a large impact on outcome.

Pancreatic Pseudocysts

Pancreatic pseudocysts occur in 5% to 15% of patients who have peripancreatic fluid collections after AP. By definition, the capsule of a pseudocyst is composed of collagen and granulation tissue, and it is not lined by epithelium. The fibrotic reaction typically requires at least 4 to 8 weeks to develop. Fig. 92.10 shows CT scans of a large pseudocyst arising in the tail of the pancreas.

Up to 50% of patients with pancreatic pseudocysts will develop symptoms. Persistent pain, early satiety, nausea, weight loss, and elevated pancreatic enzyme levels in plasma suggest this diagnosis. The diagnosis is corroborated by CT or MRI. EUS with FNA is indicated for patients in whom the diagnosis of pancreatic pseudocyst is not clear. Characteristic features of pancreatic pseudocysts include high amylase levels associated with the absence of mucin and low carcinoembryonic antigen (CEA) levels.

Observation is indicated for asymptomatic patients because spontaneous regression has been documented in up to 70% of cases; this is particularly true for patients with pseudocysts smaller than 4 cm in diameter, located in the tail, and no evidence of pancreatic duct obstruction or communication with the MPD. Invasive therapies are indicated for symptomatic patients or when the differentiation between a cystic neoplasm and pseudocyst is not possible. Because most patients are treated with decompressive procedures and not with resection, it is imperative to have a pathologic diagnosis. Surgical drainage had been the traditional approach for pancreatic pseudocysts. However, modern evidence suggests that transgastric and transduodenal endoscopic drainage are safe and effective approaches for patients with pancreatic pseudocysts in close contact (defined as <1 cm) with the stomach and duodenum, respectively. In addition, transpapillary drainage can be attempted in pancreatic pseudocysts communicating with the MPD. For patients in whom a pancreatic duct stricture is associated with a pancreatic pseudocyst, endoscopic dilation and stent placement are indicated.

Surgical drainage is generally reserved for patients with pancreatic pseudocysts that cannot be treated with endoscopic techniques for anatomic reasons and for patients who fail to respond to endoscopic treatment. Definitive treatment depends on the location of the cyst. Pancreatic pseudocysts closely attached to the stomach should be treated with a cystogastrostomy. In this procedure, an anterior gastrostomy is performed.[25] Once the pseudocyst is located, it is drained through the posterior wall of the stomach using a linear stapler (Video 92.1). The defect in the anterior wall of the stomach is closed in two layers. Pancreatic pseudocysts located in the head of the pancreas that are in close contact with the duodenum are treated with a cystoduodenostomy. Finally, some pseudocysts are not in contact with the stomach or duodenum. The surgical treatment for these patients is a Roux-en-Y cystojejunostomy. Surgical cyst enterostomy is successful in achieving immediate cyst drainage in more than 90% of cases. After initial resolution, pseudocyst formation may recur in up to 12% of cases during long-term follow-up, depending on the location of the cyst and underlying cause of the disease.

Complications of pancreatic pseudocysts include bleeding and pancreaticopleural fistula secondary to vascular and pleural erosion, respectively; bile duct and duodenal obstruction; rupture into the abdominal cavity; and infection. Percutaneous drainage is indicated only for septic patients secondary to pseudocyst infection because it has a high incidence of external fistula.

Pancreatic Ascites and Pancreaticopleural Fistulas

Although very rare, complete disruption of the pancreatic duct can lead to significant accumulation of fluid. This condition should be suspected in patients who have an episode of AP, develop significant abdominal distention, and have free intraabdominal fluid. Diagnostic paracentesis typically demonstrates

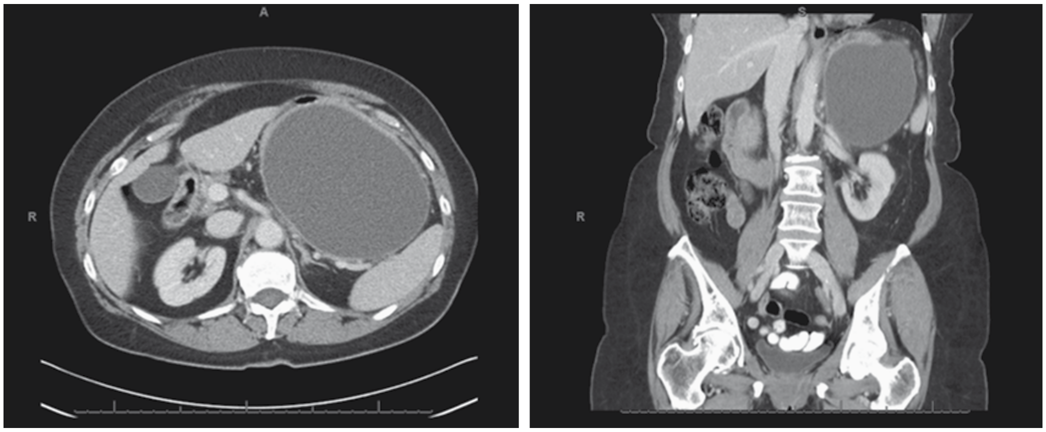

FIGURE 92.10 Computed tomography scans showing a large pseudocyst arising in the tail of the pancreas.

elevated amylase and lipase levels. Treatment consists of abdominal drainage combined with endoscopic placement of a pancreatic stent across the disruption. Failure of this therapy may require surgical treatment; it consists of distal resection and closure of the proximal stump. Pancreatic leak or pancreatic fistula is also a frequent complication after pancreatic operations, defined by the International Study Group on Pancreatic Surgery (ISGPS) as drain output (intraoperative or percutaneous) with amylase > 3 times normal serum value. In 2016 ISGPS guidelines redefined Grade A fistula as "biochemical leak," a indicating amylase-rich fluid without any clinical impact. Grade B fistula require ongoing drainage and active mangaement after 3 weeks, while Grade C includes severe outcomes such as reoperation, organ failure, or death (Table 92.4). Most fistulas are controlled by operatively placed drainage catheters, though uncontrolled fistulas may require additional drain placement or operative exploration, sometimes mandating complete pancreatectomy.

Posterior pancreatic duct disruption into the pleural space has been described rarely—a pancreatic-pleural fistula. Symptoms that suggest this condition include dyspnea, abdominal pain, cough, and chest pain. The diagnosis is confirmed with chest radiography, thoracentesis, and CT scan. Fig. 92.11 demonstrates a large, left-sided pleural effusion caused by a pancreatic-pleural fistula. Amylase levels above 50,000 IU in the pleural fluid confirm the diagnosis. It is more common after alcoholic pancreatitis, and in 70% of patients, it is associated with pancreatic pseudocysts. Iatrogenic pancreaticopleural fistulas may also be seen after placement of percutaneous drainage catheters that traverse the diaphragm. Initial treatment requires chest drainage, parenteral nutritional support, and administration of octreotide. Up to 60% of patients respond to this therapy. Persistent drainage should also be treated with endoscopic sphincterotomy and stent placement. Patients who do not respond to these measures require surgical treatment of the source of the fistula from the pancreas, similar to that described for pancreatic ascites.

Vascular Complications

AP is rarely associated with arterial vascular complications. The most common vessel affected is the splenic artery, but the SMA, cystic artery, and GDA have also been found to be affected. It has been proposed that pancreatic elastase damages the vessels, leading to pseudoaneurysm formation. Spontaneous rupture results in massive bleeding. Clinical manifestations include sudden onset of abdominal pain, tachycardia, and hypotension. If possible, arterial embolization should be attempted to control the bleeding. Refractory cases require ligation of the affected vessel. The mortality ranges from 28% to 56%.

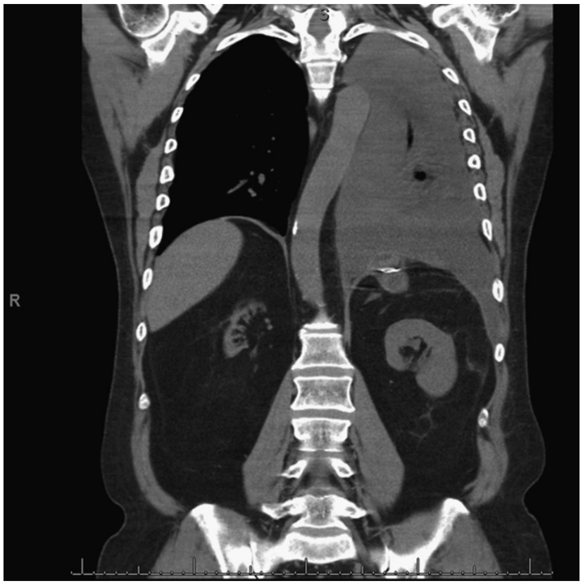

FIGURE 92.11 Massive left-sided pleural effusion secondary to a pancreaticopleural fistula.

Pancreatic inflammation can also produce vascular thrombosis; the vessel usually affected is the splenic vein, but in severe cases, it can extend into the portal venous system. Imaging demonstrates splenomegaly, gastric varices, and splenic vein occlusion. Thrombolytics have been described in the acute early phase; however, most patients can be managed with conservative treatment. Anticoagulation for splanchnic vein thrombosis related to pancreatitis has not been shown to improve recanalization rates compared with expectant management.[27]

Recurrent episodes of upper gastrointestinal bleeding caused by short gastric venous hypertension in the wall of the fundus of the stomach should be treated with splenectomy.

Pancreatocutaneous Fistula

The frequency of pancreatic fistulas is low. Only 0.4% of patients have this complication after an acute episode. However, the incidence of this complication increases in patients with other complications after AP: 4.5% in patients with pancreatic pseudocysts (4.5%) and 40% in patients with infected necrosis after surgical debridement.[23] Treatment is conservative for most patients.

CHRONIC PANCREATITIS

In contrast to AP, the histologic hallmark of chronic pancreatitis is the persistent inflammation and irreversible fibrosis associated with atrophy of the pancreatic parenchyma. These histologic

TABLE 92.4 International Study Group on Pancreatic Surgery Classification of Pancreatic Fistulas

	GRADE		
PARAMETER	**BL**	**B**	**C**
Increased amylase >3× upper normal limit	Yes	Yes	Yes
Persistent peripancreatic drainage >3 weeks	No	Yes	Yes
Clinically relevant change in management of POPF	No	Yes	Yes
POPF percutaneous or endoscopic interventions for collections	No	Yes	Yes
Angiographic procedures for POPF-related bleeding	No	Yes	Yes

features are associated with chronic pain and endocrine and exocrine insufficiency that significantly decrease the quality of life of these patients. Chronic pancreatitis affects between 5 to 8 per 100,000 adults, two-thirds of patients with chronic pancreatitis are males, and risk is higher among Blacks than among Whites.[28]

Risk Factors

The specific cause and frequency of each condition vary among countries, hospital populations, and referral practices. In general, heavy alcohol consumption is the most common cause of chronic pancreatitis (70%–80% of cases), especially in urban hospitals. Conditions such as chronic duct obstruction, trauma, pancreas divisum, cystic dystrophy of the duodenal wall, hyperparathyroidism, hypertriglyceridemia, autoimmune pancreatitis, tropical pancreatitis, and hereditary pancreatitis are rare and account for less than 10% of all cases. However, hereditary, chronic, and autoimmune pancreatitis are more common in referral centers. In up to 20% of patients, a clear cause cannot be documented, and cases are considered to be idiopathic. The natural history of chronic pancreatitis is not well understood but is currently being studied in a prospective cohort study in the United States (Prospective Evaluation of Chronic Pancreatitis for Epidemiologic and Translational Studies [PROCEED] trial).[29]

Alcohol Abuse

Prolonged alcohol abuse is the most important risk factor associated with chronic pancreatitis. The fact that only 3% to 7% of heavy drinkers develop chronic pancreatitis suggests that alcohol is only a cofactor and that other factors are required for development of this complication. Alcohol exerts multiple noxious effects in the pancreas: It increases the total protein concentration in the pancreatic juice, it promotes the synthesis and secretion of lithostathine by acinar cells, and it increases glycoprotein 2 secretion in pancreatic juice. These factors lead to protein precipitation and subsequent formation of protein plugs and, eventually, stones inside the pancreatic duct. As a result of the obstruction, acinar cells are no longer able to secrete pancreatic enzymes and are predisposed to autodigestion. In addition, several products of alcohol metabolism, such as fatty acid ethyl esters and reactive oxygen species, cause fragility of intraacinar organelles, such as zymogen granules and lysosomes, which leads to abnormal pancreatic enzyme activation inside acinar cells. Acetaldehyde, another alcohol metabolite, causes direct acinar injury. Chronic alcohol consumption is associated with enhanced NF-κB activity, decreased perfusion in the microcirculation of the pancreas, and increased intracellular calcium levels.

The identification of PSCs in the late 1990s is one of the most important discoveries in the pathophysiology of chronic pancreatitis.[30] PSCs are specialized quiescent fibroblasts found at the base of acinar cells. Once stimulated, PSCs differentiate into activated myofibroblasts, which synthesize proteins that form the extracellular matrix. Examples of these proteins include collagen I and III, fibronectin, laminin, and matrix metalloproteinases. PSCs have responses similar to hepatic stellate cells; chronic necrosis and inflammation (necroinflammation) induce the release of inflammatory mediators, such as platelet-derived growth factor, TGF-β, TNF-α, IL-1, and IL-6, which are known to activate PSCs. Consequently, the synthesis of collagen and other components of pancreatic fibrosis is increased. It has been postulated that the chronic necroinflammation induced by ethanol activates PSCs and induces pancreatic fibrosis. Interestingly, it has also been shown that alcohol and some of its metabolites (e.g., acetaldehyde) cause activation of PSCs.

Although they have been evaluated only in preclinical studies, novel therapies that target the activation of PSCs are being investigated. It has been reported that antioxidants, angiotensin-converting enzyme inhibitors, peroxisome proliferator-activated receptor gamma ligands, and vitamin A inhibit the activity of PSCs.

Smoking

Epidemiologic studies have shown that smoking increases the risk of alcohol-induced chronic pancreatitis. Active smokers develop chronic pancreatitis at a younger age compared with nonsmokers. In addition, the risk of pancreatic calcifications and diabetes mellitus is increased in patients who smoke compared with nonsmokers.

Gene Mutations

Under physiologic conditions, pancreatic enzyme activation is strictly controlled. Mutations in proteins that regulate this activation increase the risk of chronic pancreatitis. Mutations in the cationic trypsinogen gene, also known as the *protease serine 1 (PRSS1)* gene, are common in hereditary chronic pancreatitis. *PRSS1* is located on chromosome 7 and regulates trypsinogen production; mutations in this gene are associated with intraacinar trypsinogen activation. *PRSS1* mutations have been documented in hereditary pancreatitis but are uncommon in other forms of chronic pancreatitis.

SPINK-1 is a peptide secreted by acinar cells that regulates the premature activation of trypsinogen. Because *SPINK1* mutations are present in 1% to 2% of healthy patients but the prevalence of chronic pancreatitis is much lower, it has been hypothesized that *SPINK1* mutations are not enough to trigger pancreatic inflammation. However, they lower the threshold for its development and influence the severity of the disease. *SPINK1* mutations are more prevalent in alcoholic, hereditary, and idiopathic pancreatitis.

The secretion of bicarbonate and chloride in respiratory and pancreatic secretions is regulated by the *CFTR* gene. *CFTR* mutations affect the normal secretion of bicarbonate, decrease pancreatic juice volume, and augment the concentration of pancreatic enzymes inside the pancreatic duct. Homozygous *CFTR* mutations result in cystic fibrosis; heterozygous mild mutations predispose to pancreatic exocrine insufficiency and chronic pancreatitis. The prevalence of *CFTR* gene mutations is higher in patients with alcoholic, idiopathic, and hereditary pancreatitis compared with the general population. Similarly, mutation in human chymotrypsin C gene has been found to be associated with development of chronic pancreatitis. It seems that chymotrypsin C protects against pancreatitis by degrading trypsinogen and thereby curtailing harmful intrapancreatic trypsinogen activation.[31]

Although our understanding of the pathogenesis of chronic pancreatitis has evolved in a largely trypsin-centric fashion, animal studies in trypsin knockout mice suggest that even in the absence of trypsin, chronic noxious stimuli can induce chronic pancreatitis.[32] These results suggest that alternative pathways independent of trypsin may exist that can lead to chronic injury in pancreatitis, and elucidation of these pathways may lead to development of novel therapeutics.

Types of Chronic Pancreatitis

Autoimmune Pancreatitis

Autoimmune pancreatitis is a chronic inflammatory disorder that involves the pancreas. At least two different histologic variants have been defined: (1) type 1, which is the pancreatic manifestation of an immunoglobulin G4-related disease, and (2) type 2, a pancreatic-specific disorder that is not associated with immunoglobulin G4. Type 1 is the most common; it is characterized by dense, periductal lymphoplasmacytic infiltrates, storiform fibrosis, and obliterative venulitis. Plasmatic cells typically stain positive for immunoglobulin G4. In type 2, the pancreas is infiltrated by neutrophils, lymphocytes, and plasma cells that destroy and obliterate the epithelium in the pancreatic duct. Autoimmune pancreatitis is more common in males than in females. Up to 80% of patients are older than 50 years. Typical imaging findings include a "sausage-shaped" pancreas due to the edema and inflammation. Patients with autoimmune pancreatitis can develop acute symptoms, such as jaundice, or AP, closely mimicking patients with pancreatic adenocarcinoma. Similarly, patients with focal autoimmune pancreatitis may have a pseudomass on imaging that appears like a hypoenhancing mass in pancreatic cancer.[33]

Tropical Pancreatitis

Tropical pancreatitis is not common in the United States; it is more common in tropical areas within 30 degrees of the equator, particularly in India. Its pathophysiology has not been completely delineated, but it has been associated with cassava ingestion and *SPINK1* mutations. Up to 45% to 50% of patients with tropical pancreatitis have *SPINK1* mutations.

Idiopathic Pancreatitis

In up to 10% to 20% of patients with chronic pancreatitis, a clear cause that predisposed to the disease is not evident. Future identification of genetic defects associated with chronic pancreatitis may allow the identification of individuals at highest risk for development of this disease.

Clinical Manifestations

Pain is the primary manifestation of chronic pancreatitis. Initially precipitated by oral intake, the intensity, frequency, and duration of pain gradually increase with worsening disease. Quality of life of these patients is significantly affected because of decreased oral intake, interference with daily activities, and dependence on narcotic pain medications. Nausea and vomiting are not common early on; however, they may appear as the disease progresses.

Pancreatic inflammation and fibrosis not only affect the pancreatic ducts but also decrease the number and function of acinar cells. At least 90% of the gland needs to be dysfunctional before pancreatic exocrine insufficiency, as evidenced by steatorrhea, diarrhea, and other symptoms of malabsorption, develops. In severe cases, diseases associated with fat-soluble vitamin deficiency, such as bleeding, osteopenia, and osteoporosis, develop. Exocrine insufficiency occurs in 80% to 90% of patients with long-standing chronic pancreatitis.

Chronic pancreatitis also affects islet cell populations. As a result, 40% to 80% of patients will have clinical manifestations of diabetes mellitus, typically occurring years after the onset of abdominal pain and pancreatic exocrine insufficiency.

Jaundice or cholangitis occurs in 5% to 10% of patients because of fibrosis of the distal common bile duct. Extensive scarring in the head of the pancreas can also obstruct the duodenum, leading to severe nausea, vomiting, and abdominal pain. Upper gastrointestinal bleeding secondary to portal or splenic vein thrombosis is a rare manifestation of chronic pancreatitis.

Diagnosis

Imaging Studies

Cross-sectional imaging plays an important role in the diagnosis of chronic pancreatitis; however, a standardized approach to the diagnosis and assessment of disease is lacking. The most common CT findings in chronic pancreatitis include dilated pancreatic duct (68%), parenchymal atrophy (54%), and pancreatic calcifications (50%; Fig. 92.12). Other findings include peripancreatic fluid, focal pancreatic enlargement, biliary duct dilation, and irregular pancreatic parenchyma contour. CT has a sensitivity of 56% to 95% and a specificity of 85% to 100% for the diagnosis of chronic pancreatitis. In addition to establishing the diagnosis, CT is particularly useful for assessing complications, such as

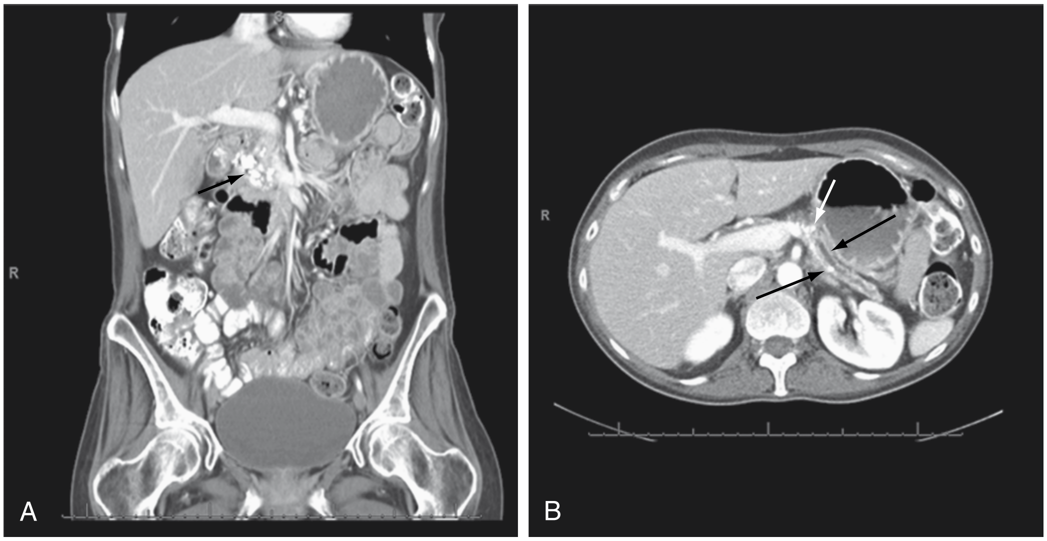

FIGURE 92.12 Typical computed tomography findings associated with chronic pancreatitis. Shown are pancreatic duct dilation *(long arrow)* and intrapancreatic calcifications, which are also typical of chronic pancreatitis *(short arrow)*.

pancreatic duct disruption, pseudocysts, portal and splenic vein thrombosis, and splenic and pancreaticoduodenal artery pseudoaneurysms.

MRI is a reliable alternative to evaluate patients with chronic pancreatitis. The sensitivity for the diagnosis of pancreatic calcifications is lower, but MRI is useful to detect changes in the pancreatic parenchyma suggestive of chronic inflammation, such as changes in intensity, pancreatic atrophy, and irregularities in the contour. In addition, MRCP with secretin injection is particularly useful to evaluate intraductal strictures and pancreatic duct disruption. Efforts to standardize imaging evaluation of chronic pancreatitis patients are underway.

Although ERCP was historically considered the "gold standard" for the diagnosis of chronic pancreatitis, current indications include patients for whom other diagnostic tests, including CT and MRCP, are contraindicated or have failed to corroborate the diagnosis. ERCP should be considered a therapeutic modality in patients who develop pancreatic duct complications amenable to endoscopic therapy, such as stricture, stone, pseudocysts, and biliary stenosis.

EUS has emerged as the most accurate technique to diagnose chronic pancreatitis in patients with minimal-change disease or in the early stages. The criteria required for diagnosis of chronic pancreatitis based on EUS are known as the *Rosemont criteria* (Box 92.5). Histologic evidence of inflammation, atrophy, and fibrosis is the gold standard for the diagnosis of chronic pancreatitis; however, current evidence does not support the use of EUS-guided FNA or Tru-Cut biopsies to diagnose this disease. Although positive Rosemont criteria are predictive of histologic pancreatitis, a finding of Rosemont "normal" has a poor negative predictive value, with as many as 55% of cases ultimately found to have chronic pancreatitis on histopathologic exam.[28]

Functional Tests

Measurement of the fecal elastase 1 level is the preferred noninvasive study to diagnose pancreatic exocrine insufficiency. It quantifies the amount of fecal elastase 1 using monoclonal or polyclonal anti–human elastase 1 antibodies. A fecal elastase 1 concentration above 200 μg/g feces is normal, a fecal elastase 1 concentration between 100 and 200 μg/g defines mild to moderate pancreatic insufficiency, and a fecal elastase 1 concentration below 100 μg/g establishes the diagnosis of severe pancreatic exocrine insufficiency.

The fecal fat and weight estimation test measures the stool content of fat after a nutritional fat intake of 100 g/day for 3 days. If the stool fat content exceeds 7 g/day, the diagnosis of steatorrhea is established.

Treatment

Medical Treatment

The main goal in the treatment of chronic pancreatitis is palliation of symptoms and removal of predisposing factors. Optimal treatment requires that a multidisciplinary team follow a systematized and well-structured therapeutic plan. Patient counseling is an important component because current evidence suggests that this disease is irreversible, but disease progression can be delayed if the predisposing condition is eradicated. Patients should

BOX 92.5 Rosemont Consensus-Based Endoscopic Ultrasound Features for Diagnosis of Chronic Pancreatitis

Parenchymal Features

Major A Criteria

- Hyperechoic foci with postacoustic shadowing

Major B Criteria

- Honeycombing lobularity[a]

Minor Criteria

- Hyperechoic, nonshadowing foci ≥3 mm in length and width
- Lobularity including three or more noncontiguous lobules in the body or tail
- Pancreatic cysts ≥2 mm in short axis
- At least three strands[b]

Ductal Features

Major A Criteria

- Main pancreatic duct calculi[c]

Minor Criteria

- Irregular main pancreatic duct contour
- Dilated side branches[d]
- Main pancreatic duct dilation (≥3.5 mm in the body or ≥1.5 mm in the tail)
- Hyperechoic main pancreatic duct margin >50% of the main pancreatic duct in the body and tail[e]

Diagnosis of Chronic Pancreatitis

Consistent With Chronic Pancreatitis

- 1 major A criterion + ≥3 or more minor criteria
- 1 major A criterion + major B criterion
- 2 major A criteria

Suggestive of Chronic Pancreatitis[f]

- 1 major A criterion + <3 minor criteria
- 1 major B criterion + ≥3 minor criteria
- ≥5 minor criteria

Indeterminate for Chronic Pancreatitis[f]

- 3 to 4 minor criteria in the absence of major criteria
- Major B criterion + <3 minor criteria

Normal

- <3 minor criteria

[a] Defined as lobularity that includes at least three contiguous lobules in the body or tail. It should be assessed in the body and tail.

[b] Strands are defined as hyperechoic lines ≥3 mm in length seen in at least two different directions in the body or tail of the pancreas.

[c] The presence of calculi in the main pancreatic duct, regardless of location, is the most predictive finding of chronic pancreatitis.

[d] Defined as at least three tubular anechoic structures, each one ≥1 mm in width, budding from the main pancreatic duct.

[e] With suggestive and indeterminate chronic pancreatitis, the diagnosis needs to be confirmed with another imaging modality.

Adapted from Catalano MF, Sahai A, Levy M, et al. EUS-based criteria for the diagnosis of chronic pancreatitis: the Rosemont classification. *Gastrointest Endosc.* 2009;69:1251-1261.

be strongly encouraged to stop drinking and smoking. Furthermore, other risk factors, such as hypertriglyceridemia, should be treated, and diet modification (i.e., low-fat diet) may benefit some patients.

Pain Management

Because most patients develop pain during the natural history of the disease, analgesic selection is a cornerstone of treatment. Nonsteroidal antiinflammatory drugs are the first line of treatment. Moderate to severe pain that does not respond to nonsteroidal antiinflammatory drugs should be treated with tramadol. Patients with severe pain that does not respond to these recommendations should be treated with potent, long-acting narcotics. It cannot be overemphasized that adjuvant measures to prevent addiction, depression, and poor quality of life should be considered for patients with severe pain who require narcotics. Alternative drugs useful in the treatment of other conditions associated with chronic pain, such as tricyclic antidepressants, selective serotonin reuptake inhibitors, combined serotonin and norepinephrine reuptake inhibitors, gabapentin, and $\alpha 2\delta$ inhibitors, may also be considered. RCTs have shown that nonnarcotic medications can reduce pain and reduce the need for opioids in chronic pancreatitis patients, highlighting the need for a multidisciplinary team that includes pain management experts. For patients with unrelenting pain, celiac neurolysis has been attempted but without sustained success in those with chronic pancreatitis. A recent randomized surgical study of 88 patients with weak to strong pain of less than 6 months in duration compared early pancreatic ductal drainage versus conventional medical/endoscopic therapy (Early Surgery Compared to Endoscopy-First Approach in Patients with Chronic Pancreatitis [ESCAPE] trial) and found a lower pain score in the surgical group (37 vs. 49, $p = 0.02$).[34] This study supported two previous RCTs that showed superiority of surgery over endoscopic therapies for pain relief with similar complication rates and mortality and a greater use of reinterventions in the endoscopic group.[35,36]

Pancreatic Exocrine Insufficiency

There is no question about the digestive benefits of pancreatic enzyme replacement in patients with pancreatic exocrine insufficiency. In the absence of pancreatic enzyme replacement therapy, patients with chronic pancreatitis may suffer from steatorrhea or diarrhea, leading to malabsorption, malnutrition, and vitamin and mineral deficiencies. A thorough nutritional evaluation should be performed before initiation of therapy; however, generally, 90,000 USP of lipase per day, usually divided by 30,000 USP per meal, is required to avoid malabsorption. Therapeutic trials with pancreatic enzymes should last at least 6 weeks and should be given along with proton pump inhibitors because acid suppression improves the effects of uncoated pancreatic enzymes.

Endocrine Insufficiency

Endocrine insufficiency and resulting diabetes are not always present early on but may develop in patients with chronic pancreatitis. Unlike more common type 1 or type 2 diabetes, patients with chronic pancreatitis may develop diabetes, which includes deficiency of insulin and other regulatory hormones such as glucagon. These patients are at higher risk of suboptimal glucose control, particularly severe hypoglycemia related to insulin use, and should be managed by an endocrinologist with experience in managing these complex patients.

Interventional Therapy: Endoscopic Treatment

ERCP is the primary modality for treating symptomatic pancreatic duct obstruction with dilation and polyethylene stent placement. Note that the differential diagnosis of pancreatic duct strictures includes pancreatic cancer. Only after a thorough evaluation that includes CT, MRCP, or EUS has completely ruled out the possibility of malignant disease should endoscopic treatment be considered. Surgical resection is indicated if any concern of malignant disease exists.

Endoscopic stone extraction should be considered for patients with pain and pancreatic duct dilation secondary to stones. Extracorporeal shock wave lithotripsy followed by therapeutic ERCP may be required for the treatment of large, impacted stones. The success rate varies from 44% to 77% for this technique. In conjunction with stone extraction, pancreatic duct stenting may benefit patients by relieving obstruction. Although this relief may be temporary, during the interim, a patient may be able to improve nutritional and functional status before further, perhaps more invasive therapy.

Biliary obstruction caused by chronic pancreatitis occurs in 10% of patients and is best treated with surgical bypass. Temporary relief of the obstruction with plastic stents is indicated for patients with cholangitis or for those who are severely malnourished.

Surgical Treatment

Several factors, including intractable pain, biliary or pancreatic duct obstruction, duodenal obstruction, pseudocyst or pseudoaneurysm formation, and the inability to rule out malignant disease, may prompt surgical intervention. The choice of surgical procedure depends on the symptoms requiring palliation and the presence or absence of pancreatic ductal dilation. In general, patients with a dilated pancreatic duct (defined as diameter >7 mm), or large duct disease, require a decompressing procedure; patients with a nondilated pancreatic duct, or small duct disease, require a resectional procedure. Several clinical scenarios that require surgical intervention are described here.

Pancreatic duct dilation secondary to duct stones or strictures. *Pancreatic duct dilation* is defined as a MPD measuring at least 7 mm in diameter. Pancreatic duct dilation can be secondary to a single stone or stricture; however, it is often caused by multiple strictures and stones in the pancreatic duct. The pancreatic duct dilation observed on pancreatography for chronic pancreatitis is classically described as a chain of lakes, which reflects the presence of multiple dilations and stenoses. When it is accompanied by intractable pain, this condition is best treated with side-to-side Roux-en-Y pancreaticojejunostomy, also known as the *modified Puestow procedure* or *lateral pancreaticojejunostomy.*

The anterior surface of the pancreatic duct is opened, and the anterior surface of the duct is completely unroofed. This tissue should be sent for frozen section analysis to rule out underlying malignant disease. The proximal extent of tissue resection can extend to the ampulla and medial duodenal wall, and the distal limit is within 1 to 2 cm of the end of the pancreas. Failure to cross the GDA into the neck and head of the pancreas may leave undrained pancreatic head or uncinate process ducts obstructed by stones or strictures, which may give incomplete relief or early recurrence of symptoms. After all stones are extracted, a standard Roux-en-Y is used to create a lateral pancreaticojejunostomy. The main advantage offered by this procedure is parenchymal conservation, which preserves endocrine and exocrine function. The modified Puestow procedure provides palliation of pain in 80% of cases; however, 30% of cases will recur, usually 3 to 5 years after surgery. Decompressive procedures temporarily relieve the ductal obstruction, but in most cases, they do not modify the natural history of the disease, and chronic pancreatitis progresses. Other factors associated with recurrence include smoking and alcohol ingestion after surgery, failure to decompress the head and uncinate process properly, and length of the pancreaticojejunostomy.

In 1987, Andersen and Frey described the local resection of the pancreatic head (i.e., "coring") with longitudinal pancreaticojejunostomy as an alternative procedure for patients in which the pancreatic head is enlarged (≥5 cm in transverse diameter). The surgical approach is similar to the Puestow procedure; however, once the anterior surface of the pancreatic duct has been completely exposed, the anterior portion of the head of the pancreas is also resected, leaving a 1-cm rim of pancreatic tissue along the duodenal margin. Fig. 92.13 shows intraoperative images of a Frey procedure. This procedure is also an alternative for patients with a dilated pancreatic duct secondary to a benign stricture in the head of the pancreas associated with severe inflammation, scarring, or portal hypertension surrounding the head of the pancreas that precludes a safe pancreaticoduodenectomy. The main disadvantage is the removal of pancreatic parenchyma. A study has demonstrated that after this procedure, 62% of patients are completely free of pain, and 95% of patients have satisfactory pain control. In the same series, 34% of patients developed endocrine or exocrine pancreatic insufficiency.[37]

Pancreatic duct dilation secondary to a single stricture or stone. On occasion, a single stricture that is proximal to the papilla produces pancreatic duct dilation. As an alternative to a Puestow or Frey procedure, a pancreaticoduodenectomy (or pancreatoduodenectomy) can be performed to relieve the obstruction. This procedure is described further in the chapter focusing on the surgical treatment of pancreatic adenocarcinoma. It must be emphasized that this procedure is absolutely contraindicated if more than one obstruction is present in the duct. Single distal obstructions can occasionally be treated with a distal pancreatectomy. The main disadvantage of both procedures is that they can be associated with pancreatic insufficiency because normal parenchyma is removed. This issue may be ameliorated with autotransplantation of islet cells derived from the resected parenchyma, further discussed later in the chapter.

Focal inflammatory mass without significant dilation of the pancreatic duct. In a small percentage of patients with chronic pancreatitis, a predominant mass in the head or, less commonly, in the tail of the pancreas without any evidence of pancreatic duct dilation is seen. Long-standing chronic pancreatitis is also a risk factor for development of pancreatic cancer; therefore, even in patients with a known history of chronic pancreatitis, finding a focal mass is concerning because it may represent an area of pancreatic adenocarcinoma that has developed in the setting of chronic pancreatitis. An EUS-guided biopsy should be obtained before any other treatment.

Once malignant disease is ruled out, resection of the pancreatic head may be done with either of two operations: pancreaticoduodenectomy or duodenum-preserving pancreatic head resection, otherwise known as the *Beger procedure.* The Beger procedure was designed to remove the pancreatic head while preserving the remainder of the foregut anatomy and therefore function. Once the pancreatic head is removed, a Roux-en-Y is created and anastomosed to the rim of pancreas or duodenum, pancreatic duct, and body—and perhaps the bile duct if it was entered. RCTs have demonstrated that the Beger procedure offers symptomatic relief that is equivalent to the pancreaticoduodenectomy and Frey procedure in appropriately selected patients.

Diffuse glandular involvement without dilation of the pancreatic duct. These patients can be treated with a Whipple resection, which removes the head of the pancreas. Despite involvement of the total gland, the head is thought to be the so-called "pacemaker" with the greatest density of nerve fibers. Although this treatment can yield durable pain relief, the most effective treatment to eliminate pain in patients without dilation of the pancreatic duct is total pancreatectomy. However, this procedure is invariably associated with diabetes mellitus. In contrast to type 1 diabetes mellitus, the severity and risk of hypoglycemia are increased in these patients. In 1977, researchers at the University of Minnesota described islet autotransplantation after total pancreatectomy to prevent the effects of surgically induced diabetes. In the largest experience there, one-third of patients who underwent this procedure were insulin independent, an additional one-third required insulin intermittently, and the other third was fully dependent. According to this study, 90% had pain relief or reduction, and 50% were able to discontinue narcotics. Similar results were demonstrated at the University of Cincinnati; up to two-thirds of patients had complete or partial islet function, and 40% were insulin independent. Narcotics were discontinued in 66% of patients.[38] Although preliminary results have been encouraging, routine implementation of this operative intervention has been controversial. Major limitations

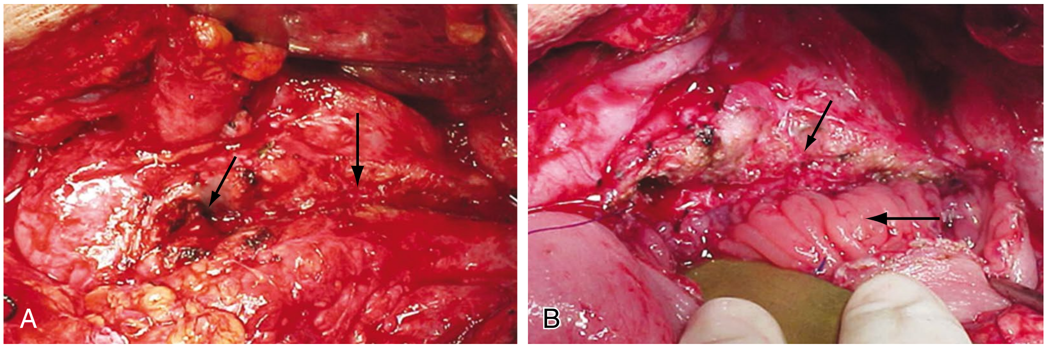

FIGURE 92.13 Frey procedure, intraoperative photographs. (A) Significant dilation of the main pancreatic duct at the level of the head *(short arrow)* and body of the pancreas *(long arrow)* after the anterior surface of the pancreas has been opened. (B) Side-to-side anastomosis between the pancreatic duct *(short arrow)* and jejunum *(long arrow).*

associated with this procedure include the cost and lack of islet-processing facilities.

As several other centers have established islet autotransplantation programs and laboratories, it has become clear that the treatment of patients with severe diffuse chronic pancreatitis should be coordinated by a multidisciplinary team. This should include a pancreatic surgeon, pancreatologist, interventional endoscopist, radiologist, anesthesia pain specialist, endocrinologist, nutritional expert, and perhaps a neuropsychologist or psychiatrist. A multifaceted approach to the decision and the type of treatment is crucial to long-term success. Groups at the Medical University of South Carolina and the University of Alabama at Birmingham have shown that patients with depression or substance abuse, such as alcoholism, have a poor outcome compared with patients without depression or alcoholism.

In pediatric patients with genetic predisposition to pancreatitis, early pancreatectomy and islet autotransplantation are highly effective at improving quality of life.

Biliary strictures. Chronic scarring and fibrosis of the head of the pancreas result in external compression of the intrapancreatic portion of the common bile duct. Up to one-third of patients with chronic pancreatitis develop radiologic evidence of bile duct dilation; however, significant biliary obstruction occurs in 6% of patients. Biliary strictures typically appear as a long symmetric narrowing that involves the intrapancreatic portion of the common bile duct in MRCP or ERCP (Fig. 92.14). IV fluid and antibiotic therapy and temporary bile duct decompression with plastic stents are indicated for patients who present with cholangitis. Pancreaticoduodenectomy is indicated for patients in whom malignant disease cannot be excluded before surgery. A Roux-en-Y hepaticojejunostomy is an alternative treatment for patients without evidence of malignant disease or significant scarring that precludes resection of the head of the pancreas. A Frey or Beger procedure can often relieve the biliary obstruction by removing the pancreatic head parenchyma that causes compression, thus avoiding the need for a separate biliary bypass.

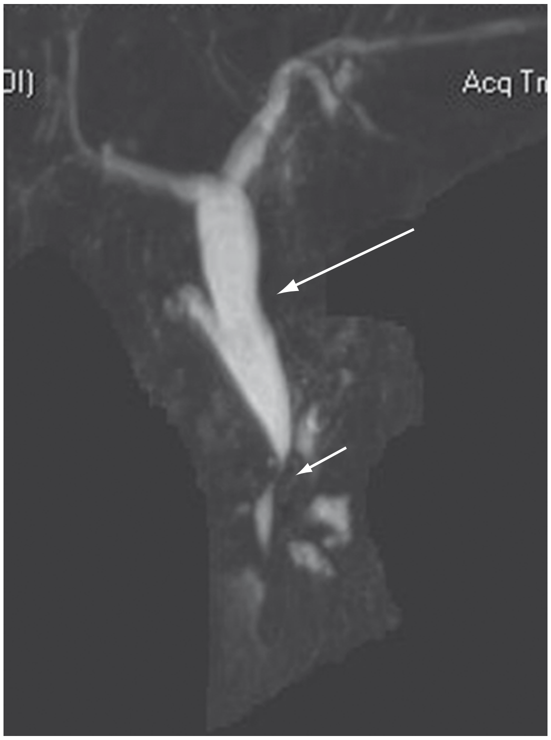

FIGURE 92.14 Bile duct stricture secondary to chronic pancreatitis. Magnetic resonance cholangiopancreatography indicates common bile duct dilation *(large arrow)* secondary to a stricture at the level of the intrapancreatic portion of the common bile duct *(small arrow).*

Duodenal stenosis. Up to 1.2% of patients with chronic pancreatitis develop duodenal strictures. Clinical manifestations include abdominal pain, nausea, vomiting, and significant weight loss. Differential diagnoses include other causes of gastric outlet obstruction secondary to upper gastrointestinal malignant neoplasms and gastroparesis. Severely malnourished patients require IV hydration, nutritional support, and gastric decompression with a nasogastric tube. Permanent treatment requires a gastrojejunostomy.

Pancreatic pseudocyst. Pancreatic pseudocysts develop more frequently in patients with chronic pancreatitis compared with AP. Up to 30% to 40% of patients develop pseudocysts during the course of their disease. Only 10% of patients have spontaneous pancreatic pseudocyst regression. Spontaneous regression is less likely to occur in these patients because pancreatic pseudocysts arise more frequently in the setting of pancreatic duct obstruction. Indications for treatment include symptoms secondary to gastric, duodenal, or biliary compression or associated complications, such as bleeding, pancreaticopleural fistulas, rupture, or spontaneous bleeding. Alternative modalities in the treatment include endoscopic and surgical drainage (see earlier).

Traditionally, management of a symptomatic or persistent pseudocyst has been open operation and, depending on location, drainage through either cystogastrostomy or Roux-en-Y cystojejunostomy. With advancements in interventional endoscopy, drainage has proven successful with ERCP. More recently, drainage with EUS has been shown to be more successful because of improved visualization of vasculature as well as fluid collections and necrosis. Small-caliber plastic stents may be used for simple pancreatic fluid collections or larger metal stents for complex collections or those with infection or necrosis. At the University of Alabama at Birmingham, a prospective randomized trial of endoscopic versus operative cystogastrostomy showed equal efficacy but quicker improvement in quality of life and less hospital expenditure from the endoscopic approach for simple pancreatic pseudocysts.[39]

CYSTIC NEOPLASMS OF THE PANCREAS

Second only to adenocarcinoma, pancreatic cystic neoplasms (PCNs) have become an increasingly recognized entity, with sometimes complex treatment decision algorithms to balance cancer prevention with the risk of (surgical) overtreatment. Currently, there are three widely recognized guidelines providing recommendations for the surveillance and management of PCNs: the American Gastroenterological Association (AGA) guidelines issued in 2015, the International Association of Pancreatology (IAP) guidelines last revised in 2017, and the guidelines from the European Study Group on Cystic Tumors of the Pancreas, last updated in 2018.[40]

PCNs are classified broadly into nonmucinous and mucinous types. Nonmucinous PCNs, such as serous cystic neoplasms (SCNs) and solid pseudopapillary neoplasms (SPNs), are lined by simple cuboidal epithelium, whereas mucinous PCNs, which include IPMNs and mucinous cystic neoplasms (MCNs), are lined by endoderm-derived columnar epithelium.[41] Table 92.5 summarizes the distinguishing features of cystic neoplasms of the pancreas.

TABLE 92.5 **Defining Characteristics of Pseudocysts and Pancreatic Cystic Neoplasms**

CHARACTERISTICS	PSEUDOCYST	SCN	MCN	IPMN	SPN
Epidemiology					
Sex	F = M	F ⩾ M (4:1)	F ⩾> M (10:1)	F = M	F >> M
Age (years)	40–60	60–70	50–60	60–70	25–40
Imaging Findings					
Location	Evenly distributed	Evenly distributed	Head ⩽ body/tail	Head > diffuse > body/tail	Body/tail
Appearance	Round, thick-walled large cyst; gland atrophy ± calcification	Multiple small cysts separated by internal septations with central starburst calcifications	Thick-walled, septated macrocyst with smooth contour; ± solid component, eggshell calcifications	Poorly demarcated, lobulated, polycystic mass with dilation of main or branch ducts	Thick-walled encapsulated structures with peripheral solid and central cystic components
Communication with ducts	Yes	No	Very rare	Yes	No
Cyst Fluid Analysis					
Cytology	Inflammatory cells	Scant glycogen-rich cells, with positive periodic acid–Schiff stain	Sheets and clusters of columnar, mucin-containing cells	Tall, columnar, mucin-containing cells	Papillary clusters with central capillaries, myxoid stroma, monomorphism, cercariform cells, and hyaline globules
Mucin stain	Negative	Negative	Positive	Positive	Negative
Amylase	Very high	Low	Low	High	Low
CEA	Low	Low	High	High	Low

CEA, Carcinoembryonic antigen; *F,* female; *M,* male; *IPMN,* intraductal papillary mucinous neoplasm; *MCN,* mucinous cystic neoplasm; *SCN,* serous cystic neoplasm.

From Tran Cao HS, Kellogg B, Lowy AM, et al. Cystic neoplasms of the pancreas. *Surg Oncol Clin N Am.* 2010;19:267-295.

Distinguishing between different types of PCNs is essential because of their varying malignant potential. SCNs are mostly benign and usually do not require surveillance, whereas IPMNs, MCNs, and SPNs are premalignant and need either surveillance or surgical resection. PCNs are known precursors for invasive pancreatic cancer; therefore, patients with premalignant PCNs are routinely monitored.[42] A multidisciplinary approach that incorporates clinical findings, cyst fluid analyses, radiologic findings, and ancillary studies is necessary to ensure accurate classification. The primary goal is to prevent malignancy and alleviate symptoms while avoiding unnecessary surgery.

Subtypes of Cystic Neoplasms

Solid Pseudopapillary Neoplasm

SPN, or Frantz tumor, is a low-grade epithelial neoplasm primarily found in young females (25–35 years). Many lesions are diagnosed incidentally, but a palpable mass is the most common presentation in symptomatic patients. The majority of SPNs have a mean size of 8 cm and are located in the body and tail of the pancreas.[43] Cyst fluid analysis typically shows low CEA and amylase. Macroscopically, they can vary from pure solid to entirely cystic or be composed of a mixture of solid and cystic areas, and they are large, round, and well circumscribed. Analysis of resection specimens has shown a characteristic mutation in the β-catenin gene and the absence of other common mutations, such as *KRAS, SMAD4,* and *TP53.*[44] SPNs are classified as malignant because of the potential for lymphatic spread, recurrence, and distant metastases and ought to be resected.[45] After complete surgical resection, the long-term outcome for patients with SPN is generally excellent, with 95.6% of patients remaining disease-free over long-term follow-up. However, around 6% of patients present with locally advanced tumors, such as vascular involvement or lymph node metastases, and 8% have distant metastases; therefore, annual lifelong follow-up is essential.[43]

Serous Cystic Neoplasm

SCNs have a predilection for the head of the pancreas and occur in patients with a higher median age. Patients commonly present with vague abdominal pain and less frequently with weight loss and obstructive jaundice. On gross inspection, SCNs are large, well-circumscribed masses. Microscopic examination reveals multiloculated, glycogen-rich small cysts. Central calcification, with radiating septa giving the sunburst appearance, is a radiographic sign on CT in 10% to 20% of patients (Fig. 92.15). With the advent of EUS, these features can now be better delineated. Recently, differential cyst fluid protein expression was observed between SCNs and IPMNs, with low CEA and amylase noted in SCNs compared with IPMNs.[23] Although serous cystic tumors are generally considered benign, pancreatectomy is suggested when the diagnosis of malignant disease is uncertain or in symptomatic serous cystadenomas. Patients with a tumor larger than 4 cm are more likely to be symptomatic and to display a more rapid median growth rate than patients with tumors smaller than 4 cm. Thus, in select patients with large (>4 cm) or rapidly growing lesions, resection of an SCN is appropriate.[46]

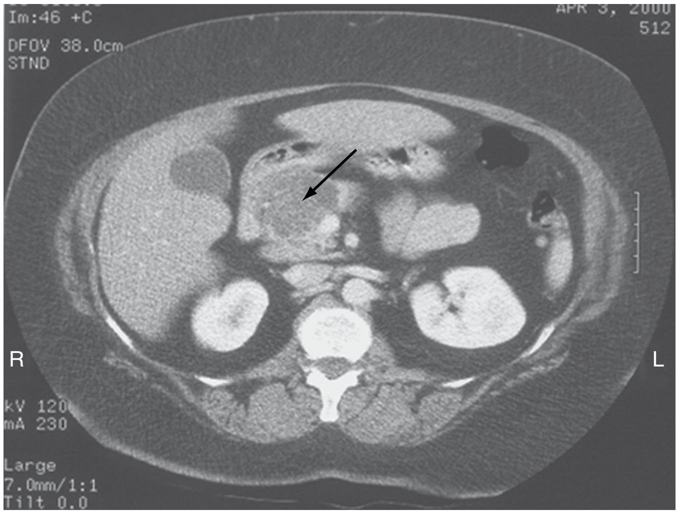

FIGURE 92.15 Computed tomography scan of serous cyst neoplasm. The *arrow* depicts the sunburst appearance and central calcification.

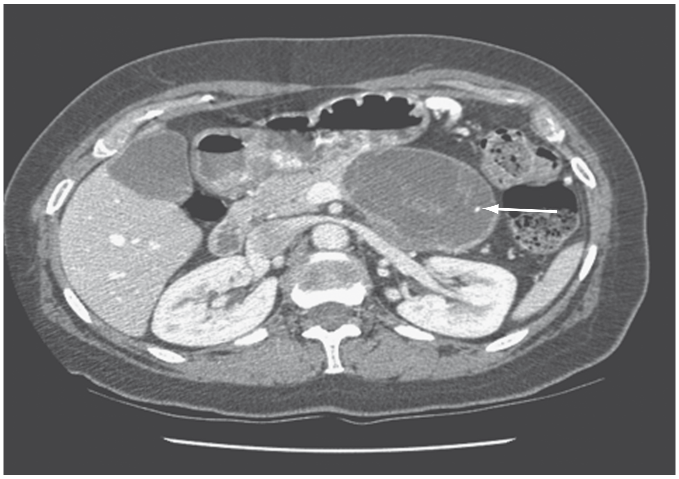

FIGURE 92.17 Computed tomography scan of the tail of the pancreas mucinous cystic neoplasm showing a large multiloculated cyst *(arrow)* in the absence of pancreatic ductal communication.

Mucinous Cystic Neoplasm

MCNs are mucin-producing cyst tumors that, unlike IPMNs (described later), lack communication with the pancreatic duct. These tumors span the histologic spectrum from benign to invasive carcinomas. MCNs contain mucin-producing epithelium and are identified histologically by the presence of mucin-rich cells and ovarian-like stroma surrounding the cyst (Fig. 92.16). Staining for estrogen and progesterone receptors is positive in most cases. Frequently seen in young females, the mean age at presentation is in the fifth decade. Males are rarely affected. MCNs are typically found in the body and tail of the pancreas but infrequently can occur in the head. Although incidental MCN is becoming increasingly common, up to 50% of patients present with vague abdominal pain. A history of pancreatitis may be found in up to 20% of patients, which explains the common misdiagnosis of pseudocyst.

The radiologic characteristic of an MCN on a CT scan is the presence of a solitary cyst, which may have fine septations and be surrounded by a rim of calcification (Fig. 92.17). Cross-sectional imaging may not be able to distinguish between benign and malignant MCNs; however, the presence of eggshell calcification, larger tumor size, or a mural nodule on cross-sectional imaging is suggestive of malignancy.

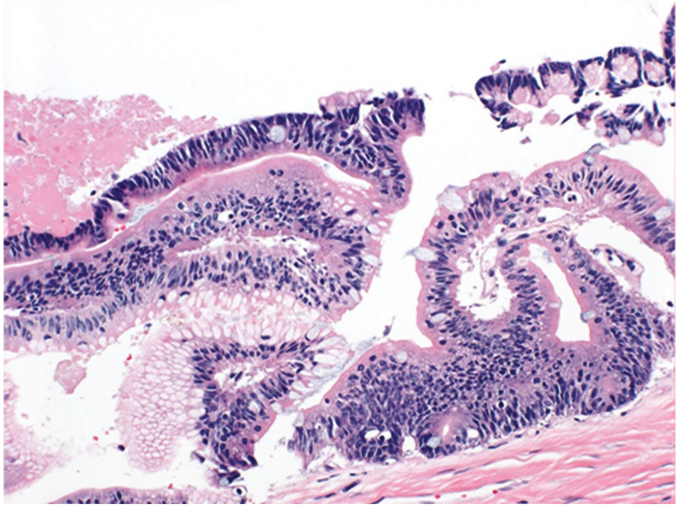

FIGURE 92.16 Ovarian-like stroma is a histologic feature often seen in mucinous cystic neoplasms.

EUS and cyst fluid analyses play an important role in the diagnosis of MCN and other cystic neoplasms. FNA with cyst fluid analysis of MCNs demonstrates mucin-rich aspirate, high CEA levels (>192 ng/mL; log scale), and low amylase. Fig. 92.18 illustrates the sensitivity and specificity of CEA in identifying mucinous neoplasms on the basis of fine-needle fluid aspiration. These fluid analyses provide accurate diagnosis in up to 80% of cases.[24]

Pancreatic resection is the standard treatment for MCNs, given the potential for malignant transformation. In the absence of invasive malignant disease, resection is curative, and no further surveillance is required. The prognosis of patients who undergo pancreatectomy for invasive MCNs is poor, although more favorable than that of patients with ductal adenocarcinoma of the pancreas that develops from other precursor lesions. Invasive

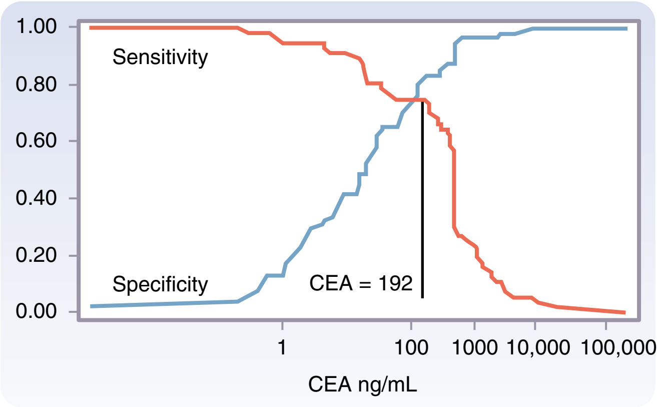

FIGURE 92.18 Sensitivity and specificity curves of cyst fluid carcinoembryonic antigen *(CEA)* concentrations (ng/mL; log scale) for differentiating between mucinous and nonmucinous cystic lesions. An optimal cutoff value of 192 ng/mL correlated with the crossover of the sensitivity and specificity curves. (From Brugge WR, Lewandrowski K, Lee-Lewandrowski E, et al. Diagnosis of pancreatic cystic neoplasms: a report of the cooperative pancreatic cyst study. *Gastroenterology.* 2004;126:1330-1336.)

MCNs exhibit slower growth, less frequent nodal involvement, and less aggressive clinical behavior compared with IPMNs or pancreatic intraepithelial (PanIN)-derived ductal adenocarcinoma; a 5-year survival of 50% to 60% can be expected after resection. Despite limited experience with invasive MCNs, most centers offer adjuvant systemic chemotherapy after surgical resection, especially when node-positive disease is present.

Intraductal Papillary Mucinous Neoplasm

IPMNs of the pancreas are mucinous epithelial neoplasms that arise from the MPDs, branch ducts, or both. IPMNs were first described by Ohashi and typically manifest in the sixth to seventh decade of life. As with other PCNs, because of the increasing use of cross-sectional imaging (CT and MRI), this entity is being increasingly diagnosed. IPMNs encompass a wide spectrum of epithelial changes. Recent efforts to standardize nomenclature for IPMN have been critical to allow for better study of diagnosis, management, and outcomes for IPMN. The terms *adenoma* and *carcinoma in situ* have been abandoned in order to standardize reporting. Current histopathologic grading includes low, moderate, or high-grade dysplasia and presence or absence of invasive malignancy.

There are three subtypes of IPMN, which are defined by the pattern of ductal involvement that is present. Neoplasia that affects only the small side branches is termed *side branch* or *branch duct IPMN* (BD-IPMN), whereas involvement of the MPD is termed *main duct IPMN* (MD-IPMN). Side branch IPMNs that extend into the main duct, often leading to upstream dilation, are termed *mixed-type IPMNs.*

Management Strategies for Intraductal Papillary Mucinous Neoplasm

Risk of malignant transformation has been described in IPMN and is related to multiple factors that have been stratified as worrisome and high risk. These factors have been identified through international consensus and are reported in the international consensus guidelines for the management of IPMN of the pancreas, most recently updated in 2017.[47]

Worrisome features of IPMN based on imaging include BD-IPMN cyst size larger than 3 cm, enhancing mural nodule smaller than 5 mm, thickened enhancing cyst wall, MPD size of 5 to 9 mm, abrupt change in caliber of MPD with distal pancreatic atrophy, and lymphadenopathy. In addition, patients who present with clinical signs of pancreatitis, an elevated carbohydrate antigen 19-9 (CA 19-9) level, or cyst growth of more than 5 mm over 2 years should be considered to have worrisome features. These features are summarized in Table 92.6.

High-risk features of IPMN include the presence of an enhancing nodule larger than 5 mm within the cyst and MPD dilation of more than 1 cm. Patients who present with clinical signs of jaundice should also be considered at high risk.

Numerous genetic mutations that may lead to malignant transformation of IPMN have been evaluated, including *GNAS, KRAS, p53, MUC,* and others. To date, genetic analysis of cyst fluid has failed to improve our ability to predict malignancy or select patients for surgical resection over existing clinical guidelines.

Branch duct intraductal papillary mucinous neoplasm. As the name implies, BD-IPMN involves dilation of the pancreatic duct side branches that communicate with but do not involve the MPD. BD-IPMNs may be focal, involving a single side branch, or multifocal, with multiple cystic lesions throughout the length of the pancreas. Multiplicity of cysts favors a diagnosis of BD-IPMN.

TABLE 92.6 **Summary of Worrisome and High-Risk Features of Intraductal Papillary Mucinous Neoplasm**

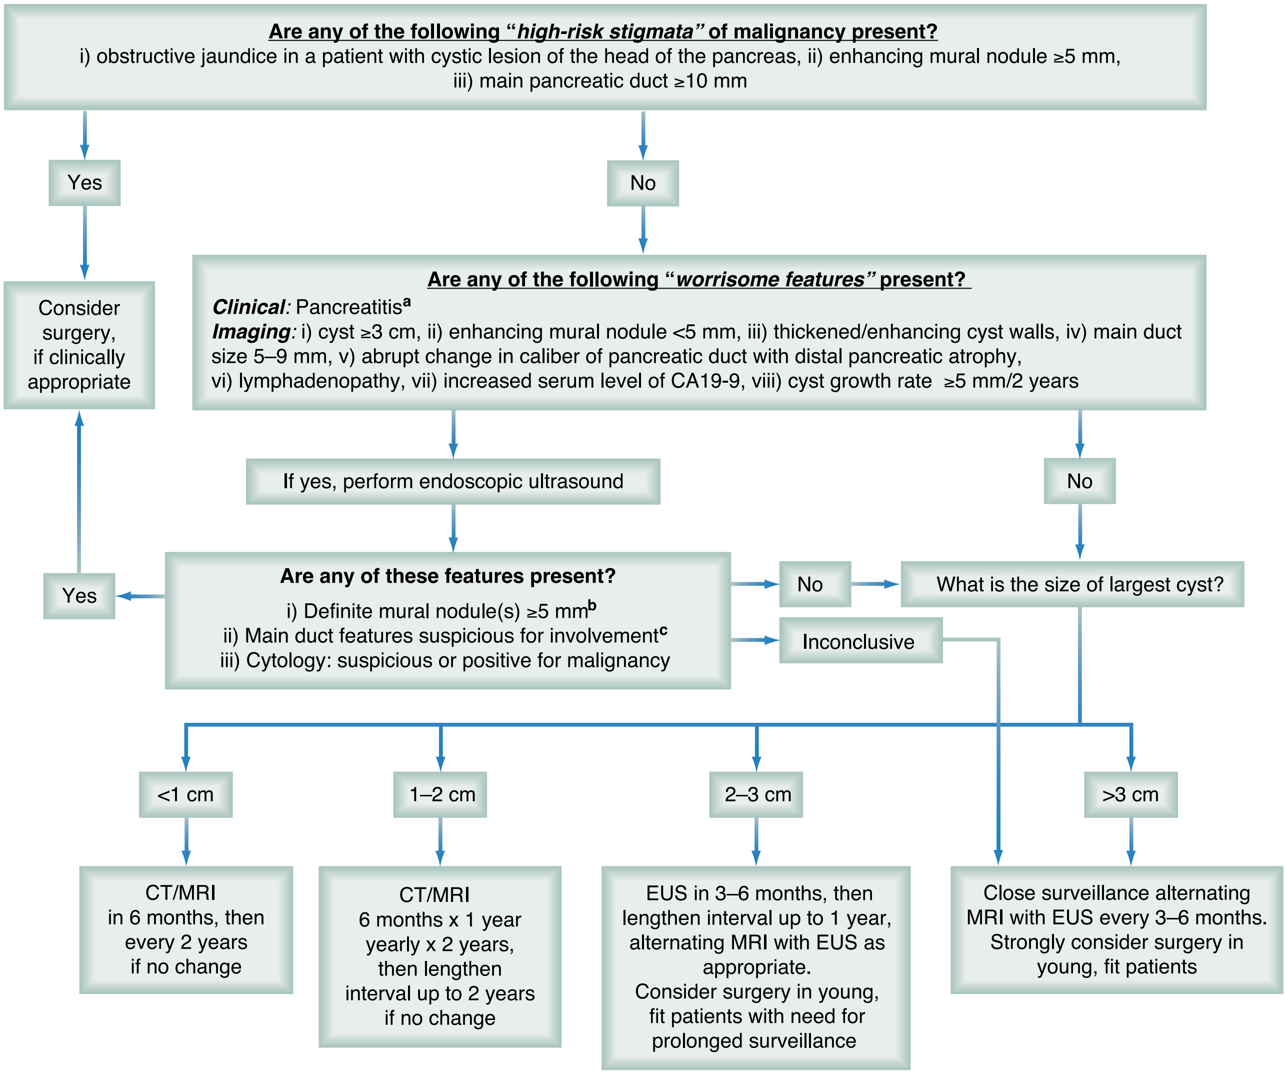
WORRISOME FEATURES	HIGH-RISK FEATURES
Main duct 5–9 mm	Main duct >1 cm
Enhancing mural nodule <5 mm	Enhancing mural nodule >5 mm
Thickened, enhancing cyst wall	Jaundice
BD-IPMN >3 cm	
Abrupt caliber change in main duct with upstream atrophy	
Lymphadenopathy	
Pancreatitis	
Increased serum 19-9	
Cyst growth >5 mm over 2 years	

BD-IPMN, Branch duct intraductal papillary mucinous neoplasm.

All cysts with worrisome features on CT or MRI should undergo EUS; all cysts with high-risk features should be resected. Recommendations for management of suspected BD-IPMN are summarized in Fig. 92.19.[46] For asymptomatic patients with BD-IPMN who have no worrisome or high-risk features, surveillance may be a reasonable initial strategy; however, multiple variables, including patient age and comorbidities, also play a role in decision-making. In BD-IPMN, new European guidelines suggest that cyst diameter over 4 cm is a relative indication for surgery, alongside factors like cytology positive for malignancy/HGD, solid masses, jaundice, enhancing mural nodules (≥5 mm), and MPD dilation over 10 mm. Relative indications also include fast cyst growth (≥5 mm/year), elevated serum CA 19-9 levels (>37 U/mL), MPD dilation of 5 to 10 mm, and symptomatic lesions (e.g., IPMN-related AP or new-onset diabetes).[48]

Any patient with symptoms or high-risk features related to BD-IPMNs (e.g., jaundice, enhancing mural nodule, and dilated MPD) should undergo surgical resection because the risk of malignant disease in symptomatic patients is heightened. Overall, the risk of invasive malignant disease in the setting of BD-IPMN is approximately 10% to 15%; however, it is increasingly clear that not all patients with IPMNs require surgery. Overall, for BD-IPMN, the risk of invasive malignant disease is approximately 2% to 3% per year. A plan for watchful surveillance with delayed intervention in these patients is reasonable because the risk for malignant transformation with small and asymptomatic branch duct tumors is low, most patients are older, and the time required for development of invasive malignant disease may be longer than the patient's life expectancy.

Main duct intraductal papillary mucinous neoplasm. In contrast to BD-IPMN, MD-IPMN indicates abnormal cystic dilation of the MPD with columnar metaplasia and thick mucinous secretions, which can be seen oozing from a patulous papilla, often described as a "fish mouth" appearance, on endoscopic evaluation (Fig. 92.20). Involvement of the MPD may be focal or diffuse; it is most relevant because of the significantly increased risk of malignant degeneration. Individuals with MD-IPMN have a 30% to 50% risk of harboring invasive pancreatic cancer at the time of presentation. Thus, surgical resection is the cornerstone of treatment. Fig. 92.21 demonstrates MD-IPMN with dilation of the entire pancreatic duct.



Are any of the following "high-risk stigmata" of malignancy present?
i) obstructive jaundice in a patient with cystic lesion of the head of the pancreas, ii) enhancing mural nodule ≥5 mm, iii) main pancreatic duct ≥10 mm
Yes
No
Consider surgery, if clinically appropriate
Are any of the following "worrisome features" present?
Clinical: Pancreatitis[a]
Imaging: i) cyst ≥3 cm, ii) enhancing mural nodule <5 mm, iii) thickened/enhancing cyst walls, iv) main duct size 5–9 mm, v) abrupt change in caliber of pancreatic duct with distal pancreatic atrophy, vi) lymphadenopathy, vii) increased serum level of CA19-9, viii) cyst growth rate ≥5 mm/2 years
If yes, perform endoscopic ultrasound
No
Yes
Are any of these features present?
i) Definite mural nodule(s) ≥5 mm[b]
ii) Main duct features suspicious for involvement[c]
iii) Cytology: suspicious or positive for malignancy
No
Inconclusive
What is the size of largest cyst?
<1 cm
1–2 cm
2–3 cm
>3 cm
CT/MRI in 6 months, then every 2 years if no change
CT/MRI 6 months x 1 year yearly x 2 years, then lengthen interval up to 2 years if no change
EUS in 3–6 months, then lengthen interval up to 1 year, alternating MRI with EUS as appropriate. Consider surgery in young, fit patients with need for prolonged surveillance
Close surveillance alternating MRI with EUS every 3–6 months. Strongly consider surgery in young, fit patients

FIGURE 92.19 Recommendations for management of suspected branch duct intraductal papillary mucinous neoplasm. *CA 19-9,* Carbohydrate antigen 19-9; *EUS,* endoscopic ultrasound. (From Tanaka M, Fernandez-del Castillo C, Adsay V, et al. International consensus guidelines 2012 for the management of IPMN and MCN of the pancreas. *Pancreatology.* 2012;12:183-197.)

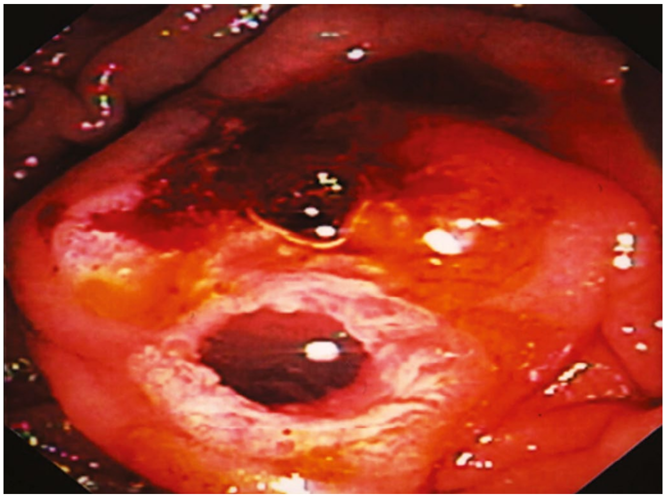


FIGURE 92.20 Classic endoscopic view of intraductal papillary mucinous neoplasm showing viscous fluid oozing from a patulous ampulla of Vater.

Unlike patients with pancreatic ductal adenocarcinomas (PDACs), 50% of patients with IPMNs of the pancreas present with abdominal pain, and up to 25% present with AP, which, not surprisingly, has led to the diagnosis of chronic pancreatitis in many series. Several investigators have studied clinical and pathologic markers as predictors of malignancy and found that jaundice, elevated serum alkaline phosphatase level, mural nodules, diabetes, and MPD diameter of 7 mm or larger are strongly associated with invasive IPMNs. Current guidelines suggest that main duct dilation of more than 5 mm is consistent with a diagnosis of MD-IPMN and a worrisome feature, whereas more than 1 cm is considered high risk. Given the overall high risk of malignant transformation, all patients with evidence of MD-IPMN should be considered for surgical resection if they are surgically fit.

The radiographic features of IPMNs on pancreatic CT scans may include a dilated MPD, cysts of varying sizes, and possibly mural nodules (see Fig. 92.21). MRCP and EUS are important secondary diagnostic studies for the evaluation of patients with suspected IPMN. MRCP may allow localization of mural nodules and pretreatment classification of suspected side branch or main

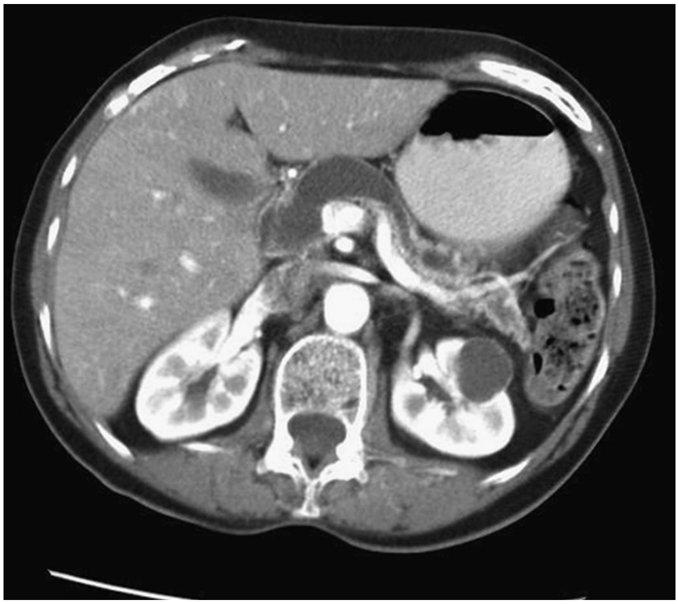

FIGURE 92.21 Cross-sectional imaging of main duct intraductal papillary mucinous neoplasm throughout the entire pancreatic gland and a prominent ampulla of Vater.

duct types of IPMN. EUS can evaluate the pancreatic duct and assess the fluid and solid components of the neoplasm. Aspirated fluid is typically viscous and clear and contains mucin. Cytology studies demonstrate mucin-rich fluid with variable cellularity; columnar mucinous cells with variable atypia may also be seen. As in MCNs and BD-IPMNs, fluid aspirates characteristically reveal an elevated CEA level (>192 ng/mL; log scale). This elevation of the CEA level is not predictive of invasive malignant disease, only the presence of mucinous metaplasia.

Mixed-type intraductal papillary mucinous neoplasm. *Mixed-type IPMN* denotes a side branch IPMN that has extended to involve the MPD to a varying degree. Concern for mixed-type IPMNs should be raised in individuals with side branch cysts who exhibit upstream dilation of the pancreatic duct because this is an indication of main duct involvement. The biologic behavior of mixed-type IPMNs most closely resembles that of MD-IPMNs, with a significant risk of invasive malignant disease at the time of presentation (30%–50%). As for MD-IPMN, surgical resection is indicated for the treatment of mixed-type IPMN.

Treatment: Surgical Resection for Intraductal Papillary Mucinous Neoplasm

Partial pancreatectomy is the primary treatment for high-risk lesions; however, the optimal extent of pancreatic resection for some patients remains unknown. For BD-IPMN, resection should target the lesion of concern, and therefore, surgical decision-making is usually straightforward. For MD-IPMN, however, it is not always possible to determine the extent of microscopic abnormality within the duct. In the absence of diffuse polyps or enhancing nodules in the main duct, a right-sided pancreatectomy is preferred. Intraoperative frozen section of the pancreas neck margin is obtained, and total pancreatectomy is reserved for those cases with high-grade dysplasia or invasive carcinoma identified at the margin. Although some investigators continue to advocate total pancreatectomy for the treatment of any IPMN, the evidence supporting this approach is decreasing with longer follow-up of patients treated by R0 and R1 partial pancreatectomy. It is appropriate to recommend partial pancreatectomy and discuss management of the pancreatic margin preoperatively, advising the patient that approximately 15% of patients will require conversion to total pancreatectomy to achieve negative parenchymal resection margins.

Survival outcomes are significantly better in patients with IPMNs than in patients with PDACs. Sohn and associates have analyzed a series of 136 patients with IPMNs; survival rates for patients with noninvasive IPMNs are 97% at 1 year, 94% at 2 years, and 77% at 5 years.[49] When the group of patients with noninvasive IPMNs was analyzed further, no survival differences were found between patients with IPMNs and those with borderline IPMNs. On the contrary, there was a significant difference in survival rate between patients with noninvasive IPMNs and those with invasive IPMNs. The 1-, 3-, and 5-year survival rates for patients with invasive IPMNs were 72%, 58%, and 43%, respectively. Therefore, survival is clearly dependent on the invasive component of the lesion.[50]

Patients diagnosed with invasive cancer associated with their IPMN on pathology should adhere to follow-up schedules akin to those established for PDAC, following the National Comprehensive Cancer Network (NCCN) guidelines. Individuals with high-grade dysplasia are advised to undergo surveillance every 6 months during the first year, shifting to once a year thereafter. Continued monitoring is also advocated for those with low- to moderate-grade dysplasia or benign conditions because the likelihood of developing a new IPMN after surgery is 25% at 5 years and 63% at 10 years.[51]

The decision to terminate surveillance should depend on the age and condition of the patient. Reoperation should be considered for patients who present with recurrence or progression of disease in the pancreas remnant.[52]

Minimally Invasive Approaches to Resection of Cystic Neoplasms

Resections of PCNs must balance the risk of malignant transformation with potential complications and long-term pancreatic insufficiency, deciding between oncologic resection, parenchyma-sparing techniques, and surveillance. If high-grade dysplasia or malignancy is suspected, oncologic resections with radical margins and lymphadenectomy are necessary, regardless of PCN etiology. Recent evidence suggests that minimally invasive approaches may benefit patients with PCNs. Most PCNs are detected in a premalignant stage, allowing for prophylactic surgical treatment.[53] Unlike patients with PDAC, those with PCNs are often younger and curable with resection, making long-term quality of life a priority. Therefore, surgery with minimal morbidity is desirable. However, the specific biology of PCNs must be considered, and minimally invasive resections should adhere to oncologic principles similar to open approaches.

The first laparoscopic pancreaticoduodenectomy was performed in 1994 by Gagner and Pomp. Since then, minimally invasive pancreaticoduodenectomy (MIPD) has seen a rise in popularity. In recent years, at least four randomized control trials have been conducted to compare laparoscopic pancreaticoduodenectomy (LPD) and open pancreaticoduodenectomy (OPD) (Video 92.2; Video 92.3). The results from the single-center, nonblinded RCTs PLOT and PADULAP showed that MIPD has significant benefits over OPD in terms of reduced blood loss, quicker recovery, and shorter LOS, despite longer operating times and having similar postoperative complications.[54–56] However, the LEOPARD-2 trial, a multicenter patient-blinded phase II/III

RCT, was closed early because of significantly increased mortality seen in the MIPD group. After enrolling 99 patients, the risk of mortality after minimally invasive surgery was 10% (five patients) versus 2% (one patient) for open surgery.[57] Debate continues as to the appropriateness of minimally invasive pancreaticoduodenectomy, and the DIPLOMA-2 trial, an RCT performed in 14 high-volume pancreatic centers in Europe, is currently underway to assess outcomes between MIPD and open PD.[58] Additionally, although postoperative outcomes have been well published, data regarding oncologic outcomes are limited. Systematic reviews and single-center retrospective analyses show no major differences between LPD and OPD.[59,60]

Given the limitations of current laparoscopic technology and the need for meticulous vascular control and complex reconstruction in pancreatic surgery, robotic pancreaticoduodenectomy (RPD) has been proposed as an alternative to LPD. The robotic approach has been gaining popularity in the United States, with most high-volume centers offering the technique. The most extensive report on RPD outcomes is from the University of Pittsburgh group, which shared insights from a decade of experience, including 500 consecutive RPDs.[61] This group observed an 8% rate of clinically relevant postoperative pancreatic fistula (CR-POPF), major complications in 24% of cases, median LOS of 8 days, and 90-day mortality rates of 3.1%. Further retrospective propensity-matched analysis of single-center and large databases has supported the association of RPD with decreased rate of CR-POPF.[62–64] Currently underway are two RCTs comparing RPD to OPD: the Dutch DIPLOMA-2 trial, as mentioned before, and the Chinese phase 3 multicenter RCT Robotic Versus Open Pancreaticoduodenectomy for Pancreatic and Periampullary Tumors (PORTAL) study using time to functional recovery as a main outcome. The EUROPA trial, a single-center phase 2b exploratory trial, was just recently published with 62 total patients (RPD, $n = 29$) and only surgeons who had conducted at least ≥40 OPDs and RPDs. Most outcomes, including complications, recovery, and oncologic metrics, were similar. Notably, there was increased delayed gastric emptying in the RPD group and, as expected, increased intraoperative time and cost.[65] RPD presents potential benefits compared with the conventional open method, including enhanced visibility, magnification, and maneuverability, all of which could lead to increased surgical accuracy. However, a critical factor to consider is the learning curve associated with this technically challenging procedure. Defining the point at which a surgeon overcomes the learning curve for RPD remains somewhat unclear, with the reported number of procedures needed ranging widely.[66,67] Looking ahead, as experience grows and robotic technology becomes more widely embraced, it is anticipated that the learning curve for RPD will become more manageable, rendering it an accessible choice for a broader range of pancreatic surgeons.

CHAPTER 93

Pancreatic Cancer

Susan Tsai and Douglas B. Evans

OUTLINE

Introduction
Epidemiology
  Hereditary Risk Factors
  Acquired Risk Factors
Pathogenesis
  Precursor Lesions
  Molecular Alterations
Clinical Management
  Clinical Presentation
  Diagnostic Studies
  Clinical Staging
  Endoscopic Procedures
  Laboratory Studies
Treatment
  Multimodality Approach to Operable Pancreatic Adenocarcinoma
  Trials comparing Neoadjuvant Therapy Versus Surgery First
  Trials Comparing Neoadjuvant Therapeutic Approaches
Surgical Management
  Preoperative Preparation
  Pancreaticoduodenectomy
Postoperative Care
  Postoperative Complications
  Pancreatic Fistula
  Delayed Gastric Emptying
  Postpancreatectomy Hemorrhage
Summary

INTRODUCTION

Pancreatic ductal adenocarcinoma (PDAC) is the third leading cause of cancer death in the United States (behind lung and colorectal cancer) and is the tenth most common cancer among males and seventh most common cancer among females.[1] As screening for colorectal cancer continues to expand, we anticipate pancreatic cancer becoming the second leading cause of adult cancer death very soon. The general population's lifetime risk of PDAC is estimated to be 1.7%.[1] The rates of the most common cancers have generally declined over the past 30 years as a result of the implementation of screening guidelines. In contrast, the annual incidence of PDAC has grown by approximately 1%, in part because of a lack of effective early detection.[2] Population-based screening for PDAC is not currently justified because of its relatively low incidence in the United States as compared with breast (30%), colon (8%), or lung cancer (12%). Unfortunately, over 80% of patients with PDAC present with metastatic disease at the time of diagnosis. Although the prognosis of patients with PDAC remains guarded, with a 5-year overall survival rate of 11.5% among all stages, the adoption of alternative treatment sequencing for the management of operable disease and expanding systemic therapies for patients with metastatic disease fuel new optimism for meaningful advancements in this disease.[2] This chapter provides an overview of the pathogenesis, diagnosis, staging, and treatment of this disease, with a focus on the historical context and latest understanding of the genetics and molecular biology of PDAC.

EPIDEMIOLOGY

The biology of PDAC is uniquely different from that of other solid tumors, with several unique features, including, at the molecular level, a near-universal presence of *KRAS* mutations and, at the histologic level, the overabundance of a desmoplastic stroma. Over two decades ago, the molecular drivers of PDAC were identified, and a conceptual framework was proposed that included the accumulation of a series of acquired mutations over years, ultimately leading to the development of invasive carcinoma. More recently, catastrophic rearrangements of the genome have been described that greatly accelerate the time to malignant conversion. This section provides an overview of the multifactorial pathogenesis of PDAC and contributions from associated risk factors, including familial risk from susceptibility gene mutations, chronic pancreatitis, pancreatic cysts, and diabetes mellitus.

Hereditary Risk Factors

The majority of patients with PDAC develop a sporadic tumor as a result of acquired molecular alterations and population-level risk factors. However, approximately 10% to 15% of patients with PDAC have a pathologic germline variant identified.[3] Current National Comprehensive Cancer Network (NCCN) guidelines recommend that all individuals diagnosed with PDAC receive a comprehensive cancer family history.[4] Any proband and their first-degree relatives are recommended to undergo genetic testing. Increased risk of PDAC has been associated with several well-described *hereditary* cancer syndromes, including breast-ovarian cancer syndromes *(BRCA1, BRCA2, PALB2),* familial atypical mole and melanoma syndrome *(CDKN2A),* and Peutz-Jeghers syndrome *(STK11).*[3] Patients with known hereditary syndromes (Table 93.1) are recommended to undergo PDAC screening and may benefit from a comprehensive screening approach to address all other at-risk sites for other associated cancers as well. Although genetic testing can identify underlying genetic susceptibility, the genetic basis of inherited susceptibility to PDAC remains largely unknown.

TABLE 93.1 **High-Risk PDAC Syndromes**

	PATHOGENIC VARIANT	GENETIC SYNDROME	LIFETIME RISK	PDAC IN AFFECTED BLOOD RELATIVE	AGE TO INITIATE SCREENING (YEARS)
High risk	*CDKN2A*	FAMM	10%–17%	None	40
	P16 Leiden Variant	FAMM	17%–58%	None	40
	PRSS1	Hereditary pancreatitis	24%–40%	None	40
	STK11/LKB1	Peutz-Jeghers	30%–60%	None	30
	Unknown	Familial PDAC	8%–12%	2 FDR	50–55
Moderate risk	*BRCA1*	Breast-ovarian	1.2%	>1 FDR or 2+	50
	BRCA2	Breast-ovarian	2%–5%	>1 FDR or 2+	50
	PALB2	Breast-ovarian	Unknown	>1 FDR or 2+	50
	ATM		Unknown	>1 FDR or 2+	50
	MLH1, MSH2, MSH6	Lynch	3.7%	>1 FDR or 2+	50
	Unknown	Familial PDAC	8%–12%	2 FDR	50

FAMM, Familial atypical multiple mole melanoma syndrome; *FDR,* first-degree relative; *PDAC,* pancreatic adenocarcinoma.

Therefore, in addition to genetic testing, individuals with an extensive family history of PDAC (in the absence of an identified high-risk germline mutation) are identified as having *familial* pancreatic cancer and are considered to be at high risk as well. Individuals with familial PDAC syndromes are defined as having at least two affected blood relatives with PDAC, including at least one being a first-degree relative.[5] Interestingly, the risk of PDAC is not uniform across individuals with hereditary versus familial PDAC syndromes. Two large, well-characterized, high-risk cohorts with long-term follow-up of more than 411 patients demonstrated a significantly greater risk of neoplastic progression to high-grade dysplasia or PDAC in individuals with hereditary cancer syndromes as compared with patients with familial pancreatic cancer syndromes.[6,7]

In addition, patients with familial pancreatitis have an increased risk of PDAC. Mutations in the *PRSS1* gene, which encodes cationic trypsinogen, are responsible for 80% of the cases of hereditary pancreatitis. Mutations in *PRSS1* result in inappropriate intrapancreatic activation of trypsin, either by enhanced autoactivation or impaired inactivation, leading to pancreatic tissue destruction. Patients with constitutional mutations in the *PRSS1* gene have a 50% risk of PDAC by age 75. The *SPINK1* gene codes for a serine protease inhibitor, which prevents the premature intrapancreatic activation of trypsinogen. Cumulative rates of PDAC by age 70 for patients with inherited pancreatitis have been estimated to be as high as 28%.[8]

Multiple different approaches have been described for surveillance, including imaging-based or endoscopic-based approaches.[5] Imaging-based PDAC screening has been demonstrated to be cost-effective among high-risk individuals. In contrast, the average lifetime risk of developing pancreatic cancer in the United States is 1.5%, which is too low for general population-based screening.[9] A meta-analysis of prospective studies on surveillance included 7085 high-risk individuals and estimated that the number needed to screen in order to identify 1 patient with either high-grade dysplasia or PDAC was 135.[6] Furthermore, high-risk screening was associated with a stage shift in those found to have invasive cancer; 60% to 80% of PDACs were resectable, and only 20% of PDACs were diagnosed with metastatic disease.[6,10,11] In addition, over the long term, individuals who underwent high-risk screening experienced decreased psychological distress and cancer worry.[12]

Acquired Risk Factors

Studies in large patient cohorts have revealed several environmental and chronic disease–related factors that increase the risk of PDAC. In particular, tobacco, alcohol, and obesity have been associated with an increased risk of PDAC. Tobacco use is associated with a 1.74-fold increased odds of cancer among smokers as compared with nonsmokers. Heavy alcohol consumption (>6 drinks/day) is also associated with a 1.60-fold increased odds of cancer when compared with nondrinking controls.

Obesity has been correlated with PDAC and has been associated with a 1.72-fold increased risk of cancer among patients with a body mass index (BMI) >30 kg/m^2 as compared with those with a BMI of less than 30 kg/m^2.[13] Patients with diabetes have an increased risk of PDAC, but this varies based on the onset of the disease. Patients with long-standing diabetes (>3 years) have a 1.5- to 2.4-fold increased risk of PDAC, whereas those with new-onset diabetes (<2 years) have a 1.5-fold increased risk. In addition, patients with new-onset diabetes in the setting of at least an 8-pound weight loss have an age-adjusted hazard ratio (HR) for PDAC of 6.75 (95% CI 4.55–10.00) as compared with those with neither.[14] In older adults, the hemoglobin A1c usually rises in response to weight gain. A PDAC diagnosis can often be associated with an elevation in hemoglobin A1c despite weight loss.

PATHOGENESIS

The pancreas contains two epithelial cell types: exocrine and endocrine cells. The majority of the gland is composed of exocrine cells, which line an organized ductal network. Acinar cells line the smallest ducts and synthesize and secrete digestive enzymes. Larger ducts are lined by intercalated duct cells and secrete bicarbonate and water. Ultimately, the ducts converge into the main pancreatic ducts, which drain into the duodenum. The endocrine cells make up only 1% of the pancreas and include the islets of Langerhans. These hormone-producing cells are primarily involved in glucose homeostasis. The principal endocrine cells include A, B, and D cells, which synthesize glucagon, insulin, and somatostatin, respectively. Although the anatomic location of PDAC supports a ductal cell of origin, studies in murine models have shown that acinar cells can give rise to premalignant lesions after pancreatic injury and metaplasia, adding controversy to the cell of origin of PDAC.

Precursor Lesions

PDAC arises from noninvasive precancerous lesions that are thought to acquire successive mutations leading to malignant transformation. Most PDACs arise from microscopic pancreatic intraepithelial neoplasia (PanIN), a neoplasm involving the pancreatic ducts. It is not uncommon to develop PanIN with age; in autopsy series, over 75% of sampled pancreata had evidence of PanINs.[15] Although these lesions have a risk for progression into PDAC, most will not progress to cancer. Morphologically, these lesions are categorized as low grade or high grade based on architectural and cytologic atypia.[16] Low-grade precancers have basally oriented nuclei and mild to moderate cytologic atypia, whereas high-grade precancers have marked architectural alterations (cribriforming micropapillae, budding), loss of nuclear polarity, and severe cytologic atypia. PanINs are rarely detected clinically. The anatomic location of precancerous lesions in the ductal system could suggest a ductal cell of origin, but numerous studies in murine models have shown that acinar cells can give rise to PanINs after pancreatic injury and metaplasia.

A much smaller proportion of PDAC (<10%) arises from intraductal papillary mucinous neoplasms (IPMNs), which are macrocystic lesions that involve the pancreatic ductal system. The least common precancerous neoplasm, mucinous cystic neoplasms (MCNs), are clinically and pathologically distinct.[17] MCNs do not involve the ductal system and have a characteristic ovarian-type stroma. They are characteristically seen in females and are more likely to involve the body and tail of the pancreas. Both IPMNs and MCNs are usually first identified as incidental findings on abdominal imaging studies. In IPMN, the grade of dysplasia is correlated with the tissue subtype, with gastric-type IPMN being enriched for low-grade dysplasia and intestinal and pancreatobiliary subtypes more likely to have high-grade dysplasia. Associated carcinomas are much more frequently associated with high-grade rather than low-grade IPMNs.[18]

Pathologically, PDAC consists of malignant glands with haphazard architecture embedded in a dense desmoplastic stroma. This pauci-cellular matrix complicates the molecular analysis of PDAC because most of the cells are nonneoplastic, and fewer than 10% of the cells may be malignant. There are also several morphologic variants, including adenosquamous carcinoma and undifferentiated carcinoma with osteoclast-like giant cells. Most PDACs are not confined to the pancreas at diagnosis, and over 50% of patients will have metastatic disease. The most common sites of metastases are the liver and peritoneum; however, a subset of patients may have lung-only metastases, which is associated with a more favorable prognosis as compared with other sites. Autopsy studies have suggested that distinct molecular alternations may increase the likelihood of local versus systemic disease progression, with distant metastases being more common in patients with somatic mutations in the gene *SMAD4.*

Molecular Alterations

PDAC is thought to arise from the accumulation of somatic mutations. The most common pathogenic variant identified involves the oncogene *KRAS,* which occurs in over 90% of PDACs. Among the *KRAS* mutations associated with PDAC, the *G12D* and *G12V* mutations are found most frequently.[19] As the most common activating mutation in PDAC, KRAS impairs the intrinsic GTPase activity of *KRAS* and prevents GTPase-activating proteins from converting the active GTP bound form to the inactive form. Recently, there is growing evidence that *KRAS* mutations affect diverse signaling pathways, leading to distinct functional consequences, and may be vulnerable to mutant-specific targeted therapies.[20] Other genes, including the tumor-suppressor genes *TP53, CDKN2A,* and *SMAD4,* are also frequently mutated in PDAC.[21] Approximately 50% to 70% of PDACs have inactivating mutations in *TP53,* which impairs DNA damage recognition and blocks cell cycle arrest. Mutations in *CDKN2A* are detected in 40% to 60% of PDACs and can lead to loss of regulation of cyclin-dependent kinase (CDK)4 and CDK6 cell cycle checkpoints. Approximately a third of PDACs have mutations in *SMAD4,* which negatively affects transforming growth factor-β (TGF-β) and promotes noncanonical TGF-β signaling. Further comprehensive whole genomic sequencing performed using samples from the Cancer Genome Atlas and the International Cancer Genome Consortium identified other genes involved in DNA repair, chromatic remodeling, and axon guidance at frequencies below 20%, including *ARID1A, BRAF, TGFBR2, SWI/SNF,* and *SMARCA4.* Remarkably, large chromosomal alterations, including copy-number alterations, chromosomal rearrangements, and chromothripsis, have also been described.[22] *Chromothripsis* refers to a phenomenon in which one or a few chromosomes contain hundreds of clustered genomic rearrangements. Investigators propose that these alterations are acquired through catastrophic DNA damage events, resulting in punctuated rather than gradual genetic evolution.

On the transcriptomic level, two predominant molecular subtypes of PDAC have been validated across multiple studies: the classical and basal-like subtypes, with the latter being associated with more aggressive tumor biology and worse prognosis.[23] In nonrandomized data, basal-like subtype has been associated with poor response to multimodality fluorouracil (5-FU)–based regimens (5-FU, irinotecan, and oxaliplatin; FOLFIRINOX). The predictive ability of RNA subtypes is being investigated in several clinical trials in patients with operable disease (PANCREAS trial, NCT: 04683315) and metastatic disease (PASS-01 trial, NCT: 04469556).

CLINICAL MANAGEMENT

Clinical Presentation

The majority of PDACs occur in the head of the pancreas, and the most common associated symptoms are jaundice, upper abdominal or back pain, and weight loss. A history of significant unintentional weight loss is not uncommon and can be a result of exocrine insufficiency, which manifests as steatorrhea, or simply resolution of chronic constipation, which is quite common in older adults. The presence of intractable nausea or vomiting may be a result of a concomitant gastric outlet obstruction and can be corroborated by radiographic findings of extreme gastric distention. Approximately 40% of patients with PDAC present with new-onset diabetes (pancreatogenic, type 3c diabetes) in the setting of weight loss. Although physical exam is often unrevealing, the presence of palpable periumbilical or left supraclavicular lymph nodes may be indicative of metastatic disease, which can be confirmed with a positron emission test (PET) scan or biopsy.

All patients with PDAC should undergo a thorough review of family history, with particular emphasis on a history of PDAC; breast, ovarian, or colon cancers; or melanoma. Routine genetic counseling and genetic testing should be offered to all patients with PDAC regardless of age or stage of disease. Identification of germline pathogenic variants may also have therapeutic implications for the patient because some genetic variants may be predictive of specific chemotherapeutic sensitivities (e.g., patients with *BRCA* pathogenic variants may have increased sensitivity to platinum agents and poly-ADP ribose polymerase inhibitors).

Diagnostic Studies

Because the majority of patients with PDAC present with jaundice, there is an impulse to perform an endoscopic retrograde cholangiopancreatography (ERCP) as the first diagnostic study because it may be both diagnostic and therapeutic. In contrast to biliary obstruction secondary to choledocholithiasis, which can occur acutely and is often associated with significant pain and cholangitis, PDAC in the head of the pancreas usually presents with gradual painless jaundice that is uncommonly associated with cholangitis. For this reason, although patients may present with jaundice and symptomatic pruritis, emergent therapeutic endoscopic intervention is rarely needed. An emphasis should be placed on obtaining a computed tomography (CT) scan in patients suspected of having PDAC before any invasive endoscopic or radiologic procedure. The incidence of ERCP-associated pancreatitis is approximately 4%, and procedure-related complications can result in significant peripancreatic inflammation, which can obscure the relationship between the primary tumor and adjacent vasculature, resulting in inaccurate assessment of the initial clinical stage (Fig. 93.1). Prioritizing a high-quality CT scan before any invasive intervention ensures accurate initial staging of the disease.

CT scan is the preferred diagnostic study for PDAC to assess the location of the primary tumor in relation to adjacent vascular structures and to assess for distant metastases. The CT scan should include the chest as well as a pancreatic-protocol CT scan. The latter includes thin (1-mm slice thickness) image acquisition of the pancreas through both late-arterial and venous phases. The late-arterial phase is usually the best phase to identify PDAC because the timing provides the maximum contrast difference between normally enhancing pancreatic parenchyma and the PDAC, which is generally hypoenhancing. In addition, this is the best phase for analyzing the tumor-artery relationships and noting the presence of any aberrant arterial anatomy. The portal-venous phase is valuable for assessing variant venous anatomy and tumor-vessel abutment or encasement. In addition, metastatic lesions in the liver are often best appreciated in the venous phase. Additional diagnostic studies, such as a magnetic resonance imaging (MRI) study or PET scan, may be helpful if indeterminate liver lesions or suspicious nodal involvement are detected on CT imaging.

In addition to delineating tumor-vessel anatomy, cross-sectional imaging provides additional valuable information as to the origin of the periampullary tumor. In general, PDAC of the periampullary region is associated with (1) a mass in the head of the pancreas; (2) a double duct sign, involving dilation of both the common bile duct and the main pancreatic duct; and (3) distal pancreatic atrophy. The absence of any or all of these findings may suggest that the tumor may be caused by a periampullary tumor other than PDAC. For example, ampullary adenocarcinomas, duodenal adenocarcinomas, or distal cholangiocarcinomas can cause biliary obstruction without concomitant pancreatic ductal obstruction or atrophy. Ampullary and duodenal adenocarcinomas may be associated with a luminal mass involving the duodenum and may be best appreciated on coronal CT reformats or by direct endoscopic evaluation. Distal cholangiocarcinoma often results in biliary obstruction with subtle enhancement of the bile duct in the absence of an anatomic mass (duodenal, ampullary, or pancreatic). Importantly, most periampullary cancers are pancreatic in origin and, as discussed in this chapter, will be most effectively treated with combined modality therapy, most often with a neoadjuvant approach.

Clinical Staging

Accurate clinical/radiographic staging provides the framework for multidisciplinary management and shared decision-making with patients. Although consensus among clinicians may not exist (Table 93.2), all published guidelines generally agree upon two overarching clinical stages of PDAC: potentially operable (resectable and borderline resectable disease) and likely inoperable (locally advanced and metastatic disease).[24] Resectable disease (Fig. 93.2) is defined by an absence of tumor extension to the superior mesenteric artery (SMA), celiac axis, or hepatic artery with limited abutment/encasement of the superior mesenteric vein (SMV)/portal vein (PV) confluence on CT imaging. Lack of arterial abutment is characterized by the presence of a normal soft tissue plane between the tumor and the visceral arteries. SMV/PV abutment/encasement also can distinguish resectable

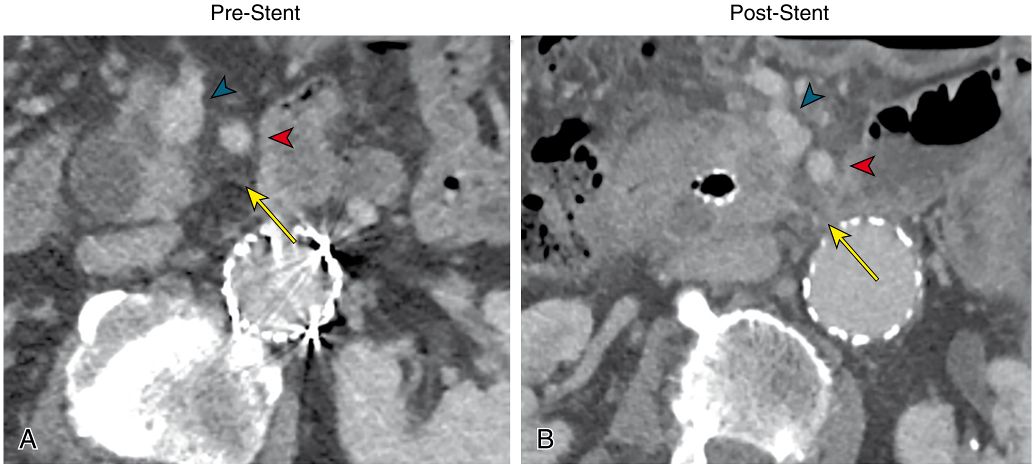

FIGURE 93.1 (A) Tumor in the pancreatic head causing pancreatic ductal dilation. SMV without narrowing *(blue arrowhead),* SMA with no soft tissue abutment *(red arrowhead),* preserved fat plane between head of pancreas and SMA *(yellow arrow).* (B) After ERCP with pancreatitis, there is now contour abnormality of SMV *(blue arrow)* and haziness of the soft tissue between the head of pancreas and SMA *(yellow arrow). ERCP,* Endoscopic retrograde cholangiopancreatography; *SMA,* superior mesenteric artery; *SMV,* superior mesenteric vein.

TABLE 93.2 Comparison of Radiographic Differences Between Clinical Stages of Pancreatic Cancer

	COMMONALITY	NCCN	AHPBA/SSO/SSAT	MDA/MCW
Resectable				
SMA, celiac artery, CHA	No abutment	No abutment	No abutment, with clear fat planes	No abutment
SMV/PV	No abutment	No abutment, or ≤180 degree contact without contour irregularity	No abutment, distortion, thrombus, or encasement	No abutment, or <50% narrowing
Borderline Resectable				
SMV/PV	Abutment	Abutment, ≤180 degree with contour irregularity, or thrombosis	Abutment, impingement, encasement, or short segment occlusion	>50% narrowing or short segment occlusion with reconstruction possible
SMA	Abutment	Abutment	Abutment	Abutment
Celiac artery	Abutment	Abutment	Abutment	Abutment
CHA	Abutment or short segment encasement	Abutment or short segment encasement	Abutment or short segment encasement	Abutment or short segment encasement
Locally Advanced				
SMV/PV	Involvement or occlusion without reconstruction options	Unreconstructable SMV/PV	Major extensive thrombosis	Occlusion without reconstruction options
SMA	Encasement	Encasement	Circumferential encasement	Encasement
Celiac artery	Encasement	Encasement	Circumferential encasement	Encasement without reconstruction options
CHA	Encasement	Encasement	Circumferential encasement	Encasement without reconstruction options

Abutment = tumor involves ≤180 degree vessel circumference.
Encasement = tumor involves >180 degree vessel circumference.
AHPBA/SSO/SSAT, Americas Hepato-Pancreato-Biliary Association/Society of Surgical Oncology/Society for Surgery of the Alimentary Tract; *CHA,* common hepatic artery; *MDA/MCW,* MD Anderson/Medical College of Wisconsin; *NCCN,* National Comprehensive Cancer Network; *SMA,* superior mesenteric artery; *SMV/PV,* superior mesenteric vein/portal vein.

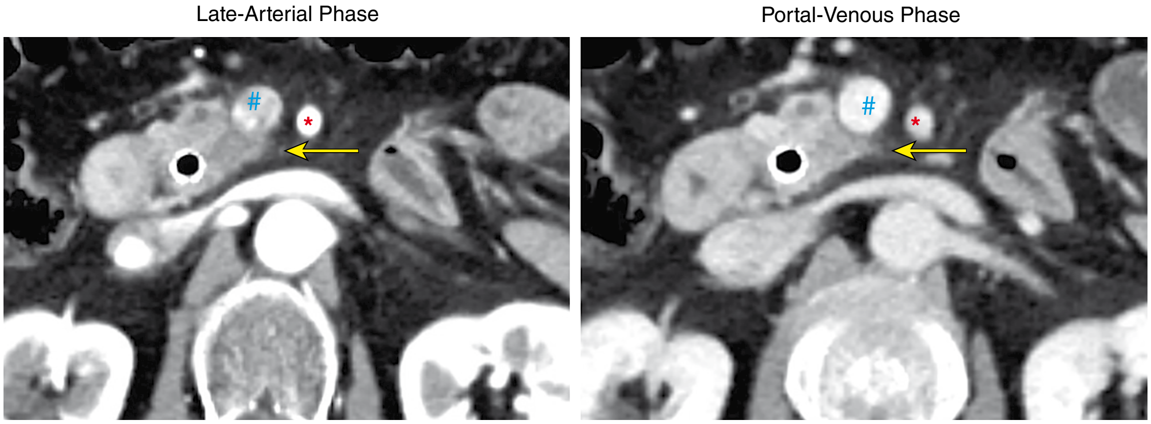

FIGURE 93.2 Resectable pancreatic adenocarcinoma. Computed tomography in the late-arterial and portal-venous phases demonstrates a low-attenuation mass completely confined to the pancreas with no tumor contact of the superior mesenteric artery *(red *)* and vein *(blue #),* with primary tumor seen best in the arterial phase. Note that the tumor is more easily identified in the late-arterial phase (*yellow arrow*).

from borderline resectable disease and often varies between staging systems used at different centers. For patients with venous encasement or occlusion, there must be adequate inflow and outflow targets for venous reconstruction to remain operable (borderline resectable). The distinction between borderline resectable (Fig. 93.3) and locally advanced disease (Fig. 93.4) is most often determined by the degree of tumor-artery interface (abutment is defined as ≤180 degrees and encasement as >180 degrees). Borderline resectable disease is defined as tumor-artery abutment (≤180 degrees) of the SMA or celiac axis. This was based on the understanding that neoadjuvant therapy may successfully sterilize at least the periphery of the tumor, thereby facilitating a margin negative (R0) resection. As the tumor-artery interface progresses from abutment to encasement, a complete gross resection of all disease is likely not possible without arterial resection. The borderline resectable

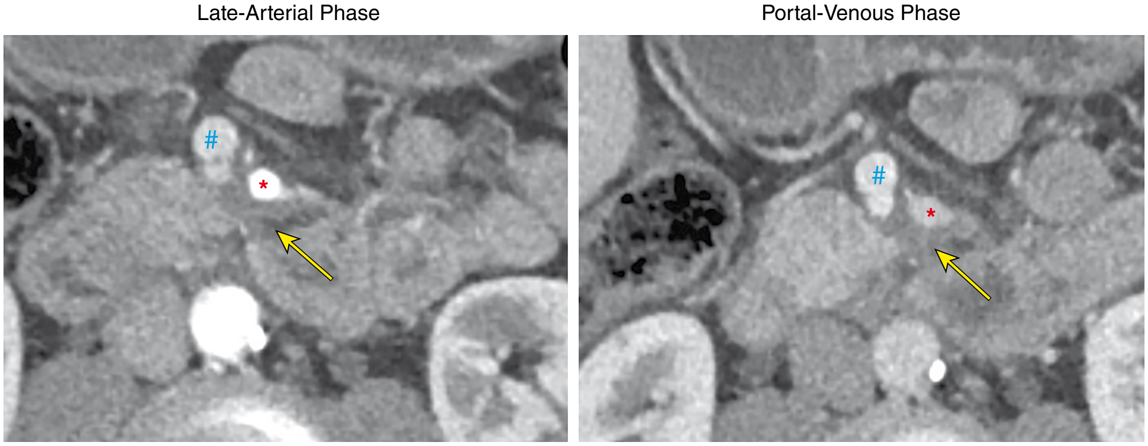

FIGURE 93.3 Borderline resectable pancreatic adenocarcinoma. Late-arterial and portal-venous phases demonstrate a mass in the uncinate process. The media margin of the tumor abuts (less than 180 degrees) the posterior walls of the superior mesenteric artery *(red *)* and vein *(blue #)*.

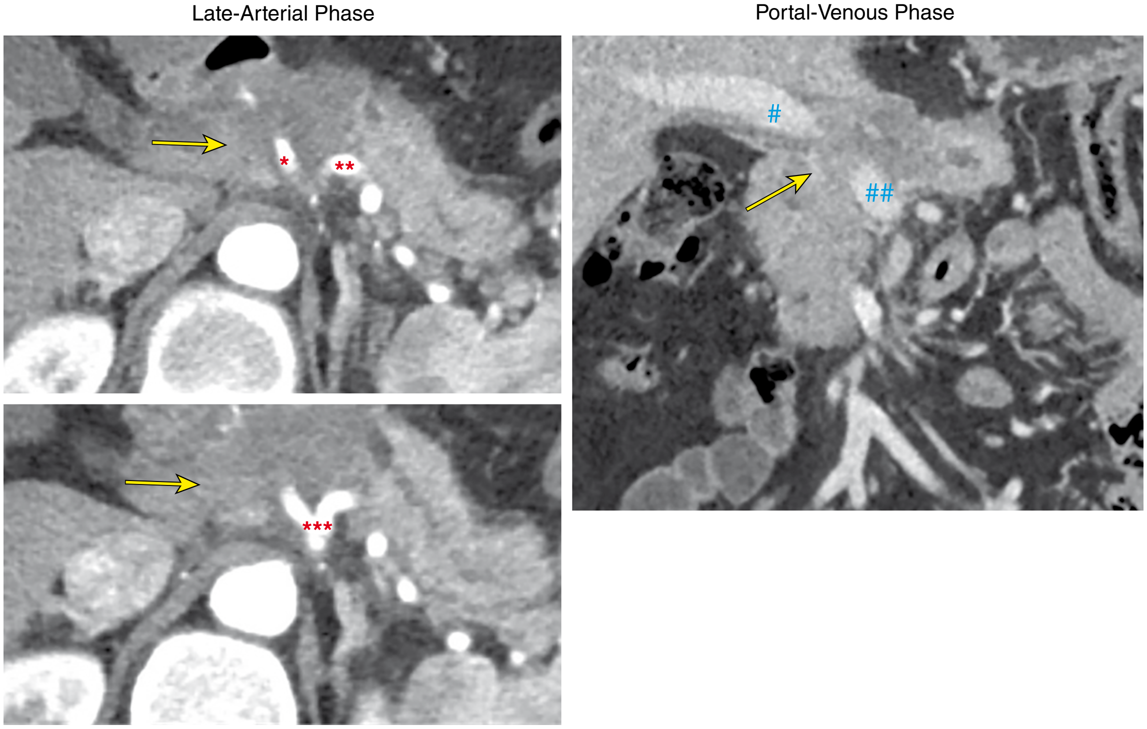

FIGURE 93.4 Locally advanced pancreatic adenocarcinoma. Late-arterial phase at two levels demonstrates a low-attenuation mass in the pancreatic body *(yellow arrow)* with advanced locoregional extrapancreatic tumor extension with soft tissue encasing (greater than 180 degrees) the common hepatic artery *(red *)* and celiac bifurcation *(red ***)* and abutment of the splenic artery *(red **)*. Portal-venous phase coronal image demonstrates the mass causing severe narrowing of the cephalad portal vein *(blue #)* and the superior mesenteric vein *(blue ##)*, with a "gap" below the portal–splenic–superior mesenteric vein venous confluence *(yellow arrow)*.

category also includes tumor abutment/encasement of a short segment of the hepatic artery, usually at the origin of the gastroduodenal artery (GDA), or an occluded SMV/PV, amenable to reconstruction. In contrast, locally advanced tumors are characterized by arterial encasement ≥180 degrees of the celiac artery or SMA. The locally advanced category also includes patients with SMV/PV occlusion with no technical option for reconstruction. Finally, metastatic disease is defined by the presence of extrapancreatic metastases.

Endoscopic Procedures

After CT imaging, an endoscopic ultrasound (EUS) with fine-needle aspiration (FNA) or FNA biopsy is preferred to facilitate a tissue diagnosis. EUS is preferred over percutaneous CT-guided biopsy, which has been associated with up to a 16% rate of peritoneal carcinomatosis, presumably related to dissemination of malignant cells along the biopsy tract. For tissue diagnosis, rapid on-site cytopathologic evaluation increases the diagnostic success of EUS/FNA biopsies by allowing for additional endoscopic sampling to be performed until an adequate cytologic specimen can be obtained. Once a preliminary cytologic diagnosis is obtained, the placement of a decompressive metal stent can be performed during the same endoscopic anesthesia and alleviates the need for two separate procedures. Ideally, this "one-stop-shop" approach facilitates simultaneous diagnosis and therapeutic intervention for the obstructive jaundice. In general, uncovered metal endobiliary stents are preferred over plastic stents for their higher patency rates (104 days vs. 83 days) and lower rates of complications (12% vs. 35%). Covered metal stents have higher rates of stent migration and higher rates of stent-related cholecystitis because the stents can cover and occlude the cystic duct orifice. Covered stents are most often employed in patients who do not have a gallbladder (prior cholecystectomy) or when a tissue diagnosis has not been obtained because they can be removed at a subsequent endoscopy (unlike uncovered stents, which usually cannot be removed).

Laboratory Studies

Standard laboratory testing for PDAC should include complete blood count, comprehensive metabolic panel, albumin, hemoglobin A1c, and tumor markers, including carbohydrate antigen (CA) 19-9, CA 125, and carcinoembryonic antigen (CEA). CA 19-9 is a sialylated Lewis blood antigen that is elevated in approximately 75% of patients with PDAC at the time of diagnosis. It can be falsely elevated in the setting of hyperbilirubinemia and should be considered evaluable only when the total bilirubin is less than 2 mg/dL. Trends in CA 19-9 levels have been correlated with treatment response and are considered an important clinical adjunct to radiographic response. Among patients who are CA 19-9 nonproducers, 25% may have an elevated CEA, and changes in CEA have been similarly observed to correlate with treatment response and prognosis. It is important to remember that CEA levels are significantly higher in smokers (to include tobacco and cannabis products) as compared with nonsmokers, and therefore, the trend in results over time is more important than an isolated value. In other solid tumors, alternative blood-based biomarkers, such as cell-free DNA, are being evaluated as quantitative biomarkers of disease burden. In general, recurrent disease can be detected by a rise in cell-free DNA approximately 3 months before traditional protein-based biomarkers or diagnostic imaging. The utility of cell-free DNA and other blood-based biomarkers is under active investigation in PDAC.

TREATMENT

The treatment of PDAC is stage specific, emphasizing the importance of accurate initial staging. Nonmetastatic PDAC often requires a concerted multidisciplinary approach that involves a multidisciplinary team, including surgeons, medical oncologists, radiation oncologists, advanced gastroenterologists, body imaging specialists, pathologists, genetic counselors, dietitians, physical therapists, and palliative care specialists. Efficient communication and care coordination are essential to provide timely and appropriate care for patients with PDAC to optimize their clinical outcomes while minimizing delays and toxicities.

Multimodality Approach to Operable Pancreatic Adenocarcinoma

Patients with operable PDAC are at risk for both local and systemic recurrence, with over 75% of patients developing recurrent disease within 1 year of surgery.[25] The high risk of both local and distant disease recurrence may be predicted by the advanced pathologic stage of most patients with PDAC. If taken directly to surgery, over 70% of patients will have node-positive (N1 or N2) disease, and 40% will have a margin-positive (R1) resection.[26,27] Of patients with recurrent disease after potentially curative surgery, the majority of patients develop metastatic disease recurrence; however, up to 25% to 33% of patients experience local-only disease recurrence.[28,29] Given the high rates of recurrent disease, adjuvant therapy is recommended for all patients with PDAC who undergo surgery first, independent of pathologic stage. Although a recent randomized controlled trial comparing adjuvant gemcitabine versus 5-fluorouracil/irinotecan/oxaliplatin (PRODIGE-24) demonstrated historic improvements in median overall survival (54 months) with the triple-therapy arm, it is important to remember that adjuvant clinical trials have an inherent selection bias in their design because patients who are enrolled in adjuvant trials must have recovered from a pancreatectomy with minimal complication, have preserved performance status, and have no evidence of disease progression on postoperative restaging before initiating adjuvant therapy.[30] When accounting for all patients who undergo surgical resection for PDAC, the delivery of any adjuvant therapy after pancreatectomy is unpredictable. Among multiple retrospective analyses of large institutional experiences, approximately 50% of patients with PDAC may never receive adjuvant therapy after surgery because complications related to surgery, the inability to fully recover from surgery, or patient refusal.[31,32] This finding was recapitulated in the results of another recent randomized controlled trial that compared perioperative (neoadjuvant and adjuvant) therapy to surgery followed by adjuvant therapy (PREOPANC trial) in patients with localized PDAC.[33] Only 65 (51%) of the 128 patients in the surgery-first arm received any adjuvant therapy. In addition, in the adjuvant setting, the primary tumor has been removed, so the ability to assess treatment response to the chemotherapy prescribed is limited or impossible. Because response to chemotherapeutic regimens is not uniform across all patients (response rates from 30% to potentially as high as 50%), at least half of the patients who receive adjuvant therapy receive no benefit and incur unnecessary toxicity.

In contrast to a surgery-first approach, neoadjuvant therapy has several advantages: (1) early delivery of systemic therapy for presumed micrometastases, which are likely present in the majority of patients at diagnosis; (2) the ability to identify aggressive tumor biology, which may be resistant to available systemic therapies; (3) assessment of treatment response in the primary tumor; and (4) improved selection of patient for surgery according to stage of disease and response to therapy. For patients with an elevated CA 19-9 level at the time of diagnosis, changes in CA 19-9 levels have been demonstrated to correspond to treatment response and be prognostic of overall survival. Among patients who receive neoadjuvant therapy, approximately one-third of patients will normalize their CA 19-9 levels before surgery, one-third of patients will normalize their CA 19-9 levels after surgery, and one-third of patients will never normalize their CA 19-9 levels even after neoadjuvant therapy and surgery.[34] Approximately 70% of patients who initiate neoadjuvant therapy will be able to complete neoadjuvant therapy and surgical resection.[35,36] Of the 30% of patients who do not undergo resection, approximately 92% of those patients have metastatic disease progression during/after neoadjuvant therapy, and in 5% of patients, performance status and medical comorbidities that argue strongly against a trip to the operating room become apparent. Local disease progression during/after neoadjuvant therapy, which precludes surgical resection, occurs in 3% or less of patients; it is a very uncommon event.

Trials Comparing Neoadjuvant Therapy Versus Surgery First

The first randomized trial to compare a neoadjuvant therapy (given as pre- and postoperative therapy) to up-front surgical resection and adjuvant therapy was the PREOPANC trial. The long-term results of the PREOPANC trial were recently published and demonstrated improved overall survival for patients with resectable and borderline resectable PDAC who received perioperative therapy as compared with a surgery-first approach (5-year overall survival: 20.5% vs. 6.5%; HR 0.73; $p = 0.025$).[37] Several institutions have also reported their outcomes with neoadjuvant therapy, and among patients who are able to complete neoadjuvant therapy and surgery, the median overall survival exceeds 40 months at most centers.[38,39] In contrast, the Norwegian Pancreatic Cancer Trial-1 (NORPACT 1) trial included 130 patients with resectable PDAC in the head of the pancreas. Patients were randomized to up-front surgical resection versus neoadjuvant chemotherapy with 5-fluorouracil, oxaliplatin, and irinotecan (FOLFIRINOX). There was no difference in median overall survival (38 mo vs. 25 mo; HR 1.52; 95% CI 1.00–2.33).[40] It is important to note that 21% of patients in the neoadjuvant arm were unable to achieve biliary drainage and underwent up-front surgical resection. In addition, only 46% of patients in the neoadjuvant arm received the full 2 months of neoadjuvant therapy. Currently, there are two ongoing clinical trials (Alliance A021806 [NCT 04340141], PREOPANC 3 [NCT 04927790]) that will further evaluate neoadjuvant versus surgery-first treatment approaches using a similar clinical trial design of 4 months of contemporary chemotherapy before surgery.

Trials Comparing Neoadjuvant Therapeutic Approaches

Many centers have already adopted neoadjuvant therapy for patients with localized PDAC based on promising outcome data from phase II and III clinical trials. Currently, all consensus guidelines recommend neoadjuvant therapy for borderline resectable disease, and an increasing number of centers advocate neoadjuvant therapy for resectable disease as well. Future investigations will be focused on defining the optimal neoadjuvant therapy for patients, including the best chemotherapeutic regimen, duration of treatment, and whether to include radiation/chemoradiation. The Southwestern Oncology Group (SWOG) S1505 trial randomized 102 patients to receive perioperative modified FOLFIRINOX (mFOLFIRINOX) versus gemcitabine/nab-paclitaxel (GnP).[35] The trial confirmed the safety of both treatment regimens, with over 84% of each arm able to complete all intended preoperative chemotherapy. However, there was no difference in efficacy observed between the two regimens (2-year overall survival: 42% vs. 49%). Currently, the selection of which chemotherapy regimen to include in neoadjuvant therapy is primarily driven by patient factors.

Although early neoadjuvant trials for patients with PDAC included radiation, the value of neoadjuvant radiation has come into question after the report of the Alliance A012501 trial.[41] This was a phase II randomized trial of 126 patients with borderline resectable PDAC who received neoadjuvant mFOLFIRINOX with or without hypofractionated radiation. There was minor variability in the radiation dose given on trial; however, the majority of patients received stereotactic body radiotherapy of 33 to 40 Gy in 5 fractions. At a planned interim analysis, the radiation arm was closed to accrual because of a larger proportion of patients who had disease progression. It is important to note that the patients in the radiation arm had an increased proportion of patients who experienced distant disease progression, not local progression, and a number of patients in both arms failed to complete intended therapy. The results of all recent trials for patients with operable PDAC have demonstrated the importance of managing treatment-associated toxicity and providing direction for physicians when an adaptive trial design is implemented. Although the value of local control for patients with operable PDAC has come under question, the patterns of first recurrence, nonetheless, suggest that 30% to 40% of patients will have local-only recurrence as the first site of recurrence. In single-institution series of patients with operable PDAC, the addition of neoadjuvant chemoradiation to surgery has been associated with less than 10% local recurrence rates, suggesting that radiation can provide a meaningful reduction in local recurrences and potentially improve long-term survival.[42] At the Medical College of Wisconsin, patients with operable PDAC (resectable, borderline resectable, and locally advanced type A) are currently being treated with a total neoadjuvant therapy approach. This consists of 4 months of neoadjuvant chemotherapy with an adaptive trial design to include interval restaging at 2 months to assess for treatment response, and in the absence of response, a change in chemotherapy is implemented. Systemic therapy is followed by preoperative radiation/chemoradiation, and we are exploring alternate fractionation schedules to include the use of stereotactic body radiation therapy as well.

SURGICAL MANAGEMENT

Preoperative Preparation

Preoperative evaluation should include a detailed history and physical exam. A pancreatic-protocol CT scan is the cornerstone of staging, and we always have a new scan within 1 month of the planned date of surgery. Reassessment of the tumor-vessel relationship is essential and should include a careful evaluation of the tumor's relationship to the SMA, SMV-PV, celiac axis, and hepatic artery. It is important to evaluate for the presence of aberrant arterial anatomy (replaced right or left hepatic artery) and the presence of median arcuate ligament compression of the celiac artery. Assessment of the venous anatomy should also note the insertion of the inferior mesenteric vein (into the splenic vein or SMV) and the location of the first jejunal branch (either anterior or posterior to the SMA). Depending on the extent of the tumor-vessel involvement, the need for autologous conduits, such as the saphenous vein or internal jugular vein, can be anticipated based on preoperative imaging. Often, it is helpful to reference the CT at the time of diagnosis to evaluate for the presence of venous narrowing or contour irregularity (bird's beak or teardrop deformity). If present, even after a robust radiographic response to neoadjuvant therapy, vascular resection and reconstruction may be necessary.

Pancreaticoduodenectomy

Pancreaticoduodenectomy is the most common operation for tumors of the periampullary region, and it involves removal of the pancreatic head, duodenum, gallbladder, and bile duct with or without removal of the gastric antrum. Before an extended abdominal incision, at the time of anesthesia induction, we recommend a diagnostic laparoscopy because up to 10% of patients will have small-volume metastatic disease that is not detected on preoperative imaging. After careful laparoscopic inspection of the liver and all visceral and parietal surfaces, we generally use an upper midline incision. The round ligament is carefully taken down from the abdominal wall and preserved as a pedicled flap upon entering the abdomen, to be used at the conclusion of the operation as a physical barrier to cover the GDA stump. The subsequent surgical resection can be broken down into six steps.

Resection of the Head of Pancreas

1. The purpose of the first step is to define the infrapancreatic SMV. The greater omentum is elevated from the transverse colon, and the hepatic flexure of the colon is mobilized to the level of the duodenum. The lesser sac is entered, and the visceral peritoneum along the inferior border of the pancreas is incised medially to laterally to expose the infrapancreatic SMV and the junction of the middle colic vein and the SMV. The middle colic vein may enter directly into the anterior surface of the infrapancreatic SMV or arise as a common trunk with the gastroepiploic vein (gastrocolic trunk). If the middle colic vein and gastroepiploic vein share a common trunk, the common trunk can be preserved (and the gastroepiploic vein divided) or the entire trunk divided. When there is extensive inflammatory change or scarring at the root of mesentery, it may not be possible to identify the infrapancreatic SMV early in the operation. In such cases, the SMV will be exposed during step 6 after the pancreatic neck is divided in a caudal direction from the level of the PV. Occasionally, when there is a large tumor in the uncinate process, it may be necessary to divide the middle colic vein and resect a portion of transverse colon mesentery en bloc with the pancreatic head. For tumors that additionally extend inferiorly and posteriorly to involve the third or fourth portions of the duodenum, a Cattell-Braasch maneuver may be necessary to allow adequate visualization of the root of mesentery. When completed, this maneuver allows cephalad retraction of the right colon and small bowel to expose the third and fourth portions of the duodenum.
2. The purpose of the second step is to mobilize the duodenum and head of pancreas. A Kocher maneuver is begun at the transverse portion (third portion) of the duodenum by identifying the inferior vena cava. The duodenum and pancreatic head are mobilized medially to the level of the left renal vein and the left lateral aspect of the aorta. It is particularly helpful to divide the leaf of visceral peritoneum that extends from the retroperitoneum to the posterior aspect of the mesenteric vessels. There are often a number of lymphatics in this tissue, which are best ligated if possible. With the head of the pancreas rotated medially, this visceral peritoneum is located at the most posterior aspect (medial to the head of pancreas). Releasing the tissue at this level from the third portion of the duodenum to the level of the foramen of Winslow greatly facilitates the subsequent dissection of the SMA.
3. The third step involves the portal dissection and defining the superior border of the pancreatic head. To begin, the common hepatic artery is identified, and the hepatic artery lymph node is removed. This will facilitate visualization of the common hepatic artery as it gives off the GDA and proper hepatic artery and often exposes the medial border of the PV. A small right gastric artery is usually anterior to the GDA, arising from the left hepatic or proper hepatic artery, and should be ligated. The origin of the GDA can be dissected, but before ligation, it is often helpful to first expose the lateral aspect of the porta hepatis, especially if there is variant arterial anatomy suspected. If the foramen of Winslow was initially obliterated as a result of adhesions, it should be reestablished in order to palpate the porta hepatis and appreciate the pulsation of an anomalous hepatic artery. If a cholecystectomy has not previously been performed, the gallbladder is taken down in a retrograde fashion, and the common hepatic duct is transected at the level of the cystic duct (Fig. 93.5). In cases where an anomalous location of the right hepatic artery has been identified on preoperative CT, we often isolate the aberrant

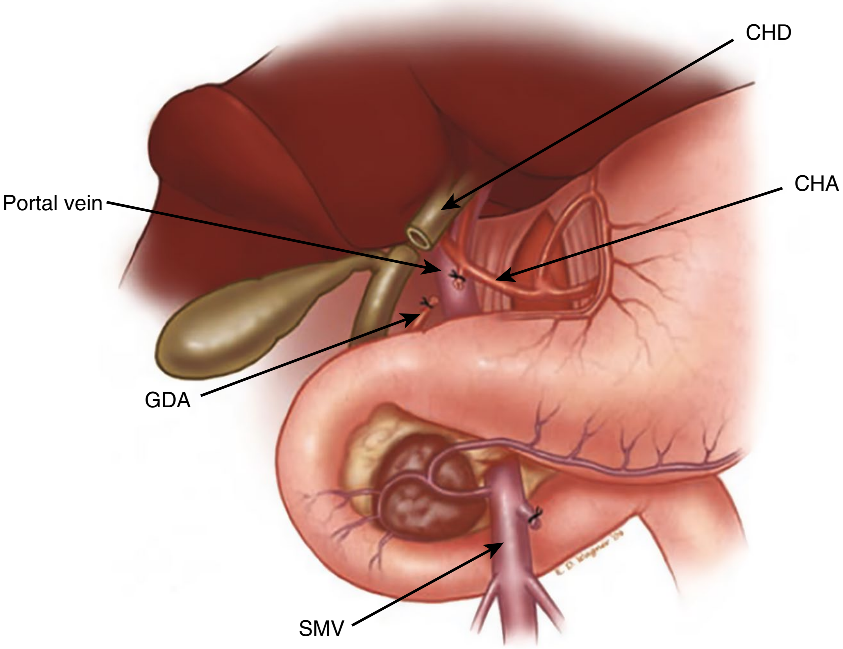

FIGURE 93.5 Step 3: Top-down cholecystectomy to identify the junction of the cystic duct to the common hepatic duct. Division of the common hepatic duct above the level of the cystic duct. *CHA,* Common hepatic artery; *CHD,* common hepatic duct; *GDA,* gastroduodenal artery; *SMV,* superior mesenteric vein.

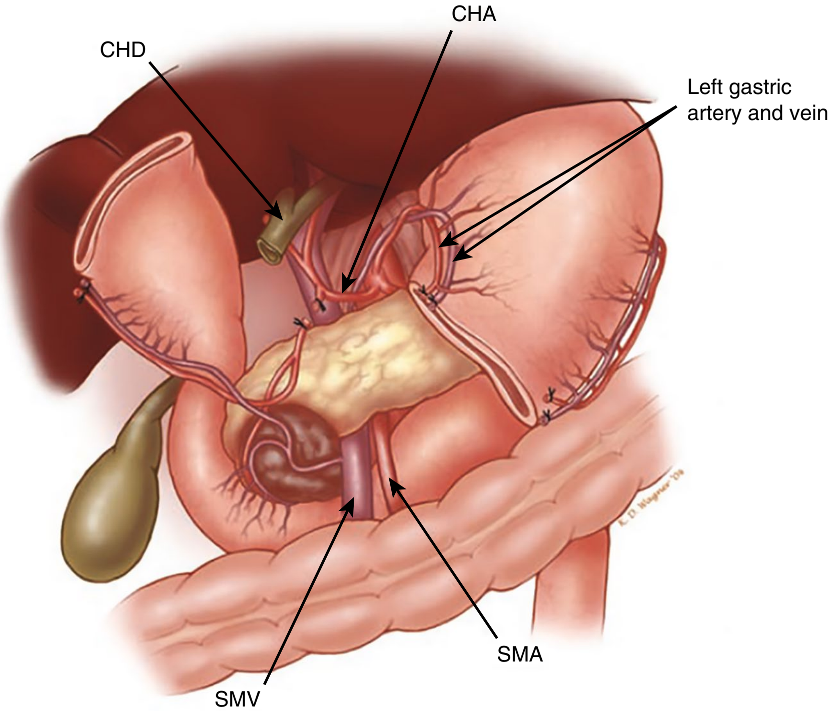

FIGURE 93.6 Step 3: Portal dissection involves identification of the common hepatic artery *(CHA)* and the origin of the gastroduodenal artery *(GDA)*. Division of the common hepatic duct *(CHD)* facilitates the exposure of the origin of the GDA for ligation. *SMA,* Superior mesenteric artery; *SMV,* superior mesenteric vein.

arterial anatomy before division of the common hepatic duct because the artery is often in close proximity of the duct and can be injured. A replaced or an accessory right hepatic artery arising from the proximal SMA usually courses posterolateral to the PV. After transection of the bile duct, biliary fluid cultures may be sent, and any indwelling endobiliary stents are removed if possible. Intraoperative bile cultures may be used to guide therapeutic antibiotic treatment postoperatively, and a bulldog clamp can be placed on the transected hepatic duct to limit spillage of contaminated bile. The bile duct margin can be sent for frozen section at this time as well. Division of the common hepatic duct allows for exposure of the anterior surface of the PV and facilitates the dissection and mobilization of the lateral aspect of the GDA and proper hepatic artery. Overly aggressive dissection at the GDA origin can result in intimal dissection of the hepatic artery. Careful sharp dissection is preferred in this area. Division of the GDA allows mobilization of the proper hepatic artery off of the underlying PV and exposes the superior border of the pancreas (Fig. 93.6). The superior pancreaticoduodenal vein (vein of Belcher) is a constant venous tributary of the PV that drains the cephalad aspect of the pancreatic head and is located at the superolateral aspect of the PV. Bleeding caused by traction injury to this venous tributary may be difficult to control at this time in the operation.

4. The fourth step involves transection of either the duodenum or stomach. Pylorus preservation may be considered in patients with small periampullary neoplasms but should not be performed in patients with bulky pancreatic head tumors or duodenal tumors involving the first or second portions of the duodenum. To ensure adequate blood supply to the duodenojejunostomy, the duodenum is generally divided approximately 2 cm distal to the pylorus. In the setting of preoperative radiation, we usually favor removal of the antrum because this area is usually within the radiation field. The stomach is transected with a gastrointestinal stapler at the level of the third or fourth transverse vein on the lesser curvature and at the confluence of the gastroepiploic veins on the greater curvature, completing a standard/modest antrectomy. When opening pars flaccida, one should specifically look for and preserve an accessory or replaced left hepatic artery arising from the left gastric artery.
5. The fifth step involves dividing the jejunum and mobilizing the ligament of Treitz. The loose attachments of the ligament of Treitz are taken down carefully to avoid injury to the inferior mesenteric vein. The jejunum is then transected with a gastrointestinal stapler approximately 10 cm distal to the ligament of Treitz, and the mesentery is divided to the level of the fourth and third portions of the duodenum, usually with an energy device. The devascularized segment of duodenum and jejunum is then reflected under the mesenteric vessels to the right side of the abdomen.
6. The final step of the resection involves the removal of the head of pancreas from the SMV/PV and SMA. Hemostatic sutures can be placed along the superior and inferior borders of the pancreas; this is helpful in controlling the vessels along the inferior border of the neck and body of the pancreas. The pancreas is most often transected with electrocautery at the level of the PV (Fig. 93.7). The pancreatic margin can be sent at this time. We usually place vessel loops around the distal SMV, PV, and splenic vein for vascular control and medial retraction of the SMV-PV confluence. With mobilization of the SMV-PV confluence, retraction of the vein medially facilitates the identification of the SMA posteriorly. Direct exposure of the SMA avoids iatrogenic injury and ensures direct ligation of the inferior pancreaticoduodenal arteries (IPDAs). Failure to fully

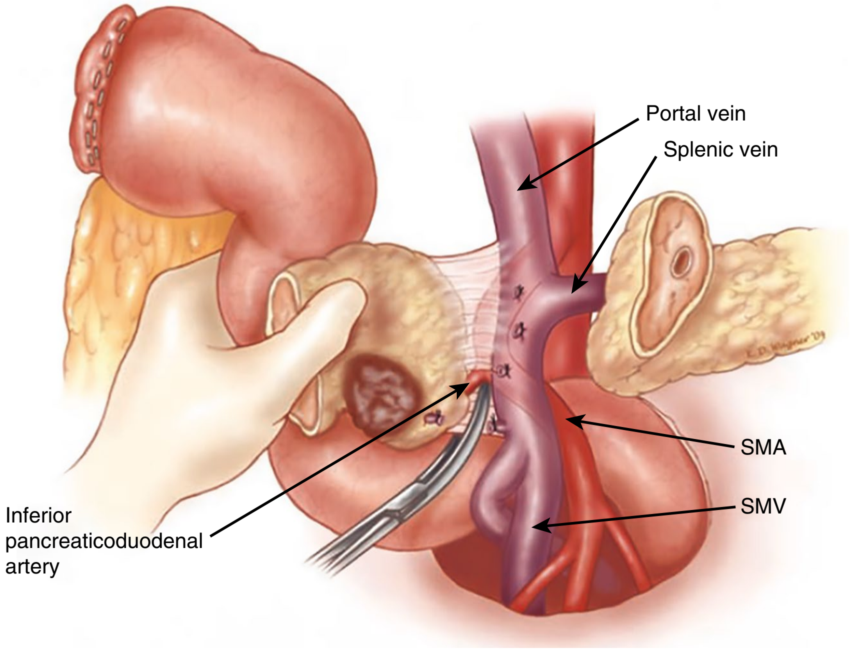

FIGURE 93.7 Step 6: Division of the neck of the pancreas and separation of the head of the pancreas from the superior mesenteric vein *(SMV)* and superior mesenteric artery *(SMA)*.

mobilize the SMV-PV confluence risks injury to the SMA and often will result in a positive SMA resection margin. The specimen is separated from the SMV by ligation and division of the small venous tributaries to the uncinate process and pancreatic head. The first jejunal branch is usually encountered at the caudal aspect of the pancreatic head. The jejunal branch can usually be preserved by ligating small tributaries to the uncinate process. Injury to the distal SMV at this level, or a tangential laceration in its jejunal branch (as it courses posterior to the SMA), is difficult to control and probably represents the most frequent cause of iatrogenic SMA injury as one attempts to suture a venous injury before full exposure of the SMA. Once the uncinate process is separated from the distal SMV, medial retraction of the SMV-PV confluence allows one to expose the SMA. Once the first jejunal branch is released, the more distal IPDA is usually encountered immediately cranially. The specimen is then separated from the right lateral wall of the SMA and sent to pathology. Direct visual exposure of the IPDAs allows for their individual ligation, which will largely eliminate early postoperative intraabdominal hemorrhage.

Vascular Resection

Resection of the SMV and/or PV may need to be performed if tumor extension precludes the safe dissection of the SMV and PV off of the pancreatic head and uncinate process. Generally, this can be predicted based on preoperative imaging because deformity of the SMV/PV resulting from tumor abutment/encasement usually portends the need for vascular resection. Importantly, preoperative anticipation of the need for vascular resection facilitates the intraoperative management as a planned event rather than an emergent response to a vascular injury. When vascular resection is anticipated, it is helpful to have included the upper thigh or neck in the sterile field to facilitate access to the saphenous vein or internal jugular vein. Historically, division of the splenic vein was considered standard practice because this facilitates exposure of the SMA medial to the SMV and allows for greater mobility of the SMV and PV for reconstruction. When possible, the splenic vein–PV confluence should be preserved because ligation of the splenic vein can result in future sinistral hypertension, especially if the left coronary vein is not preserved. A generous 2-cm segment of SMV-PV confluence can often be resected without the need for interposition grafting if the splenic vein is divided. When performing venous resection, we usually incorporate inflow occlusion of the SMA with systemic heparinization because this will minimize small bowel ischemia and edema. Marking the anterior surface of the SMV and PV before venous resection assists in maintaining the orientation of the anastomosis. The proximal and distal targets are circumferentially dissected; vascular clamps are placed 2 to 3 cm proximal (on the PV) and distal (on the SMV) to the involved venous segment; and the vein is transected, allowing tumor removal. If the resection cannot be reconstructed with a tension-free anastomosis, an autologous vein graft (e.g., internal jugular vein) can be used as an interposition graft. Autologous conduits are preferred over synthetic grafts because of the potential for infection and superior long-term patency rates. Currently, the role of major arterial resection for PDAC remains controversial, and it should only be performed in highly selected patients who have completed an extensive course of neoadjuvant therapy. Given the surgical morbidity and mortality with such procedures, arterial resections should be limited to carefully selected patients and be performed at centers with the institutional volume and experience to support these patients.

Reconstruction

Reconstruction usually starts with the pancreaticojejunostomy followed by the hepaticojejunostomy and gastrojejunostomy or duodenojejunostomy. For the pancreaticojejunostomy, mobilization of approximately 2 cm of the pancreatic remnant facilitates exposure and placement of sutures. We prefer to pass the jejunal limb through the transverse mesocolon to the left of the middle colic vessels. If the pancreatic gland is soft, a two-layer, end-to-side, duct-to-mucosa pancreaticojejunostomy is performed. If the gland is firm and the pancreatic duct is dilated, a single-layer duct-to-mucosa anastomosis can be performed. The anastomosis between the pancreatic duct and the small bowel mucosa is completed with interrupted 4-0 or 5-0 monofilament sutures. When the pancreatic parenchyma is soft, pledgets may be used to buttress the gland and prevent the sutures from tearing through the pancreatic tissue. With such high-risk glands, a pancreaticogastrostomy may also be employed, as recently described by Kazantsev.[43]

A single-layer hepaticojejunostomy is created approximately 10 cm distal to the pancreaticojejunostomy using interrupted 4-0 or 5-0 absorbable monofilament sutures. An interrupted technique is used to avoid purse-stringing of the anastomosis. It is important to align the jejunum with the bile duct to avoid tension on the pancreatic and biliary anastomoses and to allow room for the falciform ligament pedicle flap to cover the hepatic artery. Finally, an antecolic, end-to-side gastrojejunostomy is constructed in two layers at least 50 cm from the hepaticojejunostomy to minimize the risk for bile reflux cholangitis. Starting from the greater curvature, a portion of the gastric staple line is removed. The jejunal limb should be aligned so that the efferent limb is adjacent to the greater curvature of the stomach, and the gastrojejunostomy is usually constructed with an interrupted outer layer of sutures and a running inner layer. The use of drains remains an active area of controversy in the field of pancreatic surgery, and many surgeons still drain both the hepaticojejunostomy and the pancreaticojejunostomy. Finally, the previously mobilized falciform ligament is placed over the GDA stump to minimize the risk of pseudoaneurysm formation at the site of the GDA stump in the event of a pancreatic anastomotic leak.

Minimally Invasive Approaches

Pancreaticoduodenectomy is increasingly being performed with laparoscopic or, more commonly, robotic approaches. A minimally invasive approach has been associated with decreased pain, fewer wound complications, and a shorter length of hospital stay.[44,45] There is a significant learning curve for minimally invasive pancreaticoduodenectomy, requiring approximately 80 cases for proficiency, although in the setting of a formal training program with mentorship and formal skills curriculum, this learning curve can be greatly reduced.[46,47] Patient selection is key when deciding between a minimally invasive or open approach because the former approach can be challenging in the setting of chronic pancreatitis. At this time, execution of minimally invasive pancreaticoduodenectomy should be performed in carefully selected patients with favorable anatomy at an institution with surgeons experienced in this technique.

POSTOPERATIVE CARE

After surgery, a standardized approach to postoperative care can improve surgical outcomes and reduce hospital stay. Various programs have implemented protocols for enhanced recovery after surgery that emphasize avoidance of hyperglycemia, maintaining a near-zero fluid balance, early drain removal, early oral intake, minimization of narcotics, and mobilization. In general, in the absence of significant gastroparesis or preoperative gastric outlet obstruction, nasogastric tubes can be removed on postoperative day 1 or 2 with the introduction of limited clear liquids. The diet can be advanced over the next few days in the absence of nausea or vomiting. Optimal perioperative pain management may vary from center to center depending on the expertise and availability of the anesthesia pain team. Although epidurals can provide excellent pain control, associated hypotension may require additional fluid resuscitation. Alternatively, many centers use patient-controlled analgesia pumps in combination with transversus abdominis plane blocks. Early mobilization is encouraged in preventing deep venous thrombosis and reducing postoperative ileus. Early postoperative drain removal has been advocated in patients with low or intermediate risk of pancreatic fistula at postoperative days 1, 3, or 5 based on drain amylase cut points of 300 IU/L, 150 IU/L, and 50 IU/L, respectively.[48] If a drain is in place after diet advancement, the character of drain fluid should be monitored for changes suggestive of either a pancreatic fistula or a chyle leak. For most patients, surgical drains can be removed before discharge.

Postoperative Complications

In general, the most common complications after pancreaticoduodenectomy are pancreatic fistula (10%–30%) and delayed gastric emptying (10%–15%). Postpancreatectomy hemorrhage occurs less commonly (5%) but is the most dreaded complication after pancreatectomy, given its associated high mortality. Scoring systems have been developed by the International Study Group of Pancreatic Surgery (ISGPS) to define the severity of each of these complications and are summarized in Table 93.3.[49–51]

Pancreatic Fistula

Pancreatic fistula rates are related to the gland texture, main pancreatic duct diameter, and intraoperative blood loss. Based on the aforementioned features, a Fistula Risk Score Calculator was developed to predict postoperative risk of pancreatic fistula and guide the management of perianastomotic drains.[48,52] Pancreatic fistulas are generally detected by the presence of amylase-rich fluid from the surgical drains or the presence of a peripancreatic fluid collection on CT imaging. Pancreatic fistula can be associated with signs of infection (leukocytosis, fever) and can cause delayed gastric emptying or postpancreatectomy hemorrhage. If a deep-space infection is present, it is important to obtain adequate drainage not only for source control but also to prevent the fluid from necessitating out the surgical site, leading to fascial dehiscence. ISGPS grade B fistulas can usually be managed with drainage, antibiotics, and the use of somatostatin analogues. On rare occasions, patients with severe disruption of the pancreaticojejunostomy may require surgical reexploration for definitive management; in our personal experience, this is very uncommon, having only been considered in a handful of patients with a very large denominator.

Delayed Gastric Emptying

Delayed gastric emptying remains a troublesome complication after pancreaticoduodenectomy, the pathophysiology of which is not fully understood and is likely multifactorial. Differences in surgical technique have been analyzed. The incidence of delayed gastric emptying appears to be lower with antecolic as compared with retrocolic gastrojejunostomy.[53] Rates of delayed gastric emptying do not appear to be different when comparing standard pancreaticoduodenectomy with pylorus-preserving pancreaticoduodenectomy. However, it is possible that surgical technique may affect delayed gastric emptying; a recent review of robotic pancreaticoduodenectomies identified an acute angle (<30 degrees) between the stomach and the efferent jejunal limb as a risk factor for delayed gastric emptying.[54] A CT scan is often helpful to rule out a subclinical pancreatic fistula or an intraabdominal abscess as a cause of delayed gastric emptying. An upper gastrointestinal series may be helpful to assess gastric emptying. With significant stasis,

TABLE 93.3 **International Study Group of Pancreatic Surgery Consensus Definitions of Postoperative Complications**

	GRADE		
COMPLICATION	**A**	**B**	**C**
Delayed Gastric Emptying[a]			
Nasogastric tube requirement, reinsertion on POD	4–7 days, >POD 3	8–14 days, >POD 7	>14 days, >POD 14
Days of oral intolerance	7	14	21
Vomiting and gastric distention	±	+	+
Use of prokinetics	±	+	+
Postoperative Pancreatic Fistula[b]			
	Biochemical leak	Persistent drainage >3 weeks, clinically relevant change in management, percutaneous/endoscopic drainage, angiographic procedures, infection without organ failure	Reoperation, organ failure, death
Postoperative Pancreatic Hemorrhage[c]			
Onset (early ≤24 h, late >24 h)/severity	Early/Mild	Early/Severe or late/mild	Late/Severe
Location	Intraluminal/Extraluminal	Intraluminal/Extraluminal	Intraluminal/Extraluminal
Clinical condition	Good	Good to moderately impaired	Severely impaired, life threatening

[a] Delayed gastric emptying definition: functional gastroparesis after surgery without mechanical obstruction as determined by upper gastrointestinal contrast series or endoscopic evaluation.

[b] Postoperative pancreatic fistula definition: amylase >3 times upper limit of institutional normal serum amylase value.

[c] Postpancreatectomy hemorrhage definition: all postoperative episodes of hemorrhage after pancreatic resection, including gastrointestinal or intraabdominal hemorrhage, and early or delayed postoperative bleeding.

POD, Postoperative day.

nasogastric tube decompression and initiation of prokinetics (erythromycin or metoclopramide) are the mainstays of therapy. Upper endoscopy can be considered to rule out an associated marginal ulcer. In rare cases, refractory delayed gastric emptying may require percutaneous gastrostomy tube placement and parental nutrition, but it is most often self-limited and will resolve with time and supportive care. In the experience of the authors, how the gastrojejunostomy is completed is important, and the overwhelming majority of patients with delayed gastric emptying have a pancreatic leak responsible for this complication.

Postpancreatectomy Hemorrhage

Postpancreatectomy hemorrhage can be either early (within 24 hours of surgery) or late (usually postoperative day 7–14 or later). Early postpancreatectomy hemorrhage is caused by technical failures related to inadequate hemostasis and generally requires reoperation. Late postpancreatectomy hemorrhage is most commonly related to either bleeding from a pseudoaneurysm (frequently associated with a pancreatic fistula) or ulceration at the site of the gastrojejunostomy. Patients who suffer from early postpancreatectomy hemorrhage present with postoperative hypotension and blood in the surgical drains; return to the operating room is in order. Patients who present with late postpancreatectomy hemorrhage often have a herald gastrointestinal bleed in the setting of a complicated postoperative course that invariably includes a pancreatic anastomotic leak/fistula. The hemorrhage (hematemesis and occasionally melena) is often acute and sometimes can be catastrophic. Regardless of presentation, late postpancreatectomy hemorrhage requires rapid recognition, controlled resuscitation, and mobilization of the interventional radiology team. Bleeding can be controlled with either endovascular embolization of the pseudoaneurysm or stenting across the involved artery. When possible, if the bleeding is related to a GDA pseudoaneurysm and coil embolization of the aneurysm sac is not possible, stenting of the common hepatic artery is preferred over embolization. Mortality rates are high, and for those who survive the initial bleed postembolization, patients may have additional complications related to the intrabdominal abscess (present in most patients) as well as hepatic abscess and/or hepatic insufficiency.

SUMMARY

We are in an exciting time in surgical oncology, and advances in early diagnosis and the treatment of pancreatic cancer are poised to occur at a very rapid pace over the next 5 to 10 years. In the absence of an accurate blood-based test for early diagnosis, pancreatic cancer will likely become the second leading cause of adult cancer death very soon. Treatment strategies for all stages of disease emphasize early systemic therapy. Such treatment is only successfully implemented if we are able to effectively manage biliary and gastric outlet obstruction, nutrition challenges, and pain control. As therapeutic advances continue, their benefits will only be realized if we are able to deliver them successfully to the patient—likely the major challenge for healthcare and the study of healthcare disparities in the next decade. Potentially curative surgery for patients with pancreatic cancer should be completed with a close to 0% mortality and should be performed only in those who have a reasonable chance of cure. Despite the failure of past attempts to regionalize cancer surgery to high-volume centers, consolidation of health systems holds promise for the future. Although we have made significant advances in surgical care, we will be seeing more and more patients with unique toxicities from new and emerging systemic therapies, making the surgical management of this disease (and others) ever more complicated.

Appendicitis is the most common urgent or emergent general surgical operation performed in the United States and is responsible for as many as 300,000 hospitalizations annually.[1] It is estimated that as much as 6% to 7% of the general population in the United States will develop appendicitis during their lifetime, with the incidence peaking in the second decade of life.[2] Appendicitis is much less common in underdeveloped countries, suggesting that elements of the Western diet, specifically a low-fiber, high-fat intake, may play a role in the development of the disease process.[3]

ANATOMY AND EMBRYOLOGY

The appendix is a midgut organ first identified at 8 weeks of gestation as a small outpouching of the cecum. As gestation progresses, the appendix becomes more elongated and tubular as the cecum rotates medially and becomes fixed in the right lower quadrant of the abdomen. The appendiceal mucosa is of the colonic type, with columnar epithelium, neuroendocrine cells, and mucin-producing goblet cells.[3] Lymphoid tissue is found in the submucosa of the appendix, leading some to hypothesize that the appendix may play a role in the immune system. In addition, evidence suggests that the appendix may serve as a reservoir of "good" intestinal bacteria and may aid in recolonization and maintenance of the normal colonic flora.[4] Although historically, removal of the appendix was not felt to result in any adverse sequelae, this has recently been challenged. For example, patients who have had previous appendectomy have been demonstrated to have a more difficult clinical course and overall poorer outcomes in recurrent cases of *Clostridioides difficile* infection when compared with patients who have not undergone appendectomy. The theory is that the microbiome of the appendix has a protective function and that the loss of this eliminates an element of beneficial immunologic redundancy.[5] In addition, a recently published epidemiologic study found a significant link between appendectomy before age 20 and the development of prostate cancer, although a precise causative mechanism could not be elucidated.[6]

The blood supply of the appendix is through the appendiceal artery, a branch of the ileocolic artery, which is in turn a branch of the superior mesenteric artery. The appendix can be of variable size (5–35 cm in length) but averages 8 to 9 cm in length in adults. Its base can be reliably identified by defining the area of convergence of the taeniae at the tip of the cecum and then elevating the appendiceal base to define the course and position of the tip of the appendix. The appendiceal tip may be found in a variety of locations: it is retrocecal (but intraperitoneal) in approximately 60% of individuals, pelvic in 30%, and retroperitoneal in 7% to 10%. Agenesis of the appendix has been reported, as has duplication and even triplication.[3–7]

OVERVIEW OF APPENDICITIS

History

Some of the earliest descriptions of the appendix date back to 1522 by Jacopo Berengario da Capri.[8] Since then, many anatomists have struggled with the role and purpose of the appendix, a debate that continues today.[9] The first appendectomy was reported in 1735 by a French surgeon, Claudius Amyand, who identified and successfully removed the appendix of an 11-year-old male that was found within an inguinal hernia sac and that had been perforated by a pin. Although autopsy findings consistent with perforated appendicitis appeared sporadically thereafter in the literature, the first formal description of the disease process, including the common clinical features and a recommendation for prompt surgical removal, was in 1886 by Reginald Heber Fitz of Harvard University.[3]

Notable advances in surgery for appendicitis include McBurney's description of his classic muscle-splitting incision and technique for removal of the appendix in 1894 and the description of the first laparoscopic appendectomy by Kurt Semm in 1982.[3] Finally, but of no less significance, was the development of broad-spectrum antibiotics, interventional radiologic techniques, and better surgical critical care strategies, all of which have resulted in substantial improvements in the care of patients with appendiceal pathology.

Pathophysiology and Bacteriology

Appendicitis is caused by luminal obstruction.[3] The causes of the luminal obstruction are many and varied, including fecal stasis, fecaliths, lymphoid hyperplasia, neoplasms, fruit and vegetable material, ingested barium, and parasites such as ascaris or pinworm. Obstruction of the proximal lumen of the appendix leads to elevated pressure in the distal portion because of ongoing mucus secretion and production of gas by bacteria within the lumen. With progressive distention of the appendix, the venous drainage becomes impaired, resulting in mucosal ischemia. If there is persistent obstruction, full-thickness ischemia may ensue, which has the potential to lead to perforation. Bacterial stasis distal to the obstruction can lead to bacterial overgrowth within the appendix.[3] This is significant because this overgrowth results in the release of a larger bacterial inoculum in cases of perforated appendicitis. The most common sequela from appendiceal perforation is the formation of an abscess in the periappendiceal region or pelvis. On occasion, however, free perforation occurs that results in diffuse peritonitis.[3]

The flora within the appendix is similar to that found within the colon. Infections associated with appendicitis should be considered polymicrobial, and antibiotic coverage should include agents that address the presence of both gram-negative bacteria and anaerobes. Common isolates include *Escherichia coli, Bacteroides fragilis,* enterococci, *Pseudomonas aeruginosa,* and *Klebsiella pneumoniae* (Table 94.1).[10]

Differential Diagnosis

Appendicitis must be considered in every patient who has not had an appendectomy and presents with acute abdominal pain.[11,12] Consideration of the patient's age and sex may help narrow the list of possible diagnoses. In children, other considerations include but are not limited to mesenteric adenitis (often seen after a recent viral illness), acute gastroenteritis, intussusception, Meckel diverticulitis, inflammatory bowel disease, and (in males) testicular torsion. Nephrolithiasis and urinary tract infection may be manifested with right lower quadrant pain in either sex.[3,11,13] In females of childbearing age, the differential diagnosis is expanded even further. Gynecologic pathology may be mistaken for appendicitis, including ruptured ovarian cysts, *mittelschmerz* (midcycle abdominal pain occurring with ovulation), endometriosis, ovarian torsion, ectopic pregnancy, and pelvic inflammatory disease.[3,11,13] In the elderly, consideration must be given to acute diverticulitis and malignant disease as possible causes of lower abdominal pain. In the neutropenic patient, *typhlitis* (also known as *neutropenic enterocolitis*) should also be considered.[14,15] Appendicitis in these special populations is discussed in greater detail later in the chapter.

TABLE 94.1 Bacteria Commonly Isolated in Perforated Appendicitis

TYPE OF BACTERIA	ISOLATES (*N* = 694)
Gram-Negative Bacteria	
Escherichia coli	448 (64.6%)
Pseudomonas aeruginosa	114 (16.4%)
Klebsiella pneumoniae	37 (5.3%)
Citrobacter species	18 (2.6%)
Enterobacter species	10 (1.4%)
Serratia marcescens	3 (0.4%)
Raoultella planticola	3 (0.4%)
Comamonas testosterone	2 (0.3%)
Aeromonas species	2 (0.3%)
Proteus species	2 (0.3%)
Acinetobacter species	1 (0.1%)
Yersinia species	1 (0.1%)
Morganella species	1 (0.1%)
Gram-Positive Bacteria	
Enterococcus species	27 (3.9%)
Streptococcus species	20 (2.9%)
Staphylococcus species	5 (0.7%)

Adapted from Song DW, Park BK, Suh SW, et al. Bacterial culture and antibiotic susceptibility in patients with acute appendicitis. *Int J Colorectal Dis.* 2018;33:441-447.

Presentation

History

Patients presenting with acute appendicitis typically complain of vague abdominal pain that is most commonly periumbilical in origin. This reflects the stimulation of visceral afferent pathways through the progressive distention of the appendix. As the distension of the appendix progresses and the appendiceal tip becomes inflamed, it irritates the adjacent parietal peritoneum. This leads to somatic pain localized to the position of the appendiceal tip, typically the right lower quadrant. This phenomenon remains a reliable symptom of appendicitis[3,11] and should serve to further increase the clinician's index of suspicion for appendicitis.[3,11] Anorexia is often present, as is nausea with or without associated vomiting. Either diarrhea or constipation may be present as well.

Although these symptoms represent the "classic" presentation of appendicitis, the clinician must be aware that the disease may be manifested in an atypical fashion. For example, patients with a retroperitoneal appendix may present in a more subacute manner, with flank or back pain, whereas patients with an appendiceal tip in the pelvis may have suprapubic pain suggestive of urinary tract infection.[3,11]

Physical Examination

Patients with appendicitis typically appear ill. They frequently lie still because of the presence of localized peritonitis, which makes movement painful. Tachycardia and mild dehydration are often present to varying degrees. Fever is frequently present, ranging from low-grade temperature elevations ($<38.5°C$) to more impressive elevations of body temperature, although absence of fever does not exclude a diagnosis of appendicitis.[1,3,11]

Abdominal examination typically reveals a quiet abdomen with tenderness and guarding on palpation of the right lower quadrant. The location of the tenderness is classically over McBurney point, which is located one-third the distance between the anterior superior iliac spine and the umbilicus. The pain and tenderness are typically accompanied by localized peritonitis, as evidenced by the presence of rebound tenderness. Diffuse peritonitis or abdominal wall rigidity resulting from involuntary spasm of the overlying abdominal wall musculature is strongly suggestive of perforation.[1,3]

A number of signs have been described to aid in the diagnosis of appendicitis. These include the Rovsing sign (right lower quadrant pain on palpation of the left lower quadrant), the obturator sign (right lower quadrant pain on internal rotation of the hip), and the psoas sign (pain with extension of the ipsilateral hip), among others.[1] Although these are of historical interest, it is important to realize that they are simply indicators of localized peritonitis rather than a diagnostic of a specific disease process.

Rectal examination findings are typically normal. However, a palpable mass or tenderness may be present if the appendiceal tip is located within the pelvis or if a pelvic abscess is present. In female patients, pelvic examination is important to exclude pelvic disease. However, cervical motion tenderness, a finding typically associated with pelvic inflammatory disease, may be present in appendicitis because of irritation of the pelvic organs from the adjacent inflammatory process.[3,11]

Laboratory Studies

Laboratory studies should be interpreted with caution in cases of suspected appendicitis and used to support the clinical picture rather than to definitively prove or exclude the diagnosis. Leukocytosis, often with a predominance of neutrophils and sometimes an increase in bands, is present in 90% of cases. A normal white blood cell count is found in 10% of cases, however, and it should not be used as an isolated test to exclude the presence of appendicitis.[16–19] Urinalysis is typically normal as well, although the finding of trace leukocyte esterase or pyuria is not unusual and is presumably due to the proximity of the inflamed appendix to the bladder or ureter. Ketonuria has also been associated with appendicitis in recent studies.[20,21]

In addition to the white blood cell count, several biomarkers have been investigated as additional diagnostic clues to the diagnosis. These have included C-reactive protein, procalcitonin, interleukin-6, and others. Although C-reactive protein appears to be the most sensitive of these, none provides sufficient specificity to definitively diagnose appendicitis.[10,12]

Ultimately, no symptom, sign, or laboratory test has been demonstrated to be uniquely predictive of appendicitis.[1,16–18] Rather, it is the assessment of the collective body of information that allows more precise diagnosis.[1,16–18] Several clinical scoring systems have been developed to serve as predictive models for appendicitis. These have included the Alvarado score, the pediatric appendicitis score, the appendicitis inflammatory response (AIR) score, and the adult appendicitis score (AAS)—to name a few.[22–24] In the most recent consensus guidelines, use of the AIR or AAS score is recommended over the use of the Alvarado score, which can be useful in ruling out appendicitis but is not sufficiently specific.[17,18]

Imaging Studies

Imaging studies in patients suspected to have acute appendicitis can reduce the negative appendectomy rate, which can be as high as 15%.[17,25] A variety of radiographic studies may be used to diagnose appendicitis. These consist of plain radiographs, ultrasound (US), computed tomography (CT) scanning, and magnetic resonance imaging (MRI).

Plain radiographs may be obtained in the emergency department setting for the evaluation of acute abdominal pain but lack both sensitivity and specificity for the diagnosis of appendicitis and are rarely helpful. A calcified fecalith in the right lower quadrant may support the diagnosis, but this finding must be placed into the appropriate clinical context and is typically present in only 5% of cases.[26] Pneumoperitoneum, if present, should alert the clinician to other causes of a perforated viscus (e.g., a perforated ulcer or diverticulitis) because this is not typically observed in cases of appendicitis, even with perforation.[26,27]

US has been used for diagnosis of appendicitis since the 1980s. As US technology has become more advanced, so has its ability to visualize the appendix. The inflamed appendix is typically enlarged, immobile, and noncompressible (Fig. 94.1). If the appendix cannot be visualized, the study is inconclusive and cannot be relied on to guide treatment, although secondary signs such as free fluid, hyperemia of adjacent bowel loops, induration of mesenteric fat, and regional adenopathy may be considered in the overall picture and serve to increase the diagnostic accuracy of US.[28] Although US is time efficient and provides the advantage of avoiding ionizing radiation, the success of the study depends greatly on the skill of the sonographer and is, thus, highly operator dependent. The sensitivity is reported to range from 71% to 94%, whereas the specificity ranges from 81% to 98%, although again, this varies greatly based on the skill and experience of the sonographer.[17,29] Its greatest utility appears to be in the evaluation of the pediatric or pregnant patient, in whom the associated radiation exposure from CT is especially undesirable.[26] It has recently been suggested that a standardized reporting method or "template" might improve the overall results of US in this clinical setting.[18,29,30]

CT scanning is the most common imaging study used to diagnose appendicitis and is highly effective and accurate.[17,26] A recent systematic review has reported the sensitivity of CT scan to be 95%, with a specificity of 94%.[31] Contrast administration (IV, PO, or rectal) has been shown to confer a higher sensitivity in the diagnosis of acute appendicitis without affecting specificity.[31] Further, a randomized trial from 2018 showed that low-dose CT

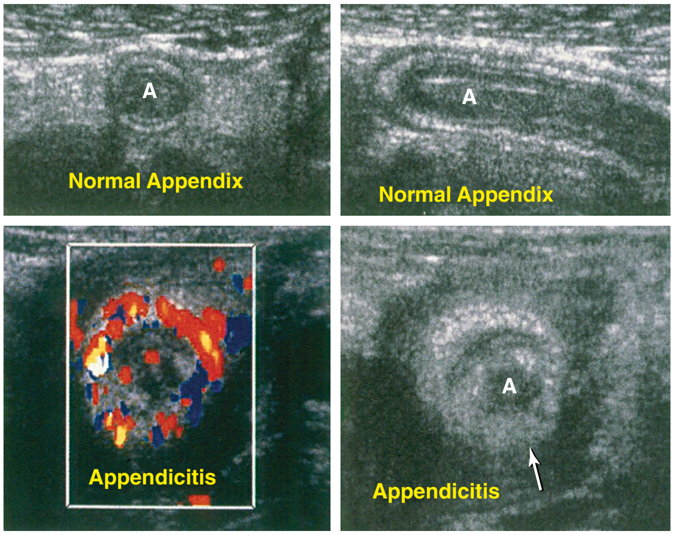

FIGURE 94.1 Ultrasound image of a normal appendix *(top)* illustrating the thin wall in coronal *(left)* and longitudinal *(right)* planes. In appendicitis, there is distention and wall thickening *(bottom, right)*, and blood flow is increased, leading to the so-called ring-of-fire appearance. *A*, Appendix.

imaging was not inferior to standard CT in diagnosing acute appendicitis.[32] Currently, contrast-enhanced low-dose CT imaging is the recommended technique for evaluation of acute appendicitis.[18]

The diagnosis of appendicitis on CT is based on the appearance of a thickened, inflamed appendix with surrounding "stranding" indicative of inflammation. The appendix is typically more than 7 mm in diameter, with a thickened, inflamed wall and mural enhancement or "target sign" (Fig. 94.2). Periappendiceal fluid or air is also highly suggestive of appendicitis and suggests perforation. In cases in which the appendix is not visualized, the absence of inflammatory findings on CT suggests that appendicitis is not present.[18,26] CT scans are recommended in any adult patient with suspected appendicitis for operative planning and ruling out other causes of peritoneal symptoms, especially given the existence of multiple pathologies with overlapping symptomatology.[31,33]

MRI is typically reserved for use in the pregnant patient and should be performed without contrast.[34,35] Criteria for MRI diagnosis include appendiceal enlargement (>7 mm), thickening (>2 mm), and the presence of inflammation.[26] A recent meta-analysis found the sensitivity of MRI to be 97%, with a specificity of 95%.[17,36,37] Drawbacks associated with the use of MRI include its higher cost; motion artifact; greater difficulty in interpretation by nonradiologists, who may have limited experience with the technology; and limited availability (especially in the after-hours emergency setting).[17,18,26,37]

Classification of Appendicitis

There are several different ways of classifying appendicitis. The first differentiation comes between acute and chronic appendicitis, with acute appendicitis evolving over the course of hours to days and chronic appendicitis referring to a chronicity that usually spans weeks to months, even years.[38]

Within acute appendicitis, the most common classification system separates the condition into "uncomplicated" and "complicated," although establishing what this means can be challenging. Traditional surgical teaching has purported that uncomplicated appendicitis will inevitably progress to complicated appendicitis without treatment; however, this is no longer believed to be the case. Multiple recent studies have made the argument that complicated and uncomplicated appendicitis have different pathophysiologic mechanisms, and as such, the traditional dogma of putting them in a continuum of disease is increasingly being shown to be erroneous.[39,40]

Uncomplicated appendicitis refers to an inflamed appendix without evidence of necrosis or perforation, whereas *complicated appendicitis* has focal or transmural necrosis that has led to or can eventually lead to perforation.[41] Complicated appendicitis can progress to appendicitis with an abscess or phlegmon, whereas uncomplicated appendicitis does not.[41] This distinction is key because patients with uncomplicated appendicitis may be able to forego emergent surgical treatment (and potentially, even surgical treatment at all), whereas patients with complicated appendicitis should be managed with appendectomy.[41] Thus, differentiating between these two entities is essential to determining appropriate management. Specifically, it is important to rule out complicated appendicitis so that patients with this pathology are not inappropriately treated with only antibiotics.[41] Unfortunately, the differentiation between complicated and uncomplicated appendicitis is not something that we are yet able to gather with great certainty before deciding on a management strategy. Certain imaging features, such as abscess, appendicolith, free air, and free fluid, have been associated with complicated appendicitis, and diagnosing a patient with a significant periappendiceal abscess or free air with complicated appendicitis is not difficult (Fig. 94.3). However, the absence of these features does not mean that complicated appendicitis is not present.[42] Atema et al. have described two new scoring systems where clinical, laboratory, and imaging characteristics can be evaluated to determine whether a patient has uncomplicated or complicated appendicitis; one uses US imaging, the Scoring System for Appendicitis Severity-US (SAS-US), and the other uses CT imaging, the Scoring System for Appendicitis Severity-CT (SAS-CT).[43] As noted by Born et al., the SAS-US and SAS-CT perform well in ruling out complicated appendicitis but are yet to be externally validated in prospective studies.[41]

TREATMENT OF APPENDICITIS

Treatment for appendicitis has been debated frequently as less invasive therapies, including nonoperative therapies, have been shown to be effective. For decades, the mainstay treatment for acute

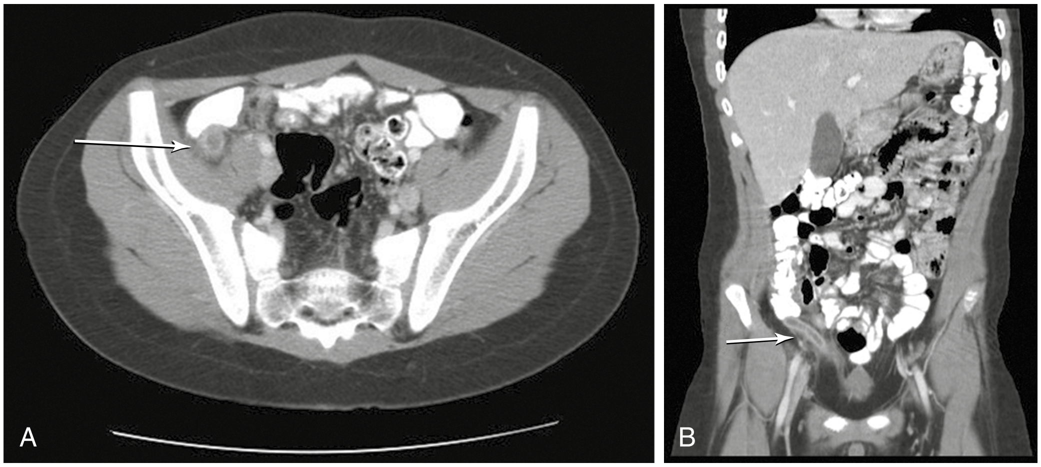

FIGURE 94.2 Computed tomography scan of the abdomen demonstrating classic findings of acute appendicitis. The *arrow* points to the thickened, elongated appendix with periappendiceal fat stranding and fluid around the appendiceal tip.

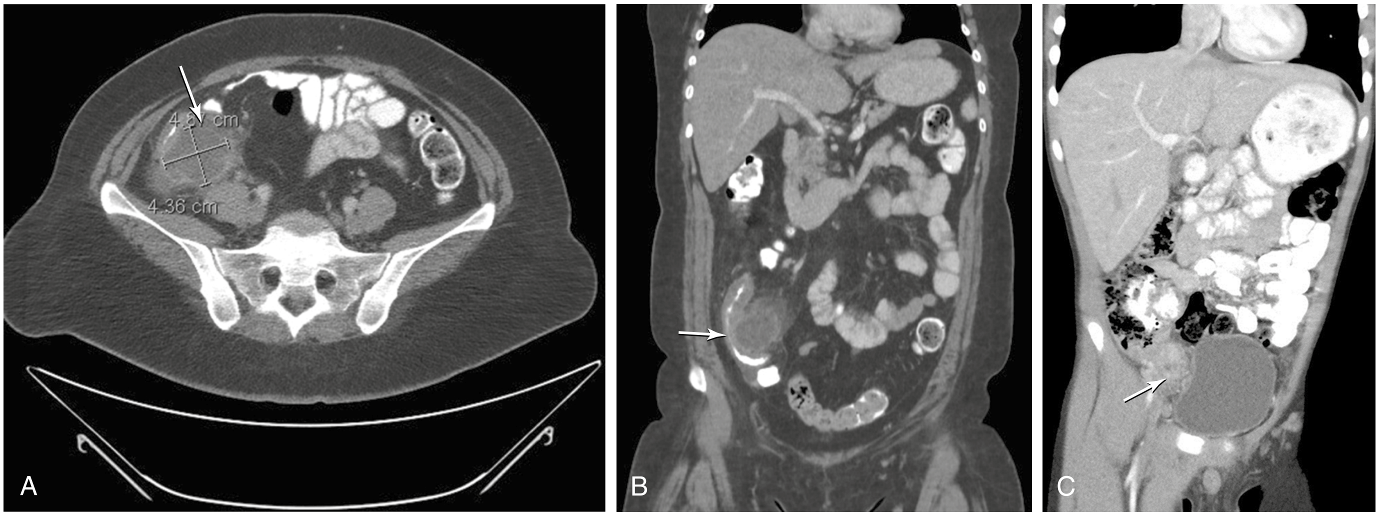

FIGURE 94.3 Computed tomography scan of the abdomen demonstrated complicated appendicitis. Sagittal (A) and coronal (B) computed tomography images demonstrate an appendiceal abscess in a patient who presented with a 2-week history of abdominal pain and was found to have a palpable mass on examination. The *arrows* point to a periappendiceal abscess cavity. The patient was successfully managed with percutaneous drainage and antibiotic therapy. (C) A similar case in which the patient presented with an appendiceal phlegmon and was successfully treated with antibiotics alone. The *arrow* points to the phlegmon. (Note the mass effect on the bladder.)

appendicitis was open appendectomy. However, newer strides in research have opened the door for a larger set of options in the management of acute appendicitis, including laparoscopic appendectomy, robotic appendectomy, single-incision appendectomy, percutaneous and transrectal drainage, and nonoperative management with only antibiotics.[44,45] As discussed earlier, determining the best strategy for management is highly dependent on the type of appendicitis being treated. For patients presenting acutely, however, the mainstay of treatment consists of fluid resuscitation and administration of broad-spectrum antibiotics targeting intraabdominal pathogens until further management plans are established based on appendicitis severity and patient preference.[17,18,44]

Acute Uncomplicated Appendicitis

Although appendectomy has traditionally been considered the gold standard in management of acute appendicitis without the presence of a phlegmon or abscess, multiple large trials over the past decade have questioned the absolute necessity for surgical intervention versus management with only antibiotics for this population. Results from the first of these large trials were published in 2015 by the Appendicitis Acuta (APPAC) multicenter clinical trial researchers. In this trial, 530 patients with acute uncomplicated appendicitis confirmed by CT imaging were randomized to early appendectomy or antibiotic treatment. The study investigators found that antibiotic treatment efficacy was –27%, which failed to meet their prespecified criteria for noninferiority (efficacy of –24%). Importantly, however, the trial did demonstrate no complications in the participants who underwent appendectomy after originally being placed in the antibiotic group.[46] Follow-up studies on quality of life for study participants at 5 and 7 years did not show a difference in satisfaction between treatment groups as long as the treatment was successful. However, they did show lower satisfaction for patients who failed treatment in the antibiotics-alone treatment group.[47,48] A meta-analysis published shortly after exploring the management of acute appendicitis nonoperatively found an initial failure rate of antibiotics of 9% (95% confidence interval [CI] 4.00%–13.0%) and a 1-year recurrence rate of 25% (95% CI 12.0%–35%).[49] Most significantly, however, the authors also noted a statistically significant increase in the likelihood of progressing to complicated appendicitis in the failed nonoperative group.[49] The authors also reported a longer length of stay with antibiotic therapy but an overall lower cost of the initial treatment. However, the subsequent downstream cost of reintervention for recurrence was not considered.[49] More recently, the Comparison of Outcomes Between Drugs and Appendectomy (CODA) investigators have published findings on their multicenter, randomized control trial comparing antibiotics versus appendectomy in patients with uncomplicated appendicitis. The original study published in 2020 found that based on a standardized measure of health status, the European Quality of Life–5 Dimensions questionnaire, at 30 days, antibiotics were a noninferior treatment option to appendectomy. However, it was found that 29% of patients did undergo a subsequent appendectomy within 90 days. Additionally, the study found that patients with appendicolith treated nonoperatively were at higher risk for appendectomy and complications than those without.[50] A smaller single-institution trial published shortly after, the Conservative Versus Open Management of Acute Uncomplicated Appendicitis (COMMA) trial, found a similar rate of recurrence of appendicitis after nonoperative treatment of 25%. The authors reported a similar quality of life between both groups early on but found a significantly lower quality of life in patients treated nonoperatively at 1 year.[51]

Based on these data, antibiotics are now considered an acceptable first-line treatment for acute uncomplicated appendicitis, and given there are two safe and effective treatment options for the disease, patient preference has become an important factor in informing the decision of whether to proceed with appendectomy or antibiotic treatment.[44,50] As such, the risks and benefits of operative intervention versus antibiotic management should be discussed with patients using a shared decision-making model to optimize patient-centered treatment for this disease. Risk of recurrence and risk of neoplasm should be presented as part of the risks of nonoperative treatment, whereas risk of surgical complications should be presented as part of the risks of operative management. Importantly, however, the patient's preferences and values with regard to pursuing operative versus nonoperative treatment should also be considered in the decision-making process. Of note, the presence or absence of an appendicolith is an important factor that modifies their risks, and as such, it should be included in any conversation about nonoperative management of appendicitis.[44,50] To help facilitate these conversations, the CODA investigators have developed a decision-aid tool that can help patients and their surgeons make treatment decisions about appendicitis care.[52]

Once a decision is made regarding whether to pursue surgical or nonsurgical intervention, these treatments can ensue in different ways. If operative intervention is chosen, an open versus laparoscopic approach may be used, with the laparoscopic approach now being significantly more common, as will be discussed in detail later. For patients managed nonoperatively, treatment consists of 10 days of antibiotics to cover gastrointestinal flora, also as described earlier, with the first 24 hours administered intravenously.[53]

Acute Complicated Appendicitis

Although antibiotic treatment is a safe and effective option for the management of acute uncomplicated appendicitis, proven or suspected complicated appendicitis without an abscess or phlegmon should be treated surgically.[41] The technique of appendectomy for complicated appendicitis is the same as for uncomplicated appendicitis; however, the level of difficulty encountered in removing a friable, gangrenous, and/or perforated appendix can be a challenge and requires gentle, meticulous handling of the appendix and inflamed periappendiceal tissues to avoid injury. Cultures are not necessary unless there is a significant concern for encountering resistant bacteria (patient with exposure to a healthcare environment or recent antibiotic therapy.)[54] In fact, intraoperative cultures have not been shown to decrease the incidence of postoperative intraabdominal abscesses or modify their treatment.[55] Once the appendix is successfully removed, careful attention should be given to the clearance of infectious material from the abdomen. This task may be accomplished by suction and irrigation, with special attention given to removal of any obvious fecaliths or spilled fecal material. Recent data suggest that simple suction aspiration of gross purulence may be just as effective as large-volume irrigation in cases of appendiceal rupture.[18] Drains are not routinely placed unless a discrete abscess cavity is present, in which case a single closed suction drain can be placed within its base. Recent data, however, suggest that prophylactic drain placement does not decrease the rate of postoperative complications in this population but can increase length of stay.[56,57] Postoperative antibiotic management in this population should continue for a maximum of 4 days after appendectomy, with recent data supporting a duration of only 2 days.[58–62] Knowledge of regional and institutional bacterial resistance patterns should be considered when choosing empiric coverage until culture results, if collected, are available.[63]

If the patient develops fever, leukocytosis, pain, and delayed return of bowel function, the possibility of a postoperative abscess must be entertained. Abscess complicates perforated appendicitis in 10% to 20% of cases and represents the major source of morbidity related to perforation.[1,3] A CT scan with IV administration of a contrast agent is diagnostic. Once an abscess is diagnosed, treatment usually consists of antibiotics and percutaneous drainage.[17,18] If CT drainage is not technically possible because of the location of the abscess, laparoscopic, transrectal, or transvaginal drainage is an alternative.

Acute Appendicitis With Abscess or Phlegmon

In patients presenting with acute appendicitis with an abscess or phlegmon, treatment should be individualized based on the nature of the presentation (Fig. 94.4). Although rare, a patient may present with diffuse peritonitis and require urgent surgical intervention for management. More commonly, however, patients present similarly to the previous description. Immediate exploration and attempted appendectomy in these patients may result in substantial morbidity, including failure to identify the appendix, postoperative abscess or fistula, and unnecessary extension of the operation to include ileocecectomy, all due to the extreme induration and friability of the involved tissues. Furthermore, nonoperative treatment is often successful and has fewer complications than immediate operative management.[64–66] That being said, there is some evidence to support immediate operative management with regard to decreased length of stay, fewer readmissions, fewer additional interventions, and lower rates of eventual bowel resection.[67–69] The current World Society of Emergency Surgeons (WSES) Jerusalem guidelines recommend nonoperative management if laparoscopic expertise is not available but support operative management in experienced hands.[18]

If a localized abscess is identified, imaging-guided percutaneous drainage should be performed for source control. Once source control is obtained, antibiotics should be continued for 4 days.[62] The drainage catheter is typically left in place until the drainage

stops or slows down to institutional standard amounts.[70,71] If percutaneous drainage is not technically feasible, laparoscopic drainage may be necessary. Postoperative management for these patients is identical to that of patients who are successfully drained percutaneously. If a periappendiceal phlegmon is present or if the amount of fluid present is not sufficient to drain, the patient may be treated with antibiotics alone, typically for 4 to 7 days, as recommended by Infectious Diseases Society of America (IDSA) guidelines for treatment of intraabdominal infection.[54] If a patient with a phlegmon fails to improve with antibiotic treatment alone, reimaging is warranted to evaluate for the interval development of a drainable abscess.

After successful nonoperative treatment of complicated appendicitis, interval appendectomy, where patients undergo removal of the appendix several weeks to months later, should be considered. The rationale for interval appendectomy is based on the potential for development of recurrent appendicitis and the subsequent risks associated with emergent removal or reperforation of the appendix. On the other hand, interval appendectomy can be challenging and consequently yield a higher risk of postoperative complications when performed.[64,72] Multiple studies have investigated the recurrence rate of appendicitis after nonoperative management, which ranges from 8% to 31.8%.[73–77] The findings in these studies as well as similar results reported by others and the costs associated with operative intervention to prevent recurrence have led to the WSES Jerusalem guideline recommendation against routine interval appendectomy.[18] However, the presence of an appendicolith on CT has been shown to be predictive of a higher risk of recurrent appendicitis and may be used as a justification to proceed with interval appendectomy in that subgroup of patients.[50,78] This selective approach to interval appendectomy has also been demonstrated to be more cost-effective than its routine performance in all affected patients.[72] On the other hand, the risk of appendiceal neoplasms in patients presenting with complicated appendicitis with phlegmon or abscess treated nonoperatively is significant, and there are population-level data to support an association between tumor risk and complicated appendicitis.[76,79–82] Importantly, the Peri-Appendicitis Acuta randomized clinical trial, a multicenter, noninferiority trial comparing interval appendectomy to MRI after initial successful nonoperative treatment of complicated appendicitis with abscess, had to be stopped early because of the high rate of neoplasm in the interval appendectomy group, with all neoplasms in patients older than 40 years.[18,81,83,84] For this reason, if no interval appendectomy is performed, colonoscopy and full-dose contrast-enhanced CT should be performed in all adult patients 40 and older as routine follow-up after nonoperative management of complicated appendicitis.[18]

The Normal-Appearing Appendix at Operation

In cases of “negative appendectomy,” in which a normal appendix is identified at operation for suspected acute appendicitis, there is controversy as to whether the appendix should be removed.[85,86] First, the abdomen should be thoroughly evaluated for other causes of pain severe enough to warrant an operation; this is easiest if the operation is laparoscopic. The terminal ileum should be examined for a Meckel diverticulum and the serosa of the small bowel for any stigmata of Crohn disease, such as inflammation, stricture formation, or the characteristic “creeping fat” appearance of the mesentery. The ileal mesentery should also be inspected for enlarged lymph nodes suggestive of mesenteric adenitis. The uterine adnexa should be examined for any evidence of tuboovarian or salpingeal disease, such as ovarian torsion, tuboovarian abscess, endometriosis, or ruptured ovarian cysts. The sigmoid colon should be examined for evidence of acute diverticulitis, especially in cases in which a redundant sigmoid colon is found in the right lower quadrant. If these are all normal, attention should be turned to the upper abdomen for examination of the gallbladder and duodenum.

If everything looks normal, including the appendix, during an operation for suspected appendicitis, appendectomy should be strongly considered. This is mainly because many causes of right lower quadrant pain mentioned earlier may be recurrent, and removal of the appendix removes appendicitis from the differential diagnosis if the patient re-presents with pain. In cases of Crohn disease suggested by findings at operation, appendectomy is advisable unless the base of the appendix and cecum are involved (in this scenario, appendectomy is deferred to avoid breakdown of the inflamed stump and subsequent fistula formation) for the same reason. In addition, abnormalities of the appendix not apparent on gross inspection at the time of operation are sometimes identified on pathologic examination.[85]

Stump Appendicitis

Stump appendicitis occurs when residual appendiceal tissue at the base of the cecum, resulting from incomplete resection at the time of appendectomy, develops recurrent inflammation. It is a relatively rare diagnosis with an incidence between 0.002% and 0.15%.[87,88] Patients with stump appendicitis usually present with similar symptoms as patients with appendicitis without prior appendectomy. Imaging is nonspecific and includes cecal wall thickening, fluid in the right paracolic gutter, infiltration of the surrounding fat, and if the stump is long enough, similar findings to those of primary acute appendicitis.[89] Stump appendicitis has been reported after both open and laparoscopic appendectomy and is associated with difficulty in visualization and, thus, identification of the actual appendiceal base during appendectomy. Appendectomy in the setting of perforation, necrosis, or abscess makes this visualization more challenging and, thus, increases the risk of stump appendicitis at a later date.[90] Stump appendicitis should be managed as recurrent appendicitis and, thus, warrants surgical resection of the remnant appendix.[91]

Chronic Appendicitis as a Cause of Abdominal Pain

On occasion, patients will present with a history of recurrent right lower quadrant pain, and a surgical opinion will be sought as to the benefit of elective appendectomy for treatment of this condition. Studies suggest that uncomplicated appendicitis may occasionally resolve without intervention, so it is conceivable that appendicitis may wax and wane in some patients.[92,93] In addition, some patients with pain are found to have a thickened appendix or an appendicolith on CT despite no evidence of a systemic illness or acute periappendiceal inflammation. In some of these cases, appendectomy will produce relief of symptoms, and in these cases, examination of the appendix will sometimes reveal findings consistent with chronic inflammation.[94,95]

More complex, however, is the patient with nonspecific lower abdominal pain in the absence of radiographic evidence of appendiceal disease. This typically requires a multidisciplinary workup involving input from specialists in gastroenterology and gynecology as well as surgery. Appendectomy is typically not offered unless disease is demonstrated radiographically. However, if diagnostic laparoscopy is performed to investigate or exclude other disease (typically by a gynecologist), it is reasonable to offer the patient an appendectomy to be performed at that time.[96,97]

This should be approached through a shared decision-making model, where the risks of appendectomy are weighed against the possible resolution of the patient's symptoms (if the appendix was the source) and the ability to remove the appendix from consideration as a source in the future and, thus, potentially avoid unnecessary imaging and facilitate the search for other sources of pain.

Incidental Appendectomy

Incidental appendectomy is the term applied when a grossly normal appendix is removed at the time of an unrelated procedure. Once commonly performed, incidental appendectomy is no longer recommended. Wen and coworkers actually demonstrated that incidental appendectomy is associated with an increase in both morbidity and mortality.[93,98] Other investigators have demonstrated that incidental appendectomy does not appear to be cost-effective as a preventive measure.[99] Finally, the recent finding that the appendix may actually have a role in the maintenance of healthy colonic flora makes the practice of incidental appendectomy even more controversial.[4,5,39] For these reasons, we advocate careful inspection of the appendix for abnormalities during abdominal operations as part of a thorough exploration but do not advocate appendectomy unless an abnormality is detected.

Laparoscopic Versus Open Appendectomy

The debate about the choice of open versus laparoscopic appendectomy for the treatment of appendicitis was historically a major point of controversy among surgeons. However, the literature now strongly supports performing appendectomy laparoscopically, including in complicated appendicitis, elderly patients, and pregnant patients.[100–103] Laparoscopic appendectomy is associated with a lower risk of complications in both complicated and uncomplicated appendicitis, including lower overall morbidity, reduced wound complications, reduced postoperative pain, and a slightly shorter recovery time, with only a slightly higher versus similar rate of postoperative intraabdominal abscess development.[104–107] Thus, although both open and laparoscopic approaches are acceptable, there are significant advantages with laparoscopy. Furthermore, laparoscopy allows examination of the entire peritoneal space, making it exceptionally useful to exclude other intraabdominal disease that may be manifested in a similar fashion, such as diverticulitis or tuboovarian abscess. Although debate remains regarding the cost-effectiveness of a laparoscopic versus open approach, the advantages of the laparoscopic approach appear to outweigh the marginally increased hospital costs associated with it.[108,109]

For open appendectomy the patient is placed in the supine position, and the appendix is approached through an oblique muscle-splitting incision (McArthur-McBurney), a transverse incision (Rockey-Davis), or a conservative midline incision. The cecum is grasped by the taeniae and delivered into the wound, allowing visualization of the base of the appendix and delivery of the appendiceal tip. The appendix is divided with the use of a stapler or crushed just above the base and ligated with an absorbable ligature. The stump is then either cauterized or, if desired, inverted by a purse-string or "Z" suture technique, although simple ligation is preferred (Fig. 94.5).[110]

For laparoscopic appendectomy, the patient is placed in the supine position with the right arm out and the left arm tucked. The bladder is emptied by a straight catheter or by having the patient void immediately before the procedure. The abdomen is entered via an open access (Hasson) or optical trocar technique (Fig. 94.6). Two additional working ports are then placed, typically in the left lower quadrant and in either the suprapubic area or supraumbilical midline, based on surgeon preference. With both the surgeon and assistant on the left side of the patient, atraumatic graspers are used to elevate the appendix. The appendix can then be divided using a laparoscopic stapler or Endoloop,[111–113] and the mesoappendix can also be divided with a laparoscopic stapler, a LigaSure, or a harmonic scalpel.[111–113] Retrieval of the appendix is accomplished using a plastic retrieval bag. The pelvis is suctioned and irrigated as needed, the trocars are removed, and the wounds are closed. Laparoscopic appendectomy may also be performed with single-site laparoscopic surgical techniques based on the experience and preferences of the surgeon. Laparoscopic appendectomy is demonstrated in Video 94.1. Video 94.2 demonstrates a single-incision laparoscopic approach (SILS) to several variants of appendiceal pathology.

APPENDICITIS IN SPECIAL POPULATIONS

Appendicitis in the Pregnant Patient

Appendicitis is the most common nonobstetric emergency in pregnancy and, consequently, the most frequent reason for general surgical intervention in this group of patients (Fig. 94.7).[114,115] In pregnancy, appendicitis has a typical clinical presentation in only 50% to 60% of cases.[114,115] The common symptoms of early appendicitis, such as nausea and vomiting, are nonspecific and are also often associated with normal pregnancy. Also, the normal febrile response to illness may be blunted and physical examination possibly altered because of the displacement of the appendix to a more cephalad location within the abdomen as a result of the gravid uterus. Finally, biochemical and laboratory indicators used to support the diagnosis of appendicitis in the nonpregnant patient are unreliable in pregnancy. For example, mild leukocytosis and elevated C-reactive protein levels may be physiologically normal findings in pregnancy. In addition, the surgeon must be concerned about the possibility of obstetric emergencies as a cause of abdominal pain, such as preterm labor, placental abruption, or uterine rupture.[114]

The impact of appendicitis on the pregnant patient is severe. The risk of preterm labor has been shown to be 11% and fetal loss 6% with complicated appendicitis.[116] On the other hand, negative appendectomy has also been associated with preterm labor and fetal loss (10% and 4%, respectively).[116] The lowest rates of preterm labor and fetal loss (6% and 2%, respectively) were seen in cases of uncomplicated appendicitis.[116] For these reasons, preoperative accuracy of diagnosis is crucial in the pregnant patient with suspected appendicitis; thus, routine imaging is recommended.

The initial study of choice for the diagnosis of appendicitis in pregnant patients is US with graded compression.[18] The criteria for US diagnosis are the same as in the nonpregnant patient. Unfortunately, the sensitivity and specificity (83%) of US are reduced in pregnancy because of the presence of the gravid uterus.[117] If US examination findings are equivocal, MRI without gadolinium contrast is the best next imaging study to pursue, given its excellent preserved sensitivity and specificity in the pregnant patient (Fig. 94.8).[18] Routine use of MRI in pregnant patients has been demonstrated to reduce the negative appendectomy rate by 47% without a significant increase in the perforation rate, and it has been shown to be a cost-effective study.[117] If US is inconclusive and MRI scanning is not immediately available, CT scanning may be used. exposure to the fetus, this can still be offered if the study is in the best interest of the pregnant patient and the patient understands the risks, which are minimal.[118] Although protocols vary, if CT is used during pregnancy, care should be taken to perform as limited a study as possible using a technique with the lowest possible radiation exposure and with avoidance of IV administration of contrast material.

Laparoscopic appendectomy is the most common approach currently used in pregnant patients[119] and is safe, provided that the surgeon has adequate experience with laparoscopy. Video 94.3 demonstrates a safe technique for appendectomy in a pregnant patient. At operation, consideration should be given to the height of the gravid uterus in choosing sites for trocar placement and entry technique to avoid inadvertent puncture of the uterus.

Appendicitis in the Elderly

Appendicitis is not infrequently seen in elderly patients and should remain in the differential diagnoses of any elderly patient presenting with acute abdominal pain who has not had an appendectomy. Data suggest that the reduced physiologic reserves and impaired immunologic and inflammatory responses in the elderly result in higher morbidity with a diagnosis of appendicitis.[17] The most important aspect when dealing with an elderly patient with abdominal pain is to realize the expanded differential diagnosis that must be considered, including but not limited to acute diverticulitis (uncomplicated or complicated), malignant disease, intestinal ischemia, ischemic colitis, complicated urinary tract infection, and perforated ulcer. Appendicitis may also be manifested in an atypical manner, so a high index of suspicion must be maintained in patients with an appendix. The higher perforation rate in the elderly population, as high as 40% to 70%, combined with the frequent coexistence of comorbidities resulting in higher morbidity, makes the diagnosis and treatment of appendicitis in the elderly a challenge, to say the least.[3,17,120]

Laparoscopic appendectomy is safe in the elderly and is the procedure of choice in this group of patients.[17] For patients too ill to undergo surgery, selective use of nonoperative therapy for appendicitis has shown success, as discussed previously. Certainly, when dealing with the elderly and the infirm, the approach must be individually tailored to the specific challenges presented by the patient.

Appendicitis in the Immunocompromised Patient

Immunocompromised patients with a concern for appendicitis should be evaluated promptly with CT imaging. This allows confirmation of the diagnosis of appendicitis as well as the exclusion of diagnoses, such as neutropenic enterocolitis (typhlitis), that may be amenable to nonoperative treatment.[14] A high index of suspicion in the management of this population is key because of their blunted ability to mount an immune response, which may result in the absence of fever, leukocytosis, and peritonitis. Appendicitis in the immunocompromised patient should be managed with appendectomy.

NEOPLASMS OF THE APPENDIX

Neoplasms of the appendix, although rare entities, are an important consideration for the practicing clinician. The annual incidence is estimated at 6 per 1,000,000 people.[121] Most cases are diagnosed incidentally because the majority of patients initially present with signs and symptoms concerning for appendicitis. Diagnosis is often achieved only after pathologic review of the appendectomy specimen. However, occasionally, these neoplasms may be detected on imaging as "incidentalomas"—including suspicion of underlying mass or mucocele. Despite their low incidence, these tumors present a management challenge for clinicians, and most general surgeons will encounter appendiceal neoplasms at some point in their careers. Their broad and diverse nature is reflected in their varying tumor biology and histopathology and the wide range of reported long-term survival, between 10% and 90%.[122] Altogether, this diversity creates confusion for practicing clinicians regarding classification, terminology, and management strategies.

In 2016, the Peritoneal Surface Oncology Group International (PSOGI) Modified Delphi Process[123] created a consensus for the terminology and classification of appendiceal neoplasms, which has been further expounded on by the 8th edition of the American Joint Committee on Cancer (AJCC) *Cancer Staging Manual*[124] in 2017 and by the World Health Organization (WHO) classification of digestive system tumors[125] in 2019. Appendiceal neoplasms are classified into "epithelial" versus "nonepithelial" tumors (Table 94.2). Epithelial tumors, as defined by PSOGI, include adenomas, serrated polyps, low-grade appendiceal mucinous neoplasms (LAMNs), high-grade appendiceal mucinous neoplasms (HAMNs), mucinous adenocarcinomas, poorly differentiated (mucinous) adenocarcinomas with signet ring cells, (mucinous) signet ring cell carcinomas, and adenocarcinomas. Nonepithelial tumors include lymphomas and sarcomas. Neuroendocrine neoplasms (NENs), although originally classified as "nonepithelial" by PSOGI, have been designated as *epithelial tumors* by the WHO. This section provides an overview of the approach to and management of appendiceal neoplasms.

Clinical Presentation

A common presentation for appendiceal neoplasms may mimic the classic symptoms of acute appendicitis: right lower quadrant pain and tenderness, nausea, anorexia, fever, and leukocytosis. An incidental mass may also be noted during radiographic workup for presumed appendicitis; however, most often, these tumors are detected postoperatively during evaluation of the appendectomy specimen. A previous retrospective study found that up to 3.7% of appendectomy specimens contained appendiceal neoplasms, with a higher frequency found in patients undergoing interval

TABLE 94.2 Classification of Appendiceal Neoplasms

SUBTYPE	NEOPLASM
Noncarcinoid epithelial tumors	• Adenoma • Serrated polyp • Low-grade appendiceal neoplasm (LAMN) • High-grade appendiceal neoplasm (HAMN) • Mucinous adenocarcinoma • Poorly differentiated (mucinous) adenocarcinoma with signet ring cells • (Mucinous) signet ring cell carcinoma • (Nonmucinous) adenocarcinoma • Goblet cell adenocarcinoma
Neuroendocrine neoplasms	• Neuroendocrine tumor (NET) • Neuroendocrine carcinoma (NEC) • Mixed neuroendocrine–nonneuroendocrine neoplasm (MiNEN)

Nonepithelial tumors	• Lymphoma
	  • Burkitt
	  • Diffuse large B-cell
	  • Non-Hodgkin
	• Myeloid sarcoma

appendectomy.[79] Intraoperatively, the diagnosis may be masked by inflammation and distortion of the surrounding anatomy. Thus, all appendectomy specimens should be sent for pathologic review, and adequate review is critical for diagnosis and subsequent management decision-making.

Efforts to distinguish features of appendicitis secondary to a neoplasm from primary appendicitis have been limited by the rarity of such masses. However, certain factors, such as age greater than 40, immunocompromised status, and presence of a periappendiceal abscess or phlegmon, have been associated with increased risk of harboring a neoplasm.[126] Studies have identified radiographic features thought to portend a higher risk of an underlying appendiceal neoplasm, such as increased soft tissue thickening and wall irregularity,[127] focal dilatation, lack of periappendiceal fat stranding, mural calcification, and luminal diameter greater than 2 cm.[128] Nevertheless, the low incidence of this condition limits the ability to draw truly definitive conclusions.

Often, an incidental mucocele—a distended, mucus-filled appendix (Fig. 94.9)—may be identified on cross-sectional imaging or encountered during appendectomy or colonoscopy. Like other appendiceal neoplasms, mucoceles are rare, and symptoms may mimic those of appendicitis. The term *mucocele* is a broad and nonspecific descriptive term, however, and not a formal diagnosis because it can present secondary to both benign and neoplastic obstructive processes. Mucoceles can be subdivided into mucinous retention cysts, mucosal hyperplasia, mucinous cystadenoma (now an outdated term largely referring to LAMN), and mucinous cystadenocarcinoma.

Most appendiceal mucinous neoplasms begin as mucoceles; however, it is difficult to differentiate between a malignant versus benign mucocele when visualized grossly intraoperatively. Therefore, upon resection, every effort must be taken to avoid rupture and inadvertent peritoneal seeding.[129] In addition, the surgeon should carefully look for any evidence of peritoneal dissemination, which may include peritoneal mucin deposits or nodularities. If any suspicious nodules or mucin deposits are identified, they should be biopsied and sent for pathologic evaluation, in addition to careful evaluation of the appendectomy specimen.

Once the diagnosis of an appendiceal neoplasm has been made by an experienced pathologist, additional management strategies can include focused oncologic history and physical examination, follow-up colonoscopy to detect the presence of synchronous colonic pathology, and cross-sectional imaging of the abdomen and pelvis with either CT or MRI (and possible chest CT based on underlying histologic subtype).[130] Most importantly, all treatment plans should involve multidisciplinary discussion in a tumor board at a high-volume treatment center.

Management of Primary Appendiceal Neoplasms by Histologic Classification

Herein, we discuss basic management principles of appendiceal neoplasms according to histologic subtype.

Epithelial Neoplasms

Appendiceal adenomas and serrated polyps are similar in behavior to their colonic counterparts. Occasionally, patients may present with obstructive symptoms, but like most appendiceal lesions, adenomas and serrated polyps are most often found incidentally after postappendectomy pathology review. These lesions, typically confined to the muscularis mucosa and lamina propria and without evidence of invasion, are sufficiently managed with a simple appendectomy. However, they are associated with an increased risk of synchronous colonic pathology and can be a manifestation of serrated polyposis syndrome.[126] Therefore, such patients should be counseled to undergo a full colonoscopy.[126,131,132]

Appendiceal mucinous neoplasms are the most common noninvasive epithelial lesions. These are adenomas marked by prominent mucin production and can be associated with extraappendiceal deposits. They can be further divided into LAMNs and HAMNs based on cytologic atypia. LAMN was previously referred to as a *mucinous cystadenoma,* now an extinct terminology. Both LAMN and HAMNs can be safely managed with simple appendectomy, but if high-grade atypia is present, careful pathologic examination must be undertaken to rule out any invasive component. In the absence of invasion, disease recurrence is low if complete resection is achieved. The presence of extraappendiceal mucin deposits or perforation is associated with an increased risk of recurrence.[121,126]

Mucinous adenocarcinomas are largely composed of mucin-producing cells, such that >50% of the tumor is composed of extracellular mucin. However, unlike LAMNs or HAMNs, these tumors are additionally characterized by infiltrative invasion.[123] They can be further subdivided based on differentiation (well, moderately, and poorly differentiated) and the presence of signet ring cells. Well-differentiated mucinous adenocarcinomas have a greater association with peritoneal spread, whereas moderately and poorly differentiated adenocarcinomas are more associated with lymphatic spread and distant metastasis.[133] Adenocarcinomas with signet ring cells portend an even worse prognosis and are considered poorly differentiated by nature.[133] When disease is localized and identified on an appendectomy specimen, interval right colectomy is typically recommended. Complete staging with imaging and tumor markers (carcinoembryonic antigen [CEA], carbohydrate antigen [CA]125, and CA19-9 have all been advocated for appendiceal neoplasms) should precede planned colectomy.

Nonmucinous adenocarcinomas of the appendix are similar in nature to adenocarcinomas of the colon and rectum and are traditionally treated as such. For all appendiceal adenocarcinomas, treatment recommendations include complete staging with cross-sectional imaging and tumor markers (CEA, CA125, and CA19-9), followed by interval right hemicolectomy, with sufficient lymph node sampling for staging, and consideration of adjuvant chemotherapy.[134]

In recent years, some studies have posited that in select patients with T1, well-differentiated tumors without evidence of lymphovascular invasion, less extensive surgical resection (i.e., simple appendectomy or ileocecectomy) may suffice,[135,136] but the rarity of this disease limits the ability to further investigate with prospective studies. Ultimately, prognostic biomarkers such as circulating tumor DNA (ctDNA) may provide further clarity on this issue.

Goblet cell adenocarcinoma, previously termed *goblet cell carcinoid,* demonstrates both neuroendocrine and mucinous features. However, the neuroendocrine component is considered relatively minor, as reflected in the updated terminology in the most recent WHO classifications.[130,137,138] In general, this histologic subtype is managed similarly to nonmucinous (colonic type) adenocarcinomas, with cross-sectional imaging for complete staging, tumor markers (including the addition of chromogranin A at some centers), interval right hemicolectomy, lymph node staging, and consideration of adjuvant therapy.[126,134]

Neuroendocrine Neoplasms

NENs originate from subepithelial neuroendocrine cells, which are largely concentrated in the tip of the appendix, explaining the propensity for NENs to arise from this region most commonly. As per WHO classifications, NENs can be subdivided into well-differentiated neuroendocrine tumors (NETs), poorly differentiated neuroendocrine carcinomas (NECs), and mixed neuroendocrine–nonneuroendocrine neoplasms (MiNENs; previously termed *mixed adenoneuroendocrine neoplasms* [MANECs]).[138] Somatostatin receptor imaging, such as ^{68}Ga-DOTATATE–positron emission tomography/CT (PET/CT), can be useful in identifying occult and distant disease, susceptibility to somatostatin receptor antagonists, and response to treatment. However, these benefits should be weighed against the tremendous costs of such imaging, and it is, therefore, not currently recommended for routine use.[126,130,137]

NETs represent the majority of appendiceal NEN cases, and although associated with an overall favorable prognosis, they have a high incidence of lymph node spread. A retrospective Surveillance, Epidemiology, and End Results (SEER) database study reported a correlation between tumor size and lymph node spread as follows: 15% of tumors measuring 1 cm or smaller, 47% of tumors between 1 and 2 cm, and 86% of tumors larger than 2 cm. The corresponding 10-year survival rates for each tumor size subgroup were as follows, respectively: 100% with either positive or negative lymph nodes, 92% with node-positive disease versus 100% with negative nodes, and 91% with node positivity versus 100% without nodal disease.[139]

National Comprehensive Cancer Network (NCCN) guidelines recommend surgical resection as the gold standard of treatment and offer the following guidance.[140] For tumors less than 2 cm in size and tumors located in the distal one-third of the appendix, simple appendectomy is sufficient. However, in cases of incomplete resection, node positivity, or positive margins, completion right hemicolectomy should be considered. For proximal NETs located at the base of the appendix or for tumors greater than 2 cm, a formal right hemicolectomy with lymph node staging is indicated. In these patients for whom colectomy is considered, complete staging with cross-sectional imaging is also recommended. The North American Neuroendocrine Society (NANETS) and European Neuroendocrine Tumor Society (ENETS) additionally recommend completion hemicolectomy if any of the following characteristics are present: positive mesenteric nodes, invasion at the base of the appendix or of the mesoappendix, a Ki-67 (proliferation) index greater than 20%, or mixed tumor histology.[141,142] It should be noted that data on survival benefit with interval colectomy are limited.

Nonepithelial Neoplasms

The nonepithelial appendiceal neoplasms are lymphomas and sarcoma. With these neoplasms being extremely rare, there is little information published in the literature. This classification includes Burkitt lymphoma; diffuse large B-cell, non-Hodgkin lymphoma; and myeloid sarcoma. As with other appendiceal neoplasms, these are typically incidental findings after appendectomy for presumed appendicitis.[143]

Management of Peritoneal Dissemination From Appendiceal Neoplasms

Pseudomyxoma Peritonei

Pseudomyxoma peritonei (PMP) (Fig. 94.10) occurs when a mucin-producing tumor of the appendix perforates through the appendix, leading to intraabdominal spread of tumor cells and mucinous ascites. Most commonly, it is associated with LAMN. PSOGI classifies PMP according to three histologic subtypes: PMP with low-grade histologic features (low cellularity with mild atypia), PMP with high-grade histologic features (more cellularity with features of invasion), and PMP with signet ring cells.[133] Standard treatment recommendations include surgical cytoreduction (CRS) with hyperthermic intraperitoneal chemotherapy (HIPEC).[134] Although the adoption of combination CRS/HIPEC has greatly improved survival compared with historical controls, outcomes after treatment vary widely and are primarily determined by underlying histologic subtype, burden of disease, and completeness of cytoreduction. Systemic therapy may also play a significant role in patients with higher-grade disease. PMP with low-grade features has the highest reported survival after CRS/HIPEC, with 5-year survival at 62.5%,[144] although it may be as high as 80% to 90%[145–148] in patients with favorable biology and complete cytoreduction. On the other hand, high-grade PMP has a reported 5-year survival of 37.7%.[144]

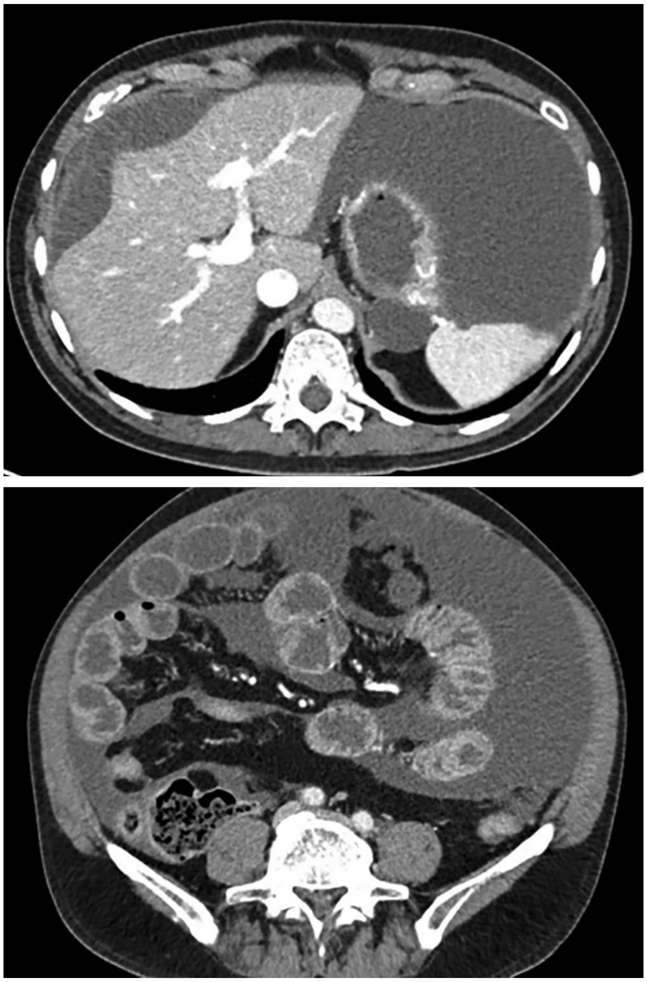

FIGURE 94.10 Computed tomography scan of the abdomen depicting mucinous ascites and disseminated peritoneal disease consistent with pseudomyxoma peritonei.

Patients with PMP should be referred to a high-volume center with expertise in the treatment of peritoneal surface malignancies. In patients who have undergone CRS/HIPEC, surveillance guidelines can vary. The American Society of Colon and Rectal Surgeons recommends that patients with low-grade PMP who have undergone CRS with HIPEC should be surveilled with CT or MRI of the abdomen and pelvis 2 months after surgery and then annually for at least 5 years. For patients with high-grade PMP, obtaining additional chest imaging and more frequent surveillance every 6 months for at least 6 years may help detect recurrent disease earlier.[130]

Peritoneal Carcinomatosis

In patients whose peritoneal disease burden has a lower degree of mucin-producing tumor, *peritoneal carcinomatosis* (PC) is the more appropriate terminology. Again, outcomes for these patients vary widely based on histologic subtype, disease burden, symptomatology, and candidacy for CRS/HIPEC. Diagnosis and determination of candidacy for CRS/HIPEC often require careful assessment with diagnostic laparoscopy because peritoneal metastases, especially lesions of small size, can be missed on standard imaging, and disease burden is frequently underestimated by cross-sectional imaging. Furthermore, systemic therapy is often a critical component for patients with PC, and surgical management frequently may center around palliative efforts rather than the ability to completely cytoreduce a patient. Moreover, treatment centers with experience in the management of peritoneal surface malignancies are important in making the best decisions around the role of systemic therapy, candidacy for CRS/HIPEC, and palliative treatment options.

CONCLUSION

Diagnosis and decision-making around the treatment of appendiceal neoplasms can be challenging because of the rarity and heterogeneous nature of these neoplasms. The histologic features of these neoplasms are complex and varied, giving rise to diverse tumor behavior. Decision-making should involve multidisciplinary tumor board discussions, and patients should be referred to high-volume treatment centers specializing in peritoneal surface malignancies. Overall, management centers around complete surgical resection with careful pathologic review. Patients with more advanced disease should be considered for systemic therapy and CRS/HIPEC.

EMBRYOLOGY OF THE COLON AND RECTUM

A sound knowledge base of the gastrointestinal (GI) tract embryologic development is important in understanding colon and rectal anatomy and pathophysiology. The primitive gut tube is formed from the endodermal roof of the yolk sac. Early in the development process, beginning in the third week of gestation, the gut tube divides into three sections: the foregut, midgut, and hindgut (Fig. 95.1).

The foregut forms the oral (buccopharyngeal) membrane, esophagus, stomach, and proximal duodenum (to the duodenal ampulla) and is supplied by the celiac artery. The midgut, including the distal part of the duodenum, small intestine, right colon,

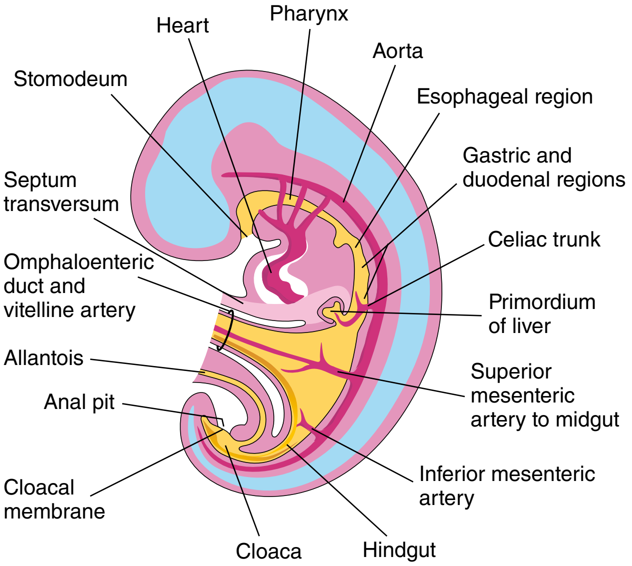

FIGURE 95.1 Median section of the embryo showing the early alimentary system and its blood supply (week 4). (From Moore KL, Persaud TVN, Torchia MG. Alimentary system. In: *The Developing Human*. 11th ed. Philadelphia: Elsevier; 2020:193-221.)

and the proximal two-thirds of the transverse colon, receives its blood supply from the superior mesenteric artery (SMA). The midgut temporarily herniates ventrally out of the abdomen, a key step in the physiologic development progress for acquiring length and correct positioning of its structures (Fig. 95.2). The hindgut develops into the distal third of the transverse colon, descending colon, sigmoid, and rectum all the way to the upper anal canal. It is supplied by the inferior mesenteric artery (IMA). The venous and lymphatic networks develop parallel to their corresponding sectional arteries.

The embryologic development of the rectum is complex and prone to developmental complications. The proximal rectum develops similarly to the colon. The distal regions develop from the terminal hindgut that enters into the cloaca (an endoderm-lined cavity in contact with the surface ectoderm at the cloacal membrane). Before 5 weeks, the intestinal and urogenital tracts terminate at a common cavity in the cloaca. During the next few weeks, the urorectal septum migrates caudally and divides the cloaca into an anterior urogenital sinus and posterior distal rectum and anal sinus (Fig. 95.3). The urorectal septum fusion with the cloacal membrane is represented in the adult by the perineal body. The external anal sphincter is formed by the posterior part of the cloacal sphincter, whereas the internal anal sphincter is formed from enlarging circular fibers of the rectum. The upper two-thirds of the anal canal is derived from the hindgut, and the lower third is derived from the proctodeum. The dentate line marks the fusion of endodermal (hindgut) and ectodermal depression (proctodeum). The anal transition zone is formed from the cloacal part of the anal canal. The hindgut part of the anal canal is supplied by the IMA, whereas the lower third is supplied by the internal pudendal artery.

ANATOMY OF THE COLON, RECTUM, AND PELVIC FLOOR

The large bowel, including the colon and rectum, is a tube of variable diameter, approximately 150 cm in length (Fig. 95.4).

Colon Anatomy

The cecum is the saccular beginning of the colon, with an average diameter of 7.5 cm and a length of 10 cm. It has no mesentery and is completely covered with peritoneum and is therefore considered an intraperitoneal structure. The cecum is variably connected to the posterior abdominal wall by a peritoneal reflection. Patients with an abnormally mobile cecum and ascending colon, found in a small proportion of patients, can be predisposed to volvulus (torsion) or cecal bascule (intermittent anterior and superior folding of the cecum associated with obstructive symptoms). The cecum has a thin wall compared with the rest of the

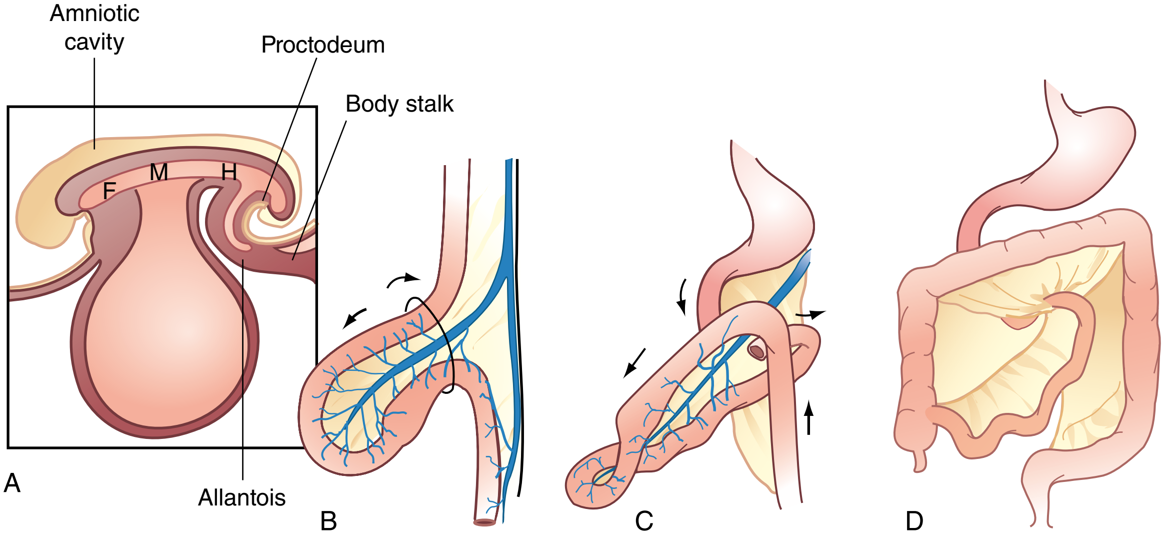

FIGURE 95.2 At the third week of development, the primitive tube can be divided into three regions (A): the foregut *(F)* in the head fold, the hindgut *(H)* with its ventral allantoic outgrowth in the smaller tail fold, and the midgut *(M)* between these two portions. Stages of development of the midgut are physiologic herniation (B), return to the abdomen (C), and fixation (D). (From Corman ML, ed. *Colon and Rectal Surgery*. 4th ed. Philadelphia: Lippincott-Raven; 1998:2.)

FIGURE 95.3 Development of the distal rectum and anus. Progressive steps between 4 and 6 weeks in subdivision of the cloaca into a ventral primitive urogenital sinus and a dorsal anorectal canal (A–D). The urorectal septum is formed by the fusion of yolk sac extraembryonic mesoderm and allantois mesoderm, which produces a tissue wedge between the hindgut and urogenital sinus during craniocaudal folding of the embryo. As the tip of the urorectal septum approaches the cloacal membrane dividing the cloaca into the urogenital sinus and anorectal canal, the cloacal membrane ruptures, thereby opening the urogenital sinus and dorsal anorectal canal to the exterior. The tip of urorectal septum forms the perineum. (A–B, D) Sections through the cloacal and related endoderm-derived structures. FIGURE 95.4 The large bowel includes the colon, consisting of ascending, transverse, descending, and sigmoid colon and the rectum, shown here in relation to neighboring anatomic structures. (From Standring S, Anand N, Rolfe B, et al. *Gray's Anatomy*. 41st ed. Philadelphia: Elsevier; 2016.)

colon, and considering its large diameter, in accordance with the law of Laplace, it is the site most likely to perforate in the presence of large bowel obstructions. Although it is distensible, acute dilation of the cecum to a diameter of more than 12 cm, which can be measured on a plain abdominal radiograph, is associated with a risk of ischemic necrosis and perforation of the bowel wall and should be treated promptly, usually with surgery. The terminal ileum empties into the cecum along its medial border through the ileocecal valve, a thickened, nipple-shaped invagination containing circular muscle. In cases of large bowel obstruction, the ileocecal valve is clinically important. An ileocecal valve that does not allow reflux of colonic contents into the ileum (competent ileocecal valve) can result in a closed-loop obstruction, a surgical emergency, whereas a valve that allows retrograde flow into the ileum (incompetent ileocecal valve) will result in less colonic distention and a less acute clinical scenario.

The vermiform appendix extends from the cecum approximately 3 cm below the ileocecal valve as a blind-ending elongated tube, 8 to 10 cm in length (Fig. 95.5). It is most commonly found in a retrocecal position (65%), followed by pelvic (31%), subcecal (2.3%), preileal (1.0%), and retroileal (0.4%) locations. In the setting of inflammation and adhesions, locating the appendix can be difficult. One can reliably reach its base by following the anterior taenia of the cecum to the convergence with the other two taeniae. The bloodless fold of Treves extends from the antimesenteric border of the terminal ileum to the base of the appendix or the anterior surface of the mesoappendix, or to both areas. This fold contains no sizable blood vessels. Because it is the only part of the ileum that has a fold on the antimesenteric side of the bowel, it can help in the recognition of the ileocecal region and the base of the appendix.

The ascending colon begins at the ileocecal junction and extends upward toward the hepatic flexure on the right side and is approximately 15 cm in length. The anterior and lateral surfaces are covered with peritoneum and are considered intraperitoneal, whereas the posterior surface is fixed against the retroperitoneum by the fascia of Toldt. The ascending colon is best mobilized along the lateral peritoneal reflection by incising the "white line of Toldt," which represents the fusion of the peritoneum with the posterior fascia of the same name. When releasing the hepatic flexure and lifting the colon medially, one must be aware of the proximity of the second part of the duodenum, which can be inadvertently injured.

The transverse colon, which is approximately 45 cm in length, is suspended between the hepatic and splenic flexures, which are fixed structures. It is completely covered by visceral peritoneum and connected to the posterior abdominal wall by the transverse mesocolon. It has a U-shaped curve, which can even reach down to the pelvis in some patients. Recognizing its variability in position is very important when attempting to exteriorize a loop of colon with a "target incision" for a transverse or sigmoid colostomy.

The greater omentum is attached to the superior aspect of the transverse colon. It has two parts, the superior gastrocolic ligament, which is composed of two serous layers, and the inferior portion, which is composed of four serous layers draping over the anterior abdominal cavity like an apron. Its size and volume are highly variable, although in most cases they are correlated with body weight. Lifting the greater omentum upward with downward traction of the transverse colon will reveal an avascular plane adjacent to the colon, most easily identified close to the midline. This plane is useful when separating these two structures. The greater omentum is commonly used to cover the intraperitoneal contents when closing abdominal incisions and is also used to fill cavities after surgery, helping to control infection. It also provides a good patch, or reinforcement, in cases when closure of inflamed and friable tissues is not possible or likely to fail, such as in the treatment of perforated duodenal ulcer. The omentum can be mobilized to create an omental pedicle that reaches the pelvis by ligating and detaching either the right- or left-sided omental vessels, achieving extra omental length while the blood supply is adequately maintained by the distal arcade from the other side. Such an omental pedicle can be positioned between the rectum and vagina to buttress a colo- or rectovaginal fistula repair or used to fill the pelvic and perineal spaces after rectal excision.

The splenic flexure, where the transverse colon flexes downward, is found adjacent and inferior to the spleen. It is usually situated higher and deeper than the right colic or hepatic flexure. The splenic flexure is suspended by four mainly avascular ligaments: the phrenicocolic ligament to the diaphragm; the splenocolic ligament to the lower pole of the spleen; the renocolic ligament to the Gerota fascia, which surrounds the left kidney; and the pancreaticocolic ligament to the tail of the pancreas. Pancreatic injuries are rare but can carry significant sequela and occur mainly during splenic flexure mobilization, with a 0.6% incidence rate reported in a recent study.[1] The splenic flexure can be released or mobilized without dividing any major blood vessels if one is separating the correct plane (Fig. 95.6). Surgeons commonly dissect the descending colon along the line of Toldt from below and then enter the lesser sac by lifting the omentum above the transverse colon. This maneuver allows mobilization of the flexure to be achieved, with minimal traction. Bleeding is most commonly encountered from excessive downward traction, resulting in avulsion of a portion of the splenic capsule.

The descending colon begins at the splenic flexure, where the intestine loses its mesentery and extends downward on the left side of the abdomen approximately 25 cm until it transitions into the sigmoid colon. It is smaller in diameter than the ascending colon. The descending colon is similar to the ascending colon with regard to its peritoneal coverage and approach to dissection.

The sigmoid colon begins at or below the level of the iliac crest, where the colon becomes completely intraperitoneal again, acquiring a mesentery covered on both sides with peritoneum. The sigmoid is thicker and more mobile compared with the descending colon, varying in length from 15 to 50 cm (average, 38 cm). The mobile portion of the sigmoid colon is attached by the sigmoid mesocolon to the posterior abdominal wall and pelvis in the pattern of an inverted *V*, creating the intersigmoid fossa (Fig. 95.7). When mobilizing the sigmoid colon, this mesenteric fold is a surgical landmark for the underlying left ureter. The sigmoid colon ends at the rectosigmoid junction, which is recognized as the point where the colonic taeniae confluence to form a complete longitudinal muscle layer, and the colon loses its mesentery, usually between the level of the sacral promontory and the S3 vertebra.

Blood Supply, Lymphatic Drainage, and Innervation of the Colon

Arterial blood supply. The anatomy of the blood supply is in accordance with the embryologic development of the GI tract. The celiac artery supplies the foregut, the SMA supplies the midgut, and the IMA supplies the hindgut. The colon receives its blood supply from the SMA and the IMA, both anterior branches of the abdominal aorta (Fig. 95.8).

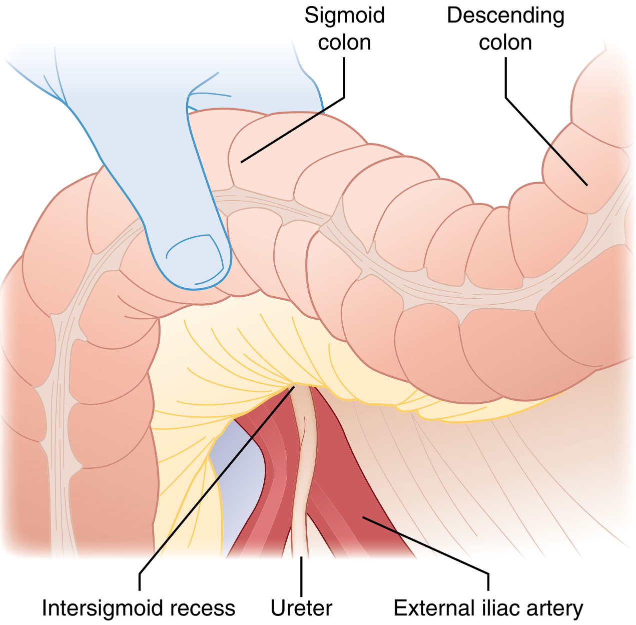

FIGURE 95.7 The intersigmoid recess, the sigmoid colon being retracted upward and to the right. (From Hollinshead WH. *Anatomy for Surgeons*. Vol 2. 2nd ed. New York: Harper and Row; 1971.)

The SMA is the second unpaired anterior branch of the aorta, arising at the level of the lower border of the L1 vertebra; it descends posterior to the pancreas and then crosses anteriorly to the uncinate process of the pancreas and the third part of the duodenum and enters the mesentery of the bowel. On the left side, it provides up to 20 branches to the small intestine. On the right, it gives off three major branches to the colon. The first branch is the middle colic artery, arising near the inferior border of the pancreas, followed by the right colic and ileocolic arteries. The ileocolic artery is the most constant of these arteries. It runs toward the ileocecal junction within the mesentery, giving off the anterior and posterior cecal arteries and the appendicular artery, supplying the terminal ileum, cecum, and appendix. The avascular space between the SMA and the ileocolic artery is a safe region to begin vascular dissection in a minimally invasive right colectomy and can also be used as a space through which one can pull the transverse or right colon through in cases of "retroileal" colorectal anastomoses to gain bowel length. The same plane along the SMA is also followed in extended lymphadenectomy (D3 lymphadenectomy) right colectomy, which is recommended in selected cases.[2] The right colic artery, absent in up to 20%, usually arises from the SMA but may be a branch of the ileocolic or left colic vessels. The middle colic artery enters the transverse mesocolon and divides into right and left branches, which supply the proximal and distal transverse colon, respectively. When lifting the transverse colon, the middle colic artery can be tracked to the base of the mesentery just to the right of the ligament of Treitz and into the proximal SMA. The middle colic artery is the main blood supply to the splenic flexure in about a third of the cases.

The IMA is the third unpaired anterior artery arising from the aorta at the level of the L2–L3 vertebrae approximately 3 cm above the aortic bifurcation. The IMA descends inferiorly and to the left, giving off the left colic artery, followed by several sigmoid branches and culminating in the superior rectal (hemorrhoidal) artery. The left colic artery divides into an ascending branch to the splenic flexure and a descending branch to the descending colon.

The marginal artery of Drummond runs along the mesenteric margin of the colon from the cecocolic junction to the rectosigmoid junction. Vasa recta from this artery branch off at short intervals and supply the bowel wall directly. The marginal artery is important clinically when one of the larger arteries is obstructed (emboli, atherosclerosis, surgical ligation, etc.). The colon can receive collateral blood supply through this artery.

The meandering mesenteric artery, or *arc of Riolan*, is an uncommon finding described as a thick, tortuous collateral vessel that runs close to the base of the mesentery and connects the SMA or middle colic artery to the IMA or left colic artery. It can have an important role in blood delivery in cases of SMA or IMA occlusion. Flow can be forward (IMA stenosis) or retrograde (SMA stenosis), depending on the site of obstruction. The presence of a large arc of Riolan suggests occlusion of one of the major mesenteric arteries.

Venous drainage. Venous drainage somewhat follows the arterial supply through the superior mesenteric vein and inferior mesenteric vein (IMV), which contribute to the formation of the portal vein. It is important to note that the IMV continues beyond the IMA along the base of the mesentery to the left of the ligament of Treitz and into the portal vein (Fig. 95.9). The IMV can be divided to achieve extra colonic length for low pelvic anastomoses.

Lymphatic system. Lymphatic drainage generally follows the vascular supply. The wall of the large bowel is supplied with a rich network of lymphatic capillaries that drain to groups of lymph nodes, paralleling the arterial supply. Most of the lymphatic drainage goes in this direction, but communications are found between groups of lymph nodes, especially at the level of the paracolic groups at the level of the marginal arteries. There is also some dual drainage from the distal transverse and splenic flexure into both the superior and inferior mesenteric lymph nodes.

Innervation. The innervation of the large intestine has both sympathetic and parasympathetic components, which generally follow the blood supply.

Rectal Anatomy

The rectum begins at the rectosigmoid junction and ends at the level of the anus. Anatomists define the distal border as the dentate (pectinate) line based on the mucosal surface, whereas surgeons define it as the proximal border of the anal sphincter complex at the level of the levator ani (about 2 cm above the dentate line). The rectum, with a total length of around 15 to 20 cm, is divided into thirds based on its peritoneal relationships. The upper rectum is covered by peritoneum anteriorly and laterally, and its lower limit extends to approximately 10 cm above the dentate line. The middle third is covered by peritoneum only anteriorly and extends from 5 to 10 cm above the dentate line. The lower third of the rectum is totally extraperitoneal, extending from 1 to 5 cm above the dentate line. The rectum has three lateral curves or valves of Houston; the proximal and distal valves fold to the right, and the middle folds to the left. They are lost after full surgical mobilization of the rectum, providing approximately 5 cm of additional length, assisting the surgeon's ability to fashion an anastomosis deep in the pelvis. Structurally, the rectum lacks taeniae coli, epiploic appendices, and haustra. The anterior peritoneal reflection between the rectum and anterior structures, the rectovesicular pouch in males and rectouterine or Douglas pouch in females, is 7 to 9 cm from the anal verge in males and 5 to 7.5 cm in females (Fig. 95.10). The anterior peritoneal reflection is the lowest dependent part of the peritoneal cavity. It is

clinically important as a common location of fluid and pus accumulation and may serve as a site of peritoneal metastases from visceral tumors. These "drop" metastases can form a mass in the cul-de-sac (Blumer shelf) that can be recognized on digital rectal examination. *Mesorectum* refers to the visceral mesentery of the rectum. Recognition of mesorectal planes during rectal surgery is extremely important because it allows for a relatively bloodless dissection with consistent excision of relevant lymphatic tissues, adhering to the basic surgical oncologic principle of removing the cancer in continuity with its blood and lymphatic supply.

Total Mesorectal Excision

Pioneered by Prof. Richard J. "Bill" Heald and colleagues in the 1970s,[3] total mesorectal excision (TME) involves meticulous dissection along the mesorectal plane (also known as the *holy plane*) during rectal cancer surgery, ensuring complete tumor removal while preserving pelvic autonomic nerves and thus increasing the preservation of urinary and sexual function. This revolutionary technique has significantly improved oncologic outcomes, lowered local recurrence rates, and become a standard in modern rectal cancer surgery. The mesorectum is relatively thick posteriorly, thinner along the sides, and very thin anteriorly.

Anatomic structures adjacent to the rectum are clinically important with regard to dissection planes and direct extension of tumors and/or fistulas. In males, the rectum is adjacent anteriorly and extraperitoneally to the urinary bladder, ureters, vas deferens, seminal vesicles, and prostate. Although injuries to these structures are uncommon, intraoperative identification of these injuries may be facilitated when a bladder Foley catheter and ureteric stents are placed at the beginning of the operation. Such consideration is especially important in patients with significant inflammation (diverticular disease, inflammatory bowel disease [IBD]), prior abdominal surgery, prior radiation, obesity, and other reasons and/or anticipated unclear anatomy. In females, intraperitoneally, the ureters are adjacent to the uterus, tubes, ovaries, and the upper part of the posterior vaginal wall. Careful dissection of the vaginal wall is needed in distal bulky anterior tumors to try to avoid injury and the possible formation of a rectovaginal fistula. Extraperitoneally,

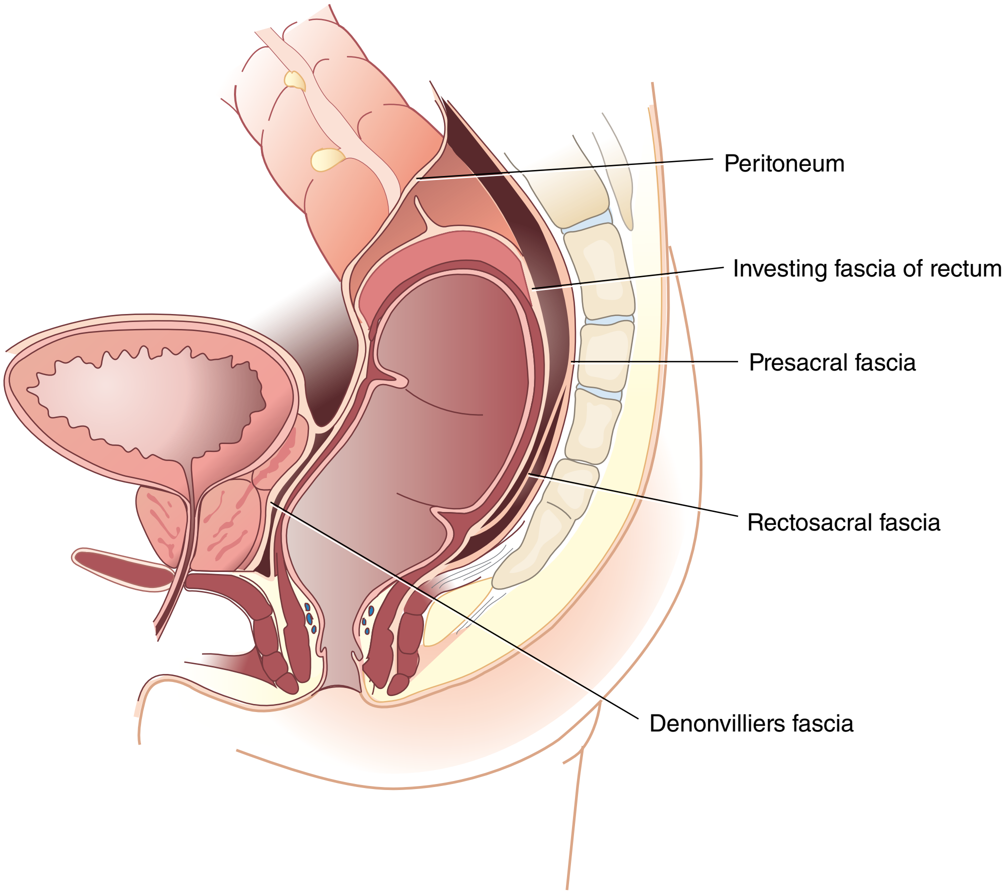

FIGURE 95.10 Fascial relationships of the rectum. (From Gordon PH, Nivatvongs S, eds. *Principles and Practice of Surgery for the Colon, Rectum and Anus*. 2nd ed. St. Louis: Quality Medical Publishing; 1999:10.)

the rectum is adjacent to the uterine cervix and posterior vaginal wall. In both sexes, the intraperitoneal cul-de-sac is commonly filled with small bowel and colon. The sacrum, sacral vessels, and sacral nerve roots are located posterior to the rectum.

The posterior aspect of the rectum is invested with a thick, closely applied mesorectum (Fig. 95.11). A thin layer of investing fascia (fascia propria) coats the mesorectum and represents a distinct layer from the presacral fascia against which it lies. During proctectomy for rectal cancer, mobilization and dissection of the rectum proceed between the presacral fascia and fascia propria. The presacral fascia covers the anterior sacrum and coccyx. A group of veins, on the presacral periosteum, the presacral veins, drains into the sacral foramina. Dissection deep to the presacral fascia can cause severe bleeding from the underlying presacral venous plexus. Such bleeding can be very difficult to control because the torn vessels tend to withdraw into the sacral foramina. The rectosacral fascia, or Waldeyer fascia, is a thick condensation of endopelvic fascia connecting the presacral fascia to the fascia propria at the level of S4 that extends to the posterior-inferior rectum. Dividing Waldeyer fascia during dissection from an abdominal approach provides access to the deep retrorectal pelvis. Laterally, the rectum is connected to the pelvic sidewall by the “lateral stalks” or ligaments. These are found in the low pelvis at the level of the prostate or midvagina. It is important to remember that in about a quarter of the cases, a branch of the middle rectal artery traverses them and may cause bleeding when cutting through them. Denonvilliers fascia, located anterior to the rectum, is a membranous layer that is an extension of the inferior peritoneal reflection and extends to the perineal body. This fascial layer separates the rectum from the previously mentioned anterior structures and is considered the anterior border of a TME.

Blood Supply, Lymphatic Drainage, and Innervation of the Rectum

The blood supply to the rectum is derived from the superior, middle, and inferior rectal (hemorrhoidal) arteries. All three rectal arteries are connected with a strong anastomotic network, which helps avoid rectal ischemia after dividing the superior rectal arteries during anterior resections (Fig. 95.12). The superior rectal artery is the end branch of the IMA. It usually divides into left and right branches that run posteriorly downward. The middle rectal arteries are paired vessels derived from the internal iliac arteries to the lower rectum through the lateral columns. They are not considered a major blood supply to the rectum and are found inconstantly. They can be inadvertently injured when dissecting the lateral ligaments. The inferior rectal arteries are branches of the internal pudendal arteries and generally supply the anus distal to the dentate line.

The superior rectal vein drains the upper two-thirds of the rectum, draining into the IMV and portal system. The lower rectum and anus drain into the middle and inferior rectal veins, which are connected to the internal iliac and systemic circulation. This drainage pattern explains the higher rate of lung metastases observed with low rectal cancers as compared with midrectal and upper rectal cancers, which are much more likely to metastasize to the liver.

FIGURE 95.12 Vasculature of the rectum, posterior view. (From Drake RL, Vogl AW, Mitchell AWM, et al. *Gray's Atlas of Anatomy*. 2nd ed. Philadelphia: Churchill Livingstone, an imprint of Elsevier; 2015.)

The lymph from the upper two-thirds of the rectum drains upward toward the inferior mesenteric and paraaortic nodes. The lower part of the rectum drains in two directions, cephalad toward the inferior mesenteric nodes and laterally and inferiorly toward the internal iliac nodes. Below the dentate line, lymph drains toward the inguinal lymph nodes. In recent years, the removal of the lateral lymph node compartments in patients with rectal cancer (lateral pelvic lymph node dissection [LPLND]) with clinically suspected lateral pelvic lymph nodes has become somewhat popular. An International Consortium for LPLND recently found that patients with lateral pelvic nodes of more than 7 mm on pretreatment MRI experienced significantly less local recurrence when treated with neoadjuvant chemoradiation, TME, and LPLND (5.7%) in comparison with neoadjuvant chemoradiation and TME alone (19.5%).[4] However, LPLND requires technical skills and is associated with increased male urinary and sexual dysfunction after surgery.[5]

The sympathetic innervation of the rectum is derived from sympathetic nerves exiting at the level of L1–L3, forming the superior hypogastric plexus (Fig. 95.13). At the level of the sacral promontory, they divide into left and right hypogastric nerves, traveling on both sides of the pelvis. These nerves supply the rectum and send branches to supply the genitourinary system anteriorly. When performing pelvic operations, it is important to be aware of these nerves and try to avoid injuring them. A high IMA ligation injuring the superior hypogastric plexus or severing the hypogastric nerves near the sacral promontory may result in sympathetic dysfunction characterized by retrograde ejaculation in males. Division of the lateral stalks too close to the pelvic sidewall may injure the pelvic plexus and nervi erigentes and cause erectile dysfunction, impotence, and atonic bladder. Injury to the periprostatic plexus when dissecting anteriorly can also cause sexual and bladder dysfunction.

Pelvic Floor Anatomy

The pelvic floor or diaphragm supports the pelvic organs and, together with the anal sphincter, regulates defecation. The pelvic diaphragm resides between the sacrum, obturator fascia, ischial spines, and pubis. The levator ani muscle, which makes up the floor, consists of three subdivisions: the pubococcygeus, iliococcygeus, and the puborectalis (Fig. 95.14). The pubococcygeus forms the levator hiatus, which ellipses the top of the anal canal, urethra, and vagina in females and the dorsal vein in males. The puborectalis originates in the lower part of the symphysis pubis and courses parallel to the anorectal junction, forming a U-shaped sling of striated muscle posterior to the rectum. The puborectalis is in a state of constant contraction, increasing the anorectal angle, a factor critical to the maintenance of fecal continence. Relaxation of the puborectalis straightens the anorectal angle and permits defecation. Puborectalis dysfunction is an important cause of defecation disorders.

PHYSIOLOGY OF THE COLON

Absorption of Fluid and Electrolytes

The major functions of the colon are water absorption and electrolyte exchange. This process converts succus from the terminal ileus into formed stool that is stored in the rectal reservoir until it can be excreted at a convenient time. The body has the ability to adapt and sustain life without a colon, making it uniquely different from small bowel. The problems associated with colonic patients provide a simplistic view of colonic function—individuals with a diverting ileostomy are at particular risk for dehydration and electrolyte derangement.

The colon, with its large surface area, is the most efficient site of absorption in the GI tract, capable of absorbing up to 5 L of fluid daily, although usually only 1 to 2 L are excreted from the ileum. By the time the digestive fluid, or succus, reaches the terminal ileum, most nutrients have been absorbed, leaving a mix of electrolyte-rich fluid, bile salts, and some undigested proteins and starches, with about 90% of the fluid in succus being reabsorbed in the colon.

Secretion

Colon secretion plays a vital role in patients with chronic renal failure, where uremic patients can maintain normal potassium levels before requiring dialysis as a result of an increase in colonic potassium secretion and fecal excretion. Aldosterone promotes colonic potassium secretion, whereas spironolactone can block this effect. Various colitis conditions, such as IBD, cholera, and shigellosis, are associated with increased potassium secretion, and other forms of colitis impair colonic absorption or induce chloride secretion. Colonic secretion of $H+$ and bicarbonate is linked to systemic acid-base metabolism through carbonic anhydrase, allowing the colon to regulate pH levels as needed.

Urea Recycling

Colonic bacteria are rich in urease, which is important for urea recycling. Because mammalian cells do not produce urease, this process relies on the symbiotic relationship found in a healthy colonic lumen. Ammonia is the byproduct of urea metabolism, and its absorption depends on the concentration of bacteria present and the intraluminal pH. Antibiotics and lactulose decrease the amount of ammonia absorbed by lowering the concentration of bacteria and reducing the pH, respectively. Absorbed ammonia is transported to the liver.

Recycling Bile Salts

The colon absorbs bile acids that escape absorption by the terminal ileum. Bile acids are passively transported across the colonic epithelium by nonionic diffusion. When the colonic absorptive capacity is exceeded, colonic bacteria deconjugate bile acids. Deconjugated bile acids can then interfere with sodium and water absorption, leading to secretory, or choleretic, diarrhea. Choleretic diarrhea is seen early after right hemicolectomy as a transient phenomenon and more permanently after extensive ileal resection.

Colonic Flora, Fermentation, and Short-Chain Fatty Acids

Large bowel contents have a concentration of 10^{11} to 10^{12} bacterial cells per gram, contributing approximately 50% of fecal mass. Over 400 bacterial species, mostly anaerobic, are present in the colon. Bacteroides species are obligate anaerobes that comprise two-thirds of the total colonic bacteria. Other species commonly found in the colonic flora are the following facultative anaerobes: *Escherichia, Klebsiella, Proteus, Lactobacillus,* and *Enterococci*. These bacteria feed on proteins sloughed from the bowel wall and undigested complex carbohydrates. In turn, colonocytes and gut-associated lymphoid tissue rely on the colonic flora for nutrients.

The main source of energy for intestinal bacteria is dietary fiber, composed of complex carbohydrates (including starches and nonstarch polysaccharides). However, not all complex carbohydrates are

fermented in the same manner. Dietary recommendations ("adding fiber," for example) generally refer to bulking agents, such as lignin and psyllium, which are nonabsorbable and nonfermentable by colonic bacteria. Bulking agents decrease intracolonic pressures and increase colonic transit time, which help prevent the formation of colonic diverticula and minimize colonic exposure to toxins.

For the fermentable complex carbohydrates available, colonic flora produce short-chain fatty acids (SCFAs). Butyrate, an SCFA, is the principal source of nutrition for the colonocyte. Because mammalian cells do not produce butyrate, the colonic epithelium and luminal bacteria form an essential and elegant symbiotic relationship. Antibiotics disrupt this cohabitation—decreased

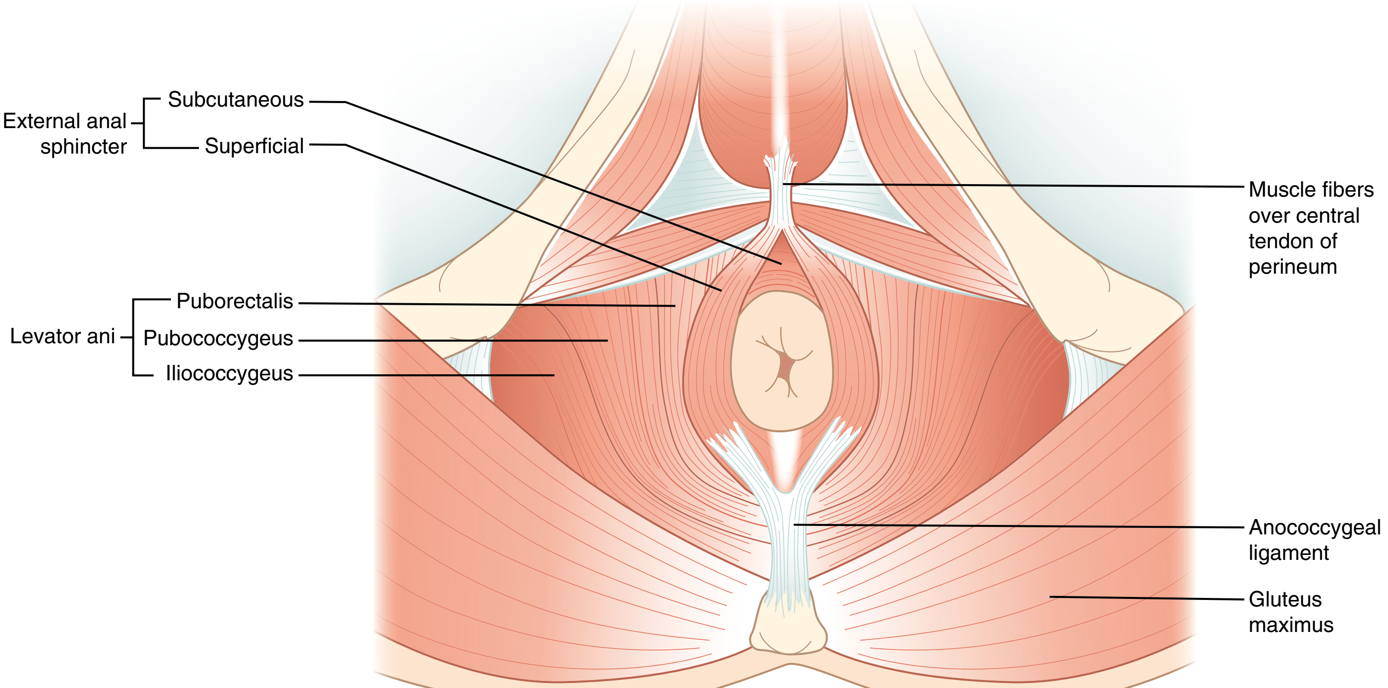

FIGURE 95.14 The pelvic musculature and innervation from below. The deep anal sphincter muscles are hidden under the superficial part. (From Netz U, Galandiuk S. Clinical anatomy for procedures involving the small bowel, colon, rectum and anus. In: Fischer JE, Ellison EC, Upchurgh Jr GR, et al., eds. *Fischer's Mastery of Surgery*. 7th ed. Philadelphia: Wolter Kluwer; 2019.)

bacteria leads to less butyrate, which, in turn, negatively affects colonocyte function, leading to diarrhea. Likewise, mucosal atrophy is seen after fecal diversion (e.g., diversion colitis). The other physiologic effects of SCFAs on the colon include stimulation of blood flow, mucosal cell renewal, and regulation of intraluminal pH for homeostasis of the bacterial flora.

The role of SCFAs in homeostasis extends beyond the colon. Besides butyrate, two other SCFAs, acetate and propionate, are produced in the colon, with acetate being the most common of all three. Over 90% of the SCFAs produced are absorbed. Hepatocytes metabolize SCFAs for use in gluconeogenesis, and muscle cells oxidize acetate to generate energy. Additionally, acetate is the primary substrate for cholesterol synthesis. The production of acetate is reduced by nonabsorbable, nonfermentable dietary fiber, such as psyllium, which in turn has a beneficial effect on cholesterol levels. Similarly, propionate, which has a glycolytic role in the liver, may also lower serum lipid levels by inhibiting cholesterol synthesis. Butyrate may also play an important role in maintaining cellular health by arresting the proliferation of neoplastic colonocytes while paradoxically being trophic for normal colonocytes.

The end products of fermentation are SCFAs and gas—carbon dioxide, methane, and hydrogen.

Probiotics and Prebiotics

Colorectal surgery can have various effects on the composition of the gut microbiota. Factors that contribute to these changes include stress and disruption of homeostasis, exposure to oxygen during surgery, tissue ischemia, the type of surgical reconstruction, and chemo-/radiotherapy. Stress can influence the gut microbiota composition, and the gut microbiota can in turn affect the host's response to stress. Exposure to oxygen during surgery can deplete beneficial anaerobic species in the gut microbiota. Tissue ischemia, caused by bowel and vascular sections, can lead to significant changes in the gut microbiota. Different types of surgical reconstruction can affect food digestion, nutrient absorption, and the gut microbiota. Chemo-/radiotherapy before surgery can also affect the gut microbiota. The hypothesis is that these factors can impair the return to a healthy gut microbiota composition, potentially leading to surgical complications and compromised immune function.

Researchers have investigated the manipulation of gut microbiota using probiotics, prebiotics, and synbiotics to achieve a healthier balance between harmful and beneficial bacteria. Probiotics, live microorganisms offering health benefits primarily in the colon, have shown various positive properties, including antiinflammatory effects and the ability to counteract harmful bacteria growth. Probiotics have been shown to prevent *Clostridioides difficile*–associated diarrhea, but there are insufficient data to recommend probiotics for the primary prevention of *C. difficile* infection (CDI).[6] Additionally, prebiotics, nonviable components promoting the growth of beneficial microbiota, have also been explored. Recent meta-analyses have shown that the administration of probiotics and synbiotics resulted in a significant reduction in postoperative infectious complications, especially in colorectal surgery patients. The use of these interventions was also associated with a shorter hospital stay and improved postcolectomy quality of life. Moreover, no significant adverse effects were reported.[7] Currently, the routine use of probiotics is not supported in clinical guidelines except for certain pathologies, including necrotizing enterocolitis in neonates, ulcerative colitis (UC), pouchitis, and constipation. Further research is needed, but the evidence for probiotic use in various settings is encouraging.

Prebiotics are nutrients that support the growth of probiotic bacteria. Prebiotics are nondigestible oligosaccharides (e.g., inulin) that help the host by stimulating the growth of certain species of beneficial intestinal bacteria. There is a growing body of data suggesting health benefits; however, there is currently little evidence to guide recommendations for their use.

Colonic Motility

In the colon, there is extrinsic and intrinsic innervation from the autonomic nervous system and enteric nervous system, respectively. The autonomic nervous system is composed of parasympathetic and sympathetic innervation. Parasympathetic innervation is excitatory, and it reaches the colon via the vagus nerve and the rectum via the sacral nerves (S2–S4) through the pelvic plexus. Sympathetic innervation is, conversely, inhibitory. Sympathetic fibers originate from lumber ventral roots (L2–L5), postganglionic hypogastric nerves, and the splanchnic nerves (T5–T12), which reach the colon and rectum through perivascular plexuses (see also the Colon Anatomy section).

The intrinsic colonic nervous system consists of the myenteric (Auerbach) plexus and the submucosal (Meissner) plexus. These plexuses regulate colonic motility, as well as colonic blood flow, absorption, and secretion. The interstitial cells of Cajal are the primary pacemaker cells governing the function of the enteric nervous system and are important for colonic motility. Most motility is involuntary and is divided into two primary patterns[1]: low-amplitude propagated contractions (LAPCs)[2] and high-amplitude propagated contractions (HAPCs). LAPCs allow mixing, which promotes optimal absorption, and are bursts of short-duration contractions. HAPCs propagate colonic contents distally in a coordinated fashion, and their role lies in shifting large quantities of contents through the colon one to three times per day. Other factors affecting motility are circadian rhythms and food ingestion.

Defecation

Normal defecation requires adequate colonic transit time, stool consistency, and fecal continence. The frequency of defecation is just as variable among individuals as their perception of abnormal stool frequency. The definitions of diarrhea and constipation differ by individual patients and providers; therefore reporting stool frequency and consistency provides a clearer understanding of defecation patterns.

Many factors influence colonic transit rate. Colonic transit is longer in females than in males and longer in premenopausal than in postmenopausal females. Supplementation with nonstarch polysaccharides shortens colonic transit time in individuals with idiopathic constipation.

PREOPERATIVE EVALUATION

Nutritional and Risk Assessment

Over the past 20 years, since the original work on the National Veterans Administration Surgical Risk Study, few parameters have been as reliable at predicting postoperative complications as preoperative serum albumin level. Unfortunately, this laboratory value is seldom obtained preoperatively in elective surgery patients and therefore needs to be explicitly ordered. Another important tool in the preoperative assessment of patients before surgery is prealbumin. Prealbumin is a small protein produced primarily in the liver. It has a short half-life of 2 to 3 days, making it a responsive indicator of nutritional status and more accurate than albumin because of its short half-life. In addition, it can be important because follow-up of prealbumin levels helps monitor the effectiveness of nutritional interventions and aid in personalized care for better surgical outcomes. As with albumin, prealbumin is seldom ordered before surgery and should be considered as part of the preoperative evaluation. There are numerous preoperative indices, such as the Physiological and Operative Severity Score for the Enumeration of Mortality and Morbidity (POSSUM), Colorectal Physiological and Operative Severity Score for the Enumeration of Mortality and Morbidity (CR-POSSUM), and the American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP) calculators, among others, that have been used to predict operative risk. If operating on a patient with a condition such as diverticulitis or IBD, the addition of an inflammatory markers such as C-reactive protein (CRP) and pro-calcitonin can be beneficial. In general, patients with albumin less than 3 are considered higher risk. Some studies suggest that preoperative correction of risk factors may result in improved postoperative outcomes.

Body mass index (BMI) is also a widely used but imperfect marker for nutritional assessment, and its reliability has been a subject of debate. Although it provides a simple and easy-to-calculate measure of body weight in relation to height, it does not differentiate between lean body mass and fat mass. As a result, individuals with higher muscle mass, such as athletes, may have a higher BMI but not necessarily be malnourished. Conversely, older adults or individuals with muscle wasting may have a lower BMI but could still be malnourished. Additionally, BMI does not take into account the distribution of body fat, which can be relevant in assessing surgical risk. Visceral fat, located in the abdominal cavity, is associated with a higher risk of surgical complications compared with subcutaneous fat. To obtain a more comprehensive understanding of the patient's nutritional status before surgery, healthcare providers often use BMI in conjunction with other nutritional markers and clinical assessments, recognizing its limitations as a standalone measure.

There is a growing field of immunonutrition suggesting that consumption of nutritional supplements rich in arginine may, in fact, boost the immune system and lead to a reduction in postoperative infectious complications, such as surgical site infection (SSI).[8]

Patients who are at particularly high risk are those who have chronic partial bowel obstruction and cancer and those who have lost a significant amount of weight (greater than 10% of body weight) in unintentional weight loss.

Preoperative Bowel Preparation

Because human feces can have as much as 10^{12} bacteria/gram, colon surgery has been associated with a higher rate of SSI than small bowel and upper GI surgery. Issues of antibiotic prophylaxis have focused on the choice of an antibiotic with an appropriate spectrum, administration before making the surgical incision, and discontinuation of the antibiotic postoperatively. Over the past 20 years, performing or omitting preoperative bowel preparation has been a cyclical phenomenon.

Studies suggest that mechanical bowel preparation alone is not beneficial before *colon* resection. These recommendations were based on findings that bowel preparation generally led to fluid and electrolyte abnormalities that, in turn, led to large volumes of fluid administration during surgery and subsequent bowel edema and ileus. In addition, bowel preparation is poorly tolerated in the elderly and in those with multiple medical comorbidities.

Lower-volume bowel preparations generally have higher patient compliance. Higher rates of spillage of liquid as opposed to more formed stool at the time of surgery after mechanical bowel preparation were thought to be the cause of the higher observed rates of SSI. However, for many surgeons performing rectal resection, either with minimally invasive or open techniques, particularly when inserting intraluminal staplers for the purpose of creating intestinal anastomoses, it was felt to be more convenient and safer to have the large bowel free of solid particulate matter. Recently, large administrative database studies have demonstrated that the combination of a mechanical and an oral antibiotic bowel preparation is associated with a very low rate of postoperative infectious complications in patients undergoing colorectal surgery. Mechanical bowel preparation and oral antibiotics are used before colorectal surgery to reduce the risk of SSIs and complications. Mechanical bowel preparation involves cleansing the colon to decrease the bacterial load, minimizing the chances of contamination during surgery. Oral antibiotics further target specific bacteria in the colon that could lead to infections. Although these practices have been routine in the past, their benefits have been debated recently, and some centers adopt a selective approach based on individual patient risk factors and surgeon preference.

Preoperative nutritional optimization and infection prevention strategies also play a vital role in enhancing surgical outcomes for colorectal surgery patients. The decision to use these measures should be carefully considered, weighing the potential benefits against the risk of adverse effects.

Therefore preoperative oral antibiotics alone without mechanical bowel preparation may be a safe alternative in patients who cannot tolerate full bowel preparation. A large-scale multicenter randomized study performed in Spain examined the role of oral antibiotics alone in reducing the rate of SSIs and found that administering oral antibiotics the day before surgery significantly reduced the occurrence of SSIs without the use of mechanical bowel preparation.[9] Generally, many surgeons believe that a formal mechanical bowel preparation is not required for patients undergoing surgery for IBD because these patients are already having numerous liquid bowel movements. Bowel preparation is also not used for patients with partial obstruction.

Planning Intestinal Stomas

When operating on a patient in whom there may be a need for a diverting stoma (e.g., patients with Crohn disease, diverticular disease, intestinal obstruction, and low rectal cancer), it is *always* wise to mark the patient for a preoperative stoma site. *Most* patients do not have an ideal abdomen. The area of the abdomen that usually is chosen for a stoma, the infraumbilical fat mound (Fig. 95.15), may not look the same in a patient who is sitting up as it does when they are recumbent. In many patients, there are skin folds that may prevent a stoma bag from sealing properly. It is essential to mark the patients in a sitting position and to avoid old scars and any skin folds that may interfere with adherence of a stoma appliance. Fig. 95.16 shows how important it is to avoid skin folds that would interfere with normal adherence of a stoma appliance and how this can be underestimated if the patient is supine (Fig. 95.17).

Stoma Types

Many different types of stoma configurations can be chosen at the time of surgery (Fig. 95.18). Stomas can be differentiated by whether they:

- Are small bowel stomas or colostomies
- Drain stool or urine

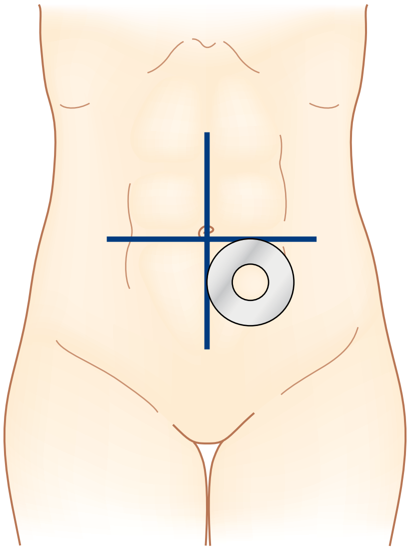

FIGURE 95.15 Demonstration of the infraumbilical fat mound that is the ideal stoma site in many patients, here showing marking for a descending colostomy.

- Are temporary or permanent
- Are end, loop, end-loop, or double-barrel stomas
- Are continent or incontinent stomas

Temporary stomas are often chosen to aid in anastomotic healing or in the presence of sepsis or other conditions when it is not considered safe to perform an unprotected anastomosis. Loop ileostomies are often chosen for temporary diversion because of their lack of odor, ease of care, and ease of closing. Loop descending or sigmoid colostomies can be similarly easily closed. Transverse loop colostomies should seldom be used because they are large and are very prone to prolapse, and it can be difficult to maintain pouch adherence because they are frequently located in an area around the patient’s belt line or mid-upper abdomen. In some cases, a double-barrel ostomy is needed to divert fecal matter away from a specific area in order to allow healing, prevent disease progression, or avoid complications. A double-barrel ostomy is typically needed in emergency cases, cases with significant inflammation, or during complex surgical procedures, and the decision to perform a double-barrel ostomy is often made intraoperatively based on clinical judgment.

Temporary diversion can be performed for a number of situations. Most often, temporary diversion is used to aid in healing of distal anastomosis. Alternatively, diversion of the fecal stream is sometimes recommended in patients undergoing treatment of distal pathology, such as obstructing rectal cancer. In these scenarios, a diverting stoma is anticipated to be closed after healing of the anastomosis or after conclusion of treatment. Unlike a standard ileostomy, a ghost ileostomy involves preparing and marking a loop of the ileum (part of the small intestine) that is sutured beneath the abdominal wall but not immediately functional. It acts as a safety net, allowing for a quick conversion into a functioning ileostomy if an anastomotic leak occurs after surgery.[10]

Permanent stomas are often required when a section of the bowel (either the colon or rectum) has to be removed because of diseases like colorectal cancer (CRC), IBD (e.g., Crohn disease or UC), certain types of injuries, or obstructions. In addition, patients with significant incontinence and/or bedridden patients should be consulted for permanent ostomy, which can potentially

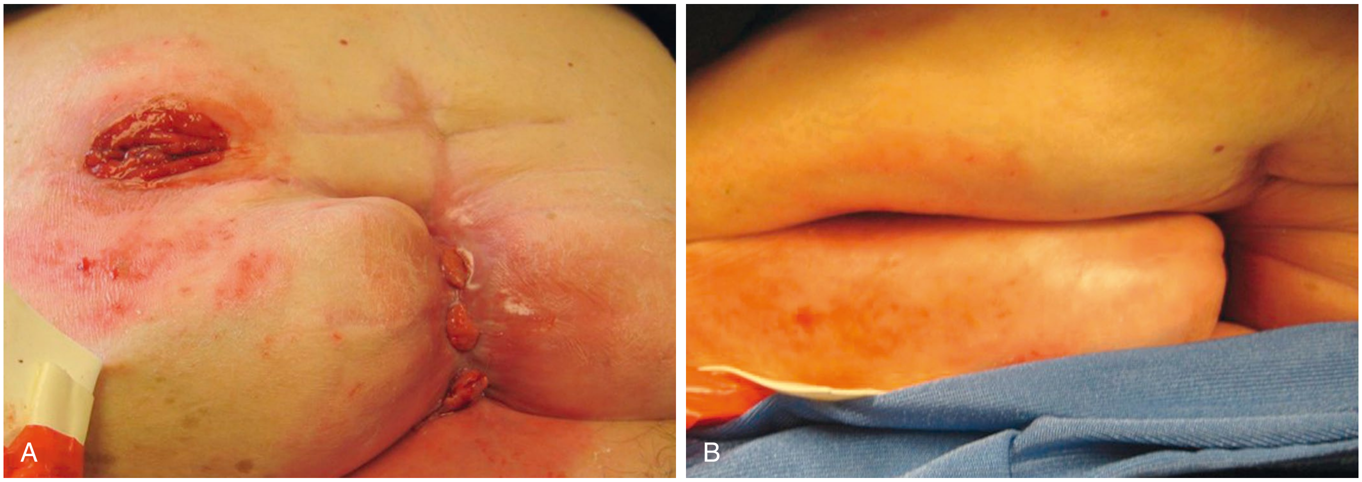

FIGURE 95.16 Patient referred after surgery for ischemic colitis without preoperative stoma marking. (A) Patient in supine position. (B) Patient sitting up. Note that the colostomy "disappears" within folds of the abdominal wall, making pouching extremely difficult.

improve their quality of life. When planning a permanent stoma, surgeons should opt for a comfortable and discreet location to allow patients better handling of their ostomy in daily life. Caregivers should be aware of the psychological and emotional impacts of a permanent stoma. Professional stoma care nurses, support groups, and counseling can all help someone adjust to life with a stoma. It is also important for people with stomas to receive regular follow-up care to monitor for potential complications, such as skin irritation, infection, herniation, stenosis, or prolapse.

The stoma nurse, often referred to as an *ostomy* or *enterostomal therapist,* is a specialized healthcare professional who guides patients through the process of ostomy surgery. Their responsibilities encompass preoperative education about the procedure and postoperative stoma care, including hygiene, pouch system management, and potential complications. They also offer invaluable emotional support because adapting to life with a stoma can be emotionally taxing, and they keep patients updated on the latest in stoma care resources and products.

During the preoperative phase, the stoma nurse determines the optimal stoma site by considering the patient's anatomy and daily activities. This process involves assessing the abdomen in various positions, including sitting, standing, and bending, to avoid natural creases or folds. Additionally, the nurse inquires about the patient's clothing preferences, such as the type of attire they wear and their use of belts, to ensure the stoma's placement does not interfere with their lifestyle or cause discomfort.

Each of the three different types of stomas (end, loop, and end loop) has advantages and disadvantages. The **consistency** and **amount** of stoma effluent can differ significantly depending on the following:

- Whether the small bowel or the colon is selected for stoma construction

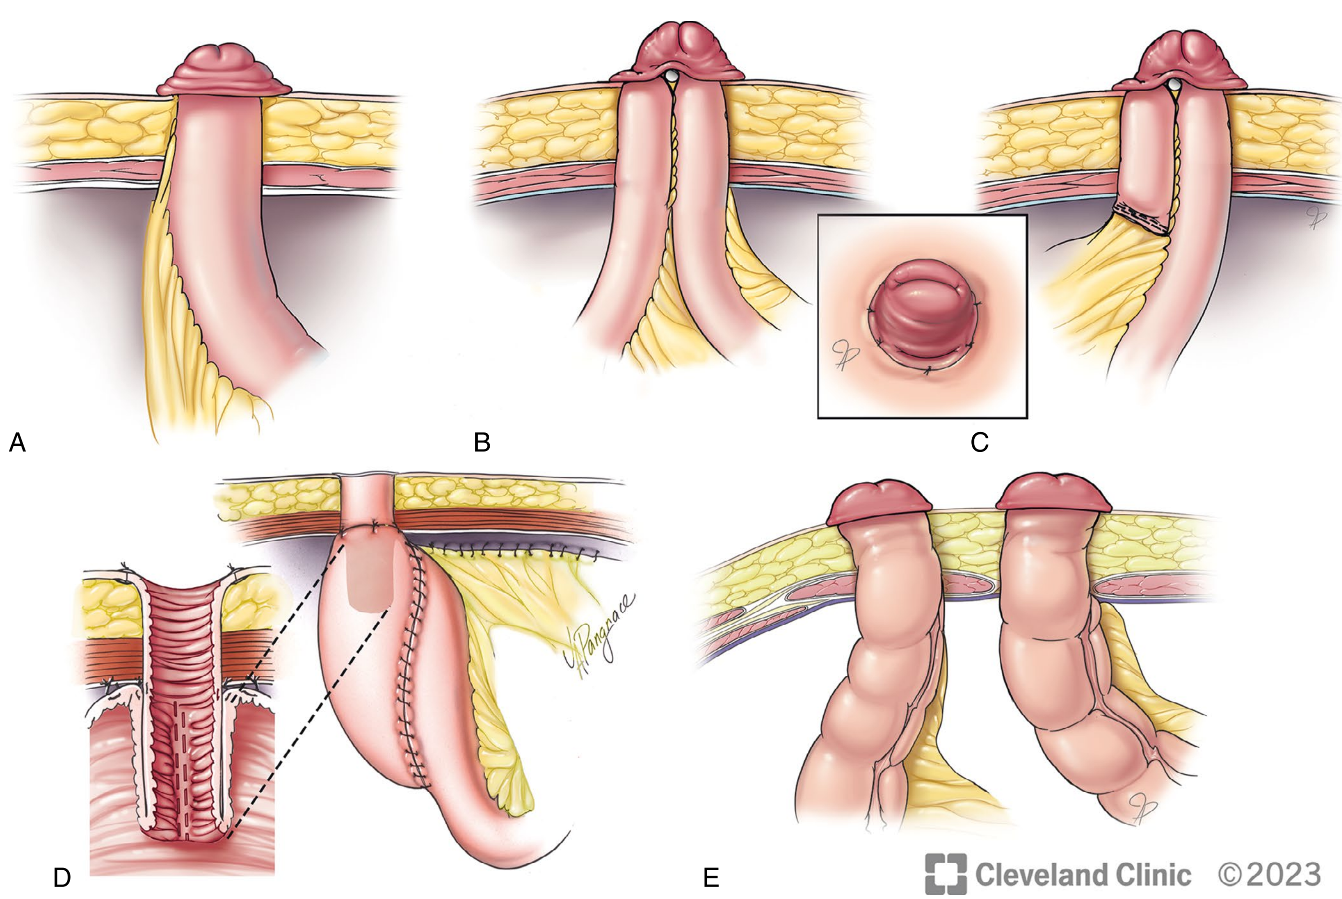

FIGURE 95.18 Different types of intestinal stoma. (A) End stoma. (B) Loop stoma. (C) End loop stoma. (D) Continent ileostomy. (E) Double-barrel stoma. (Reprinted with permission, Cleveland Clinic Foundation ©2024. All Rights Reserved.)

- If the colon is selected, which site of the colon is selected for stoma construction
- What types of treatment (e.g., radiation) the patient has undergone
- Previous bowel resection(s) the patient may have undergone

It is imperative that every **stoma must be well made.** Proper stoma construction as a prophylactic maneuver is vastly superior to any therapeutic options to attempt to improve upon a suboptimally constructed stoma. Any questions about viability can be addressed with indocyanine green perfusion assessment. The solution for an inadequately perfused intended stoma is to use a more proximal segment of well-perfused intestine. A key aspect of creating a good stoma is to create a large enough aperture in the abdominal wall to allow the stoma to reach the skin without tension but not to create such a wide opening that the patient will develop a hernia at the site.

Prophylactic mesh in ostomy construction surgery serves as a potentially preventive measure against parastomal hernias, a common postoperative complication where the intestine protrudes near the stoma site. By reinforcing the abdominal wall, the mesh aims to reduce hernia risk, thereby enhancing patient comfort and overall quality of life. The choice of mesh type, whether synthetic or biologic, and the surgical technique employed are pivotal for its success. However, although the mesh offers notable benefits, it is essential to weigh these against potential complications, such as infections, mesh erosion, or allergic reactions, ensuring that its application is both judicious and tailored to individual patient needs. A recent meta-analysis of 12 randomized controlled trials determined that the preventive use of mesh decreases the risk of a parastomal hernia by 40%. Yet, when the authors examined randomized controlled trials conducted in the past 5 years, no advantages were observed. Additionally, postoperative complications and mortality rates remained comparable.[11]

Colostomy

Ascending colostomies tend to have a higher amount of liquid effluent, whereas descending and left-sided colostomies are usually preferable because most of the colon is in circuit, allowing for more colonic water absorption, with a more formed effluent, while still providing proximal diversion.

With the increasing BMI of patients in the United States today, creating a well-functioning stoma can be a challenge. Both early and late complications can occur with stoma construction. Typically, creating an aperture that will admit two fingers is adequate (Fig. 95.19). In addition, one should ensure that the patient is marked for a stoma site preoperatively, as discussed earlier. It is important to create a muscle-splitting stoma aperture within the rectus muscle and sharply divide the rectus sheath (Fig. 95.20). In creating a colostomy in an obese patient, especially with the left side of the colon, one frequently has to perform the same central vascular ligation as one does for a cancer resection merely to achieve the same degree of mobilization and mobility to enable the colon to reach to the abdominal wall in a tension-free manner. This can be particularly true with patients who have a very rigid

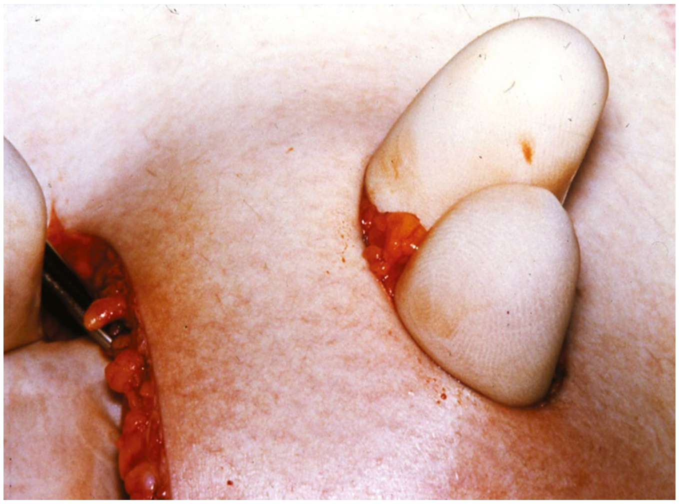

FIGURE 95.19 A stoma aperture that admits two fingers is typically of adequate size to allow the bowel and mesentery to pass without tension. In cases of obstruction or an obese mesentery, a larger aperture will be needed.

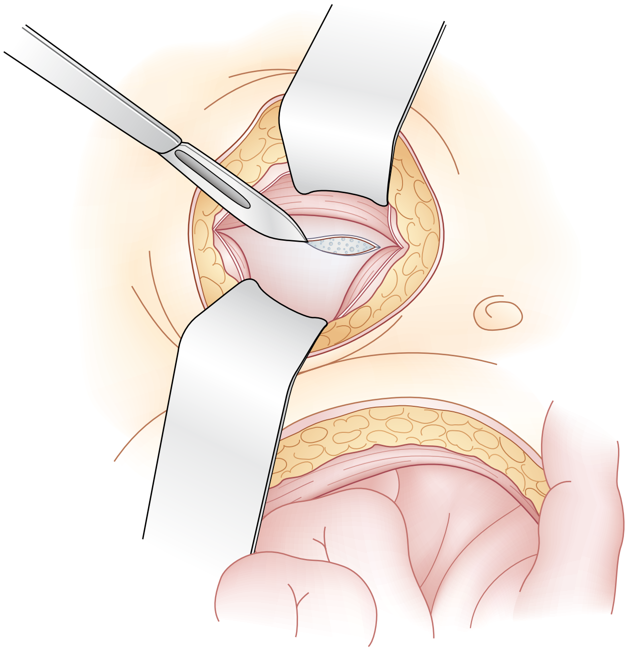

FIGURE 95.20 In making the stoma aperture in the abdominal wall, the rectus muscle is split and the rectus sheath is divided sharply. In laparoscopic cases, one can cut down directly on the trocar inserted through this site.

abdominal wall and those with a very thick layer of subcutaneous tissue. In constructing an end colostomy, this typically does not need to protrude more than 0.5 to 1 cm above the level of the abdominal skin. However, there are some circumstances where the patient may be expected to have a more liquid effluent (e.g., as a result of receiving chemotherapy), and one may wish to have the stoma protrude more to permit easier pouch placement and adherence. In the presence of a liquid effluent, a protruding “spoutlike” stoma is always easier to maintain pouch adherence compared with a flatter stoma. In the obese patient, it is sometimes easier to construct an end-loop colostomy than an end colostomy if complete fecal diversion is required. This is constructed in a similar fashion as a loop-end ileostomy (see later), whereby a loop of mesentery is brought up rather than an end of mesentery. Remember, traditional loop colostomies are not always completely diverting. If one wishes total diversion, an end-loop stoma, with tacking of the distal limb in close proximity to the stoma site, may be a preferable option. Also remember that in obese individuals, the thinnest part of the abdominal wall is often in the upper abdomen.

Ileostomy

As with colostomy, an ileostomy can be constructed as an end ileostomy, loop, or end-loop ileostomy (Fig. 95.21). Ileostomies are generally favored by colorectal surgeons for fecal diversion because they are easier to construct, especially in obese individuals; are usually easier to close; and do not risk compromising the marginal vessels of the colon that are so important to the viability of low and ultra-low colorectal and coloanal anastomoses. Ileostomy effluent usually has a less offensive odor, in contrast to colostomy effluent, which usually has an odor associated with colonic flora. However, in contrast to a colostomy, an ileostomy will empty continuously and has a high rate of associated chemical dermatitis because of the more alkaline pH associated with small bowel effluent as opposed to the stool of the colon. Loop ileostomy is commonly performed, often at the time of ileal pouch–anal anastomosis (IPAA), low colorectal anastomosis, and coloanal anastomosis, especially in patients who have received neoadjuvant chemoradiation. Additional scenarios include patients who are immunosuppressed, patients with tension on their anastomosis, patients in whom complex pelvic reconstructions are planned, and situations in which fecal diversion is performed when trying to avoid total proctocolectomy. Examples include patients with severe perianal Crohn disease and patients in whom perineal reconstructive operations are planned. Minimally invasive diversion is particularly convenient for these cases.

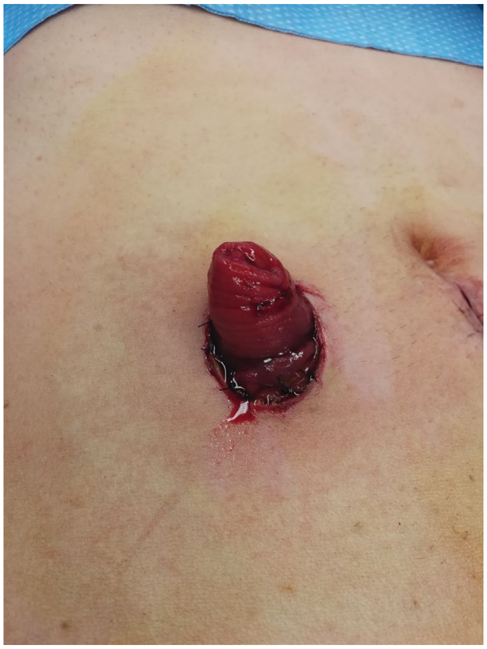

FIGURE 95.21 The intraoperative photo showing the “matured” loop ileostomy protruding 2 to 3 cm above the abdominal wall. The distal limb at skin level is located inferiorly.

BOX 95.1 Interventions to Reduce Readmissions for Ileostomy Patients

- Patient education: Comprehensive guidance on stoma care and potential complications.
- Follow-up appointments: Regular postoperative checks.
- Nutritional counseling: Dietary guidance to regulate stoma output.
- Hydration management: Emphasis on staying hydrated and recognizing dehydration signs.
- Home care services: Access to professional care at home.
- Support groups: Connection to peer support and advice.
- Telemedicine: Virtual consultations for minor concerns.

An end-loop ileostomy, a configuration in which the small bowel is transected and the proximal diversion is brought up as a loop with the staple line immersed in the stoma site, can be used when there is difficulty maturing an end stoma, typically because of an elevated BMI. There is also a much higher risk of dehydration with an ileostomy, which is a frequent reason for hospital readmission after elective colorectal surgery. Before hospital discharge, one should ensure that the 24-hour stoma output is less than 1000 mL. If the output is greater than this amount, the patient is at high risk of hospital readmission (Box 95.1).

Reducing readmissions for patients with ileostomies requires a multifaceted approach. Comprehensive preoperative education can ensure patients and caregivers understand how to manage the ileostomy, identify signs of complications, and adjust solid and liquid alimentation. Regular prompt postdischarge follow-ups, preferably with a stoma care nurse and/or visiting nurses, can facilitate early identification and management of issues. Easy access to outpatient care or telemedicine for minor concerns can prevent these issues from escalating into major problems requiring hospital readmission. High-output ileostomies, characterized by a large volume of stool output (>1200 mL), require strategies to prevent dehydration, electrolyte imbalances, and malnutrition. Dietary modifications to lower fiber intake and include stool-thickening foods can help control output. Adequate hydration and electrolyte intake are crucial to maintain balance. Medications that slow the movement of food through the digestive tract can reduce stool volume, and supplemental nutrition may be required in severe cases. Regular follow-ups with the healthcare team and patient education on recognizing signs of complications, such as dehydration, are key to early intervention and management. The management plan should always be personalized to the patient's individual needs and circumstances.

The timing of ileostomy closure, the reconnection of the bowel after a temporary ileostomy, traditionally occurs several months after initial surgery, typically between 3 and 6 months. However, recent research has proposed early ileostomy closure, within 2 months of the initial surgery, as a safe, feasible option for selected patients. Early closure advantages include a reduced period with a stoma, lowering the overall risk of stoma-related complications and potentially improving the patient's quality of life. Early closure is not suitable for all individuals; careful patient selection, considering factors such as nutritional status, overall health, healing of the initial surgical site, and complicating factors (e.g., ongoing chemotherapy), is crucial. Optimal closure timing should involve patient preferences and circumstances, determined through shared decision-making.

Continent Ostomies

A continent ileostomy, or Kock pouch, facilitates controlled waste drainage through a catheter rather than continuous drainage into an external bag, as with the conventional ileostomy. Despite the benefits of increased control and discretion, continent ileostomies are more complex procedures associated with higher rates of complications, such as pouchitis, valve slippage, and stoma obstruction. A recent meta-analysis found a pooled complication rate of over 60% for Kock pouches with a revision rate of 46% and a failure rate of 12.9%, with increased BMI and previous IPAA, correlated with increased risk for complications.[12] These recurrent complications often necessitate multiple surgical interventions. Indeed, many patients eventually undergo stoma pouch resection because of these persistent issues, leading to the conversion of their ostomy to a noncontinent variant. Although continent ileostomies have declined in use because of alternatives like IPAA, they remain an option for certain patients when IPAA is not possible or desired. A potential alternative to avoid the need for an external appliance are continence devices, which are designed to allow the ostomates to selectively empty intestinal contents. A variety of both externally fixed and internally implanted alternatives have been devised during the last several decades. A recent meta-analysis evaluated the effectiveness of these devices, focusing on their ability to improve continence and quality of life. The findings indicated that these devices can significantly improve both continence and quality of life for ostomates, with patients often reporting a preference for them over traditional pouching systems. Additionally, the devices were associated with relatively low leakage rates, although some complications were noted.[13]

Another type of continent ostomy is the Malone antegrade continence enema (MACE) procedure, a surgical intervention primarily developed to manage chronic constipation and fecal incontinence, particularly in pediatric patients with spina bifida or other congenital anomalies and trauma patients. Surgically creating a conduit, usually using the appendix, allows for the antegrade introduction of fluids into the large bowel, facilitating regular and predictable bowel evacuations. However, similar to other continent ostomies, the MACE procedure has limitations, including the risk of valve malfunction, the requirement for routine catheterization, and an increased susceptibility to infections and surgical revisions.

ENHANCED RECOVERY PROTOCOLS

Enhanced Recovery Protocols (ERPs) (Box 95.2), or Enhanced Recovery After Surgery (ERAS) protocols, are evidence-based strategies aimed at optimizing patient recovery after surgical procedures, including colorectal surgery.[14] These protocols incorporate a range of perioperative interventions to minimize surgical stress, maintain postoperative physiologic function, and expedite recovery. Key elements of ERAS protocols in colorectal surgery involve preoperative counseling to educate patients about the surgical procedure, the expected recovery process, and the significance of early mobilization and nutrition after surgery. Preoperative nutrition is also a crucial aspect, often involving carbohydrate loading before surgery to mitigate postoperative insulin resistance. In many ERAS protocols, there is an avoidance of mechanical bowel preparation preoperatively because research suggests it may not enhance outcomes and could potentially worsen them. Anesthetic management generally encompasses a multimodal approach to analgesia, including regional techniques, and a focus on maintaining euvolemia rather than administering excessive intravenous fluids.

Encouraging patients to mobilize and begin oral intake of fluids and food soon after surgery stimulates gut function and can

BOX 95.2 Interventions

Preoperative Interventions

- Patient education
- Nutritional screening
- Preoperative carbohydrate loading
- Bowel preparation (minimal or none)
- Avoidance of preoperative fasting
- Optimization of comorbidities
- Thromboprophylaxis
- Antibiotic prophylaxis

Intraoperative Interventions

- Goal-directed fluid therapy
- Minimally invasive techniques
- Avoidance of drains and nasogastric tubes
- Regional anesthesia/transversus abdominis plane (TAP) block
- Maintenance of normothermia
- Short-acting anesthetic agents

Postoperative Interventions

- Early mobilization
- Early oral feeding
- Multimodal analgesia
- Avoidance of nasogastric tubes
- Stimulating bowel function
- Early removal of catheters
- Postoperative nausea and vomiting (PONV) prophylaxis
- Structured follow-up

improve patient morale and well-being. The use of drains and nasogastric tubes is often avoided whenever possible because they can cause discomfort and delay recovery.

ERAS protocols have been associated with reduced lengths of hospital stay and postoperative complications without increasing readmission rates. However, successful implementation requires a multidisciplinary team approach, significant efforts in patient education, staff training, and process redesign. Patient adherence to the protocol is also vital for achieving desired outcomes. Pre-hospitalization education is essential for the patient and family to help ensure compliance.

Although these protocols generally are not intended for nonelective cases, components of ERPs can be applied to urgent/emergent patients. ERPs have shown efficacy in reducing morbidity rates and length of hospital stay without increasing readmission rates in colorectal surgery. ERPs are also associated with reduced healthcare costs, improved patient satisfaction, lower complication rates, and decreased mortality. They improve outcomes irrespective of laparoscopic or open surgery and are safe and effective in elderly patient populations. However, their implementation should not be dogmatic, but requires ongoing compliance evaluation and continuous quality improvement. Better adherence to ERPs is linked with decreased complications and shorter hospital stays.[15]

Preoperative Interventions

Counseling before surgery to set expectations on milestones and discharge criteria is considered a cornerstone of successful ERPs. This education helps to set patient expectations, reduce anxiety, and increase compliance with the ERP pathway. In addition, chronic conditions such as diabetes, hypertension, and heart disease should be optimally managed before surgery. This might involve working closely with primary care doctors or specialists to ensure the patient is in the best possible health before surgery. Furthermore, some medications may need to be adjusted or temporarily stopped before surgery, especially those that could increase the risk of surgical complications. If an ostomy is a part of the planned operation, marking, education, and counseling on dehydration should be started in the preoperative period.

Prehabilitation before surgery is also a fairly new concept that aims to enhance a patient's functional capacity before surgery, which is particularly beneficial for deconditioned patients or those with multiple comorbidities. Pre-habilitation can involve physical exercises, nutritional optimization, mental health support, and patient education, with the goal of reducing postoperative complications and promoting more efficient recovery. The underlying premise is that patients with higher preoperative fitness levels possess more physiologic reserves, enabling them to better withstand surgical stress and recover more efficiently. The evidence supporting prehabilitation is still evolving but suffers from lack of standardization and outcome reporting bias. Studies have suggested potential benefits, including improved physical fitness and reduced postoperative complications in patients undergoing abdominal or colorectal surgery. However, a recent meta-analysis focusing on high quality randomized controlled trials examining the impact of excercise-based prehabilitation on postoperative outcomes in colorectal surgery found that, while prehabilitation was associated with shorter length of stay and improved preoperative functional outcomes (e.g., better walking distance), it did not reduce post operative complication or readmission rates compared to standard care.[16] Further research is needed to identify specific patient populations that would benefit most from pre-habilitation with optimization of intervention protocols.

Preadmission Nutrition and Bowel Preparation

There is strong evidence to support the recommendation of a clear liquid diet up until 2 hours before the induction of anesthesia. However, there is weaker evidence to support the use of per os carbohydrate loading before surgery.

Mechanical bowel preparation alone has not been shown to be beneficial (strong recommendation based on high-quality evidence, 1A). In the United States, mechanical bowel preparation plus oral antibiotics preparation has become the preferred preparation to reduce complications, including SSIs, especially when left-sided and rectal resections are anticipated. In the American Society of Colon and Rectal Surgeons Clinical Practice Guidelines for the Use of Bowel Preparation in Elective Colon and Rectal Surgery, this practice was given a strong recommendation based on moderate-quality evidence (1B). Interestingly, a recent randomized controlled trial found no evidence to support this practice for elective colon resection compared with no bowel preparation as a mechanism to reduce SSIs or postoperative morbidity.[17] It is important to note that the majority of reported studies, including this one, were performed in patients undergoing colon as opposed to rectal resections.

Perioperative Interventions

ERPs commonly involve preset orders for the preoperative, intraoperative, and postoperative care for all patients. These pathways can typically include 20 or more individual components that span the entire surgical process, from preoperative preparation through intraoperative management to postoperative care.

However, the exact number can vary based on the specific ERAS protocol in use, the type of surgery, and the individual hospital's policies and guidelines. Standardization requires collaborative buy-in from different stakeholders, which helps avoid confusion and promotes timely adherence to care.

Colorectal surgery patients have up to a 20% risk of developing a postoperative SSI. Bundles of care aimed at SSI reduction have shown SSI rates to be significantly reduced. These bundles include some, if not all, of the following measures: preoperative chlorhexidine shower; mechanical bowel preparation with oral antibiotics; prophylactic antibiotic administration within 1 hour of incision; the use of wound protectors during surgery; changing gown, gloves, and instruments before fascial closure; euglycemia; and normothermia. The degree to which each element affects the reduction of SSIs is unclear. A recent meta-analysis found that although larger bundles were not associated with a larger effect, perioperative care bundles that contained a high proportion of evidence-based interventions showed a more substantial impact in preventing SSIs.[18]

There is strong evidence to support the use of multimodal, opioid-sparing pain management plans starting before the induction of anesthesia. Minimizing opioids is associated with earlier return of bowel function and shorter length of stay. Acetaminophen, nonsteroidal antiinflammatory drugs (NSAIDs), and gabapentin have all been incorporated into various ERPs. Transverse abdominis plane (TAP) block with local anesthetic, including liposomal bupivacaine, has shown promising results for short-term pain. A recent meta-analysis revealed that the TAP block significantly reduced the need for opioids and pain intensity within 24 hours of both laparoscopic and combined surgeries, but it did not significantly affect the overall opioid consumption during the hospital stay. Epidural analgesia is generally recommended for open, but is not commonly performed for laparoscopic surgery.

The use of goal-directed fluid therapy in the intraoperative and postoperative phases of care is associated with a reduction in time to return of bowel function and length of stay. Lastly, minimally invasive surgical (MIS) approaches should be used, when possible, with avoidance of routine use of intraabdominal drains and nasogastric tubes.

Postoperative Interventions

Postoperative interventions in the ERP occupy a crucial role in accelerating recovery and mitigating the risks of complications. These tenets include a multimodal approach to pain management to minimize opioid use, promoting early mobilization postsurgery, and reintroducing a normal diet within 24 hours to stimulate gut function and provide essential nutrition. Proactive management of postoperative nausea and vomiting as well as the prevention of ileus are other key aspects to ensure patient comfort and facilitate early feeding.

Further postoperative interventions include careful fluid management to prevent fluid overload and electrolyte imbalances; early catheter removal to reduce urinary tract infection risk and promote patient mobilization; prophylactic measures against deep vein thrombosis (DVT), such as medication and compression stockings; and avoidance or early removal of drains. Regular patient follow-ups are performed to monitor recovery, manage complications, and provide ongoing support. Although these ERAS interventions are widely accepted to enhance recovery, reduce complications, and shorten hospital stays, it is crucial that they be personalized to each patient's unique needs and supervised by a healthcare professional. In summary, ERPs are evidence-based protocols that benefit colorectal surgery patients. Local implementation involves buy-in for a range of stakeholders that may be in opposition to the preferences of individual healthcare professionals. Adherence to the constellation of ERP components and the outcomes of interest should be continually monitored and evaluated.

DIVERTICULAR DISEASE

Background

Diverticular disease is used to describe a spectrum of manifestations associated with colonic diverticulosis. Diverticula are saccular outpouchings of the bowel wall. They are described as "true" diverticula when they contain all layers of the bowel wall; these are rare and usually congenital. The vast majority of diverticula in the colon are "false" diverticula (pulsion, pseudodiverticula), containing only the mucosa and muscularis mucosa. Diverticulitis is thought to be mainly a disease of the modern world, coinciding with dietary changes after the Industrial Revolution. Additionally, as the average life span has steadily increased over the past several decades, the incidence of diverticular disease, which predominantly presents in older individuals, has also been on the rise.

Pathophysiology and Epidemiology

Hypertrophy of the muscular layers of the colon wall, combined with a narrowed lumen and disordered colonic motility, causes localized high-pressure zones in which the mucosa herniates through areas of relative weakness. Diverticula are classically formed on the mesenteric side of the colonic wall in regions where vasa recta traverse through the muscular layer to provide blood to the mucosa (Fig. 95.22). These small blood vessels supplying the colon are considered potential weak spots in the bowel wall. When increased pressure, inflammation, impaired blood supply, or trauma occurs at these weak points, it can lead to a perforation in the diverticulum, which leads to infection and, as a result, a significant local inflammatory response. When perforations occur on the mesenteric side, as they do in most cases, the surrounding mesentery often serves as a natural barrier, helping to contain the

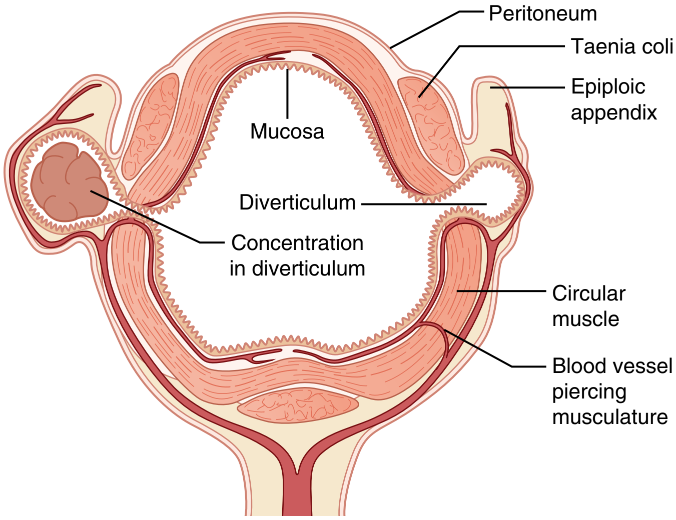

FIGURE 95.22 Pathogenesis of diverticulosis. (From Netter FH. *Netter Collection of Medical Illustrations.* Vol 9. Philadelphia: Elsevier Saunders; 2016:145.)

infection or inflammation to a localized area. The infected diverticulum can then form an abscess or walled-off area of infection within the confines of the mesenteric tissues, preventing further spread of bacteria into the peritoneal cavity, which could lead to peritonitis, a more serious and widespread infection. Therefore, the majority of diverticulitis cases are "contained" or localized because of this protective effect of the mesentery. However, if the infection or inflammation is not adequately controlled or treated, it could potentially spread beyond these barriers, leading to more serious complications, such as a generalized peritonitis and sepsis.

The sigmoid and descending colon are typically affected, whereas the rectum, having an extra layer of muscle, is generally not affected (Fig. 95.23). This has implications for surgery and is why the distal anastomosis margin in operations for diverticulitis should always be within the rectum, to reduce the likelihood of recurrence. Diverticulosis increases with age and is relatively rare in young adults. Colonic diverticula are noted in approximately 40% of individuals between the ages of 50 and 60 years and in over 60% of individuals over the age of 80 years (Fig. 95.24). The mechanism for developing diverticulitis is thought to be a result of obstruction of the orifice of a diverticulum, with stasis leading to bacterial overgrowth, inflammation, and increased pressure within the diverticulum, causing ischemia and microperforation. Interestingly, only a small proportion of patients with diverticulosis develop diverticulitis. Modern estimates indicate that fewer than 5% of patients with diverticulosis will develop diverticulitis; however, because of the high prevalence of diverticulosis, it has become a significant clinical and financial burden, accounting for more than 2.7 million outpatient visits in the United States annually and more than 200,000 inpatient admissions for diverticulitis at an estimated cost of more than $2 billion.

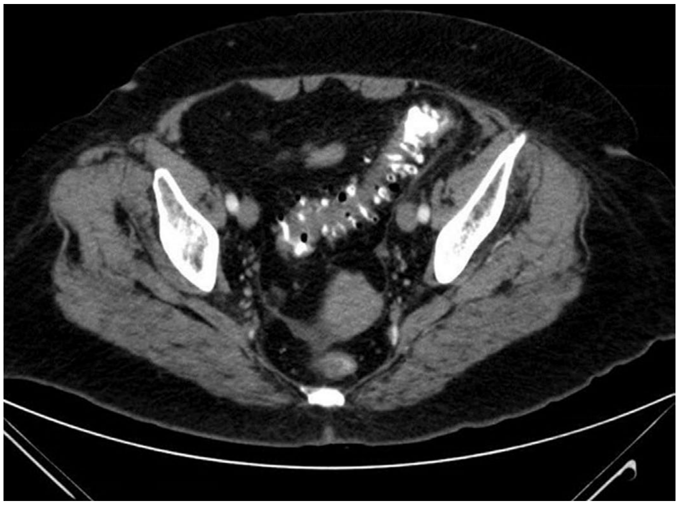

FIGURE 95.23 Computed tomography scan of the pelvis showing extensive sigmoid diverticulosis.

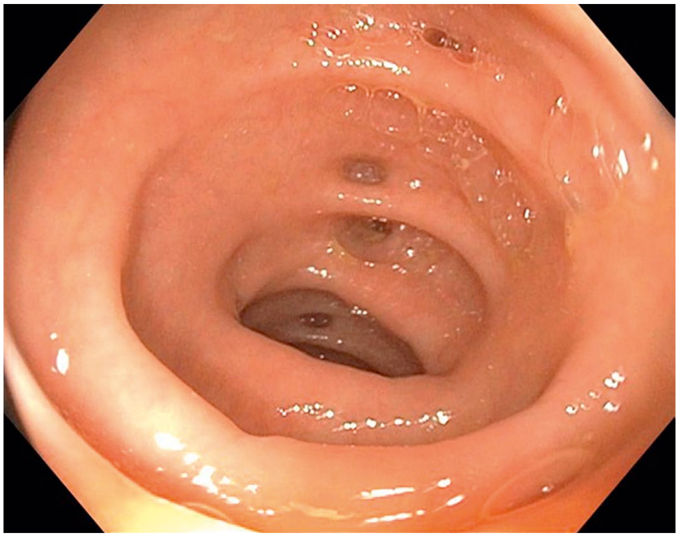

FIGURE 95.24 Endoscopic view of diverticulosis.

Diet and lifestyle factors play an important role in diverticular disease. Western dietary patterns high in red meat, fat, and refined grains are associated with an increased risk of the disease, whereas increased fiber intake, with abundant fruit, vegetables, and whole grains, reduces the risk of diverticulitis.[19] Intake of nuts, seeds, and popcorn does not appear to increase the risk. Central obesity and smoking increase the risk, whereas physical activity, such as running, has been correlated with a decreased risk. The European Prospective Investigation into Cancer and Nutrition (EPIC) study, a prospective cohort analysis, found that a vegetarian diet and high fiber intake significantly reduce the risk of diverticular disease. After 11.6 years of follow-up, vegetarians showed a 31% lower risk, and participants with the highest fiber intake (≥25.5 g/day for females and ≥26.1 g/day for males) showed a 41% lower risk of hospital admission or death from the disease compared with meat eaters and those individuals with low fiber intake.[20]

Clinical Evaluation

Diverticular disease can manifest as diverticulitis, but it is also the most common reason for massive lower GI bleeding. Because diverticulitis is caused by inflammation and perforation of a colonic diverticulum, signs and symptoms will generally result from the pericolonic inflammation. Patients will commonly present with abdominal pain localized to the left lower quadrant (following the location of the inflamed sigmoid colon). Additionally, fever, change in bowel habits, anorexia, and urinary urgency (in cases where the bladder is secondarily inflamed) are frequent. On physical examination, localized tenderness is noted, commonly with moderate abdominal distention. A tender mass can be palpable if there is a significant phlegmon. Rectal bleeding is rare in the presentation of acute diverticulitis and should raise suspicion of another diagnosis, such as ischemic colitis or IBD. Leukocytosis and other elevated inflammatory markers are common laboratory findings.

Several imaging modalities have been used to evaluate patients with suspected diverticular disease. Flat and upright plain films can be used to diagnose obstruction or free intraperitoneal air but are generally nonspecific. Contrast studies, ultrasound, and magnetic resonance imaging (MRI) have also been used, but, currently, computed tomography (CT) has become the most useful tool to confirm the diagnosis, exclude other diagnoses, and classify the severity of the disease. Signs of diverticulitis on CT include the presence of diverticula, colonic wall thickening, pericolic fat stranding, and abscess formation. CT studies have the capacity to localize abscesses and fistulas and define the extent of the disease. The modified Hinchey classification[21] is the most commonly used tool to describe the severity of diverticulitis (Table 95.1).

Grade 0, not included in the original publication, is commonly used to describe mild clinical diverticulitis. If CT is performed,

TABLE 95.1 Modified Hinchey Classification System

Stage 0	Mild clinical diverticulitis
Stage Ia	Confined pericolic inflammation—phlegmon
Stage Ib	Confined pericolic abscess (within sigmoid mesocolon)
Stage II	Pelvic, distant intraabdominal or intraperitoneal abscess
Stage III	Generalized purulent peritonitis
Stage IV	Fecal peritonitis

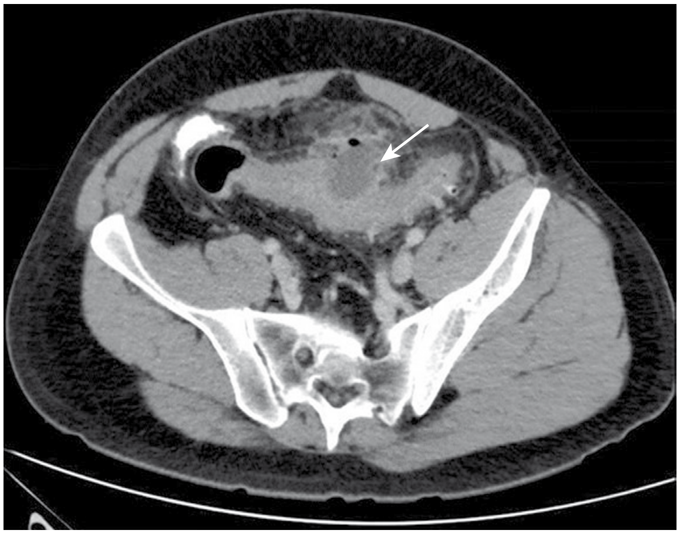

FIGURE 95.25 Computed tomography of the pelvis demonstrating sigmoid diverticulitis with a thickened bowel wall, fat stranding a pericolonic abscess *(arrow)*, modified Hinchey grade 1b.

colonic wall thickening without pericolonic fat stranding can be seen. Grade 1a presents with a phlegmon with colonic wall thickening and pericolonic fat stranding, whereas grade 1b also includes a pericolonic or mesocolic abscess (Fig. 95.25). Patients with grade 2 disease have distant intraabdominal or pelvic abscesses. Patients with grade 3 disease have generalized purulent peritonitis, and those with grade 4 disease have fecal peritonitis. The ability of a CT scan to distinguish between grade 3 and grade 4 is limited, and in these cases, accurate diagnosis is usually made in the operating room.

Flexible endoscopy during the acute setting should be approached with caution because distention of the colon may result in worsening perforation. Colonoscopy has traditionally played a pivotal role in the evaluation of diverticulitis by confirming the presence of diverticular disease, assessing its extent and severity, and crucially, excluding other colorectal conditions. By visualizing the diverticula in the colon and other potential abnormalities, endoscopy helps to exclude diagnoses like CRC, IBD, and ischemic colitis. This evaluation typically follows a 6- to 8-week period after an acute diverticulitis episode to minimize the risk of complications, such as bowel perforation.

However, recent studies have clearly demonstrated a shift in perspective, suggesting that a routine colonoscopy may not be necessary for all patients after acute diverticulitis, particularly in cases of uncomplicated diverticulitis diagnosed via a CT scan. Research demonstrates that the risk of CRC in these patients is low and comparable to that of the general population. Consequently, the necessity for endoscopy should be decided on an individual basis, considering factors such as diagnostic certainty, the presence of ongoing symptoms, patients' CRC risk factors, and the potential risks of the procedure itself.[22,23]

Management

Uncomplicated Diverticulitis

The treatment of uncomplicated diverticulitis depends on the severity of symptoms, and the approach is thus individualized. The majority of these patients can be managed as outpatients. The mainstay of treatment is based on pain medications, short-term alteration of diet, and antibiotics. Commonly, patients are initially prescribed clear liquids, followed by a low-residue diet until the inflammation subsides. Antibiotics have traditionally been prescribed to cover colonic bacteria. A systematic review and meta-analysis assessing the effect of antibiotic administration in patients with uncomplicated diverticulitis has not shown the use of antibiotics to accelerate recovery or prevent complications or subsequent surgery.[24] As a result, some physicians have stopped prescribing antibiotics for uncomplicated diverticulitis. Outpatient treatment of uncomplicated diverticulitis has also been investigated in recent years. A recent meta-analysis found that outpatient management of uncomplicated diverticulitis is safe and cost-effective, leading to low readmission rates and minimal complications while also providing substantial healthcare cost savings.[25]

A small proportion of patients diagnosed with diverticulitis will actually have a colonic neoplasm mimicking diverticulitis. Overall, this finding is currently estimated at around 1% to 3%, with significantly higher rates observed in the background of complicated disease.[26] Upon recovery, it is recommended that patients undergo a colonoscopy after 4 to 8 weeks to exclude malignancy.

After the initial episode of acute, uncomplicated diverticulitis, only 10% to 35% of individuals will have another episode.[27] After more episodes, the chances of recurrence increase significantly. In an attempt to avoid severe complicated diverticulitis, elective surgery was previously suggested after uncomplicated diverticulitis, depending on the number of episodes, with the thought that more episodes would lead to more chances of recurrence and a higher chance of severe complicated diverticulitis. However, recurrences generally tend to follow the severity of the initial episode. As a result, the number of attacks of uncomplicated diverticulitis has fallen out of favor as an indication for surgery. In addition, the traditional approach to elective surgery for diverticular disease, which considered young age (under 50 years old) as an indication, has been challenged by recent evidence. Contrary to previous assumptions, studies suggest that younger patients do not necessarily have a more aggressive disease course and often respond well to conservative management. Moreover, elective surgery carries inherent risks, such as infections, bleeding, potential damage to nearby organs, and the possible need for a permanent colostomy. This, coupled with potential impacts on quality of life, particularly for active younger individuals, has led to a more conservative approach, favoring surgery primarily for complicated disease or disease unresponsive to medical treatment. Personalization of care, considering individual risk factors, disease characteristics, lifestyle, and patient preferences, remains vital in management decisions. The DIRECT trial, which aimed to examine the long-term benefit on quality of life in patients suffering from recurrent disease, showed that elective sigmoidectomy improved quality of life in patients with recurring diverticulitis and/or ongoing complaints compared with conservative management.

Despite surgical risks, nearly half of conservatively managed patients eventually required surgery because of severe complaints.[28] Currently, an individual assessment is performed that includes the frequency of attacks, ongoing symptoms, and their effect on quality of life versus the age and medical condition of the patient and their surgical risk.[29]

The aim of elective surgery is to remove the affected segment of the colon (usually the sigmoid colon) and perform a primary anastomosis of the healthy remaining bowel. When removing the sigmoid colon, the proximal margin should be in soft, pliable bowel, but it is not necessary to include all proximal diverticula. The distal anastomosis, however, should be to the upper rectum because leaving a section of distal sigmoid colon is associated with a higher risk of recurrent diverticulitis. Surgery can be performed by either an open, laparoscopic, hand-assisted, or robotic approach. MIS for diverticular disease has been shown to be safe, with advantages of more rapid recovery of bowel function, less pain, and shorter hospitalization. Ureteric stents are often used to mitigate ureteric injury risk by serving as guides amid inflamed tissues, with their usage being case specific and dependent on such factors as disease severity and surgical complexity.

Complicated Diverticulitis

Patients with complicated diverticulitis are characterized by the presence of an abscess, fistula, obstruction, or free perforation.

Abscess. Signs and symptoms will depend on the size and location of the abscess, with diagnosis usually provided on imaging. Smaller abscesses can often be treated successfully with antibiotics alone. Larger abscesses will require drainage. After recovery, patients who present with a diverticular abscess often experience recurring episodes. Although substantial data suggest that many of these recurrences can be nonoperatively managed, the risks of recurrence and complications are increased in patients who present with a diverticular abscess. However, even with this recurrence risk, some studies suggest that surgery might not always be required, and nonoperative management can lead to acceptable outcomes in certain situations. Despite these findings, the most recent guidelines from the American Society of Colon and Rectal Surgeons (ASCRS) recommend considering elective resection after successful nonoperative treatment of a diverticular abscess. This recommendation is based on moderate-quality evidence, recognizing the balance between managing recurrence risk and avoiding unnecessary surgery. Patients with abscesses not amenable to percutaneous drainage and unresponsive to treatment require urgent surgery.

Fistula. Fistulas are abnormal connections to surrounding epithelial-lined organs and are a relatively common complication of diverticulitis. They are a result of the local inflammation and development of an abscess that decompresses into a neighboring organ. The most common type, especially in males, is a colovesical fistula to the dome of the bladder. Patients will present with recurrent urinary tract infections, which are, in many cases, polymicrobial. Pneumaturia and fecaluria may also be present. CT can reveal air or contrast in the bladder in the absence of prior instrumentation. Cystoscopy will usually disclose inflammation at the site of the fistula. Colovaginal fistulas occur almost exclusively in females who have undergone previous hysterectomy and present with vaginal discharge and passing of air per vagina. Colocutaneous fistulas usually present at a previous drain site in patients who have undergone percutaneous drainage. Patients with fistulas usually do not need emergency surgery because the abscess has usually decompressed through the fistula. Initial management includes broad-spectrum antibiotics to decrease the inflammation. Patients are then investigated with colonoscopy and appropriate imaging (e.g., cystoscopy) to exclude malignancy and Crohn disease. Surgical principles then encompass resection of the involved colon and fistula tract with primary anastomosis. If possible, the fistula opening into the secondarily involved organ is primarily suture repaired; however, in many cases, the opening is small and difficult to recognize. In the case of the bladder, with small fistula openings, drainage of the bladder with a Foley catheter for 7 to 10 days will usually allow for healing. A cystogram can be done to confirm fistula healing before Foley removal. Fistulas to the small bowel will characteristically require resection and primary anastomosis.

Obstruction. Patients with recurrent and chronic diverticulitis can develop fibrosis of the colonic wall, leading to stricture formation. In most cases, these patients will present with insidious symptoms and a partial obstruction. Small bowel obstruction may also be seen as a result of a small bowel loop adhering to an area of inflamed colonic tissue or abscess. Management depends on the degree and type of obstruction. Patients with a partial obstruction can usually be initially treated with a nasogastric tube for decompression, antibiotics, fluids, and bowel rest. If the obstruction resolves, elective resection can be planned. It is usually important before resection to perform a colonoscopy to rule out malignancy. In cases where the stricture is impossible to pass using a colonoscope, virtual colonoscopy or a retrograde contrast study can be helpful to visualize the remainder of the bowel. Patients with a complete obstruction unresponsive to therapy will require emergency surgery.

Perforation. Patients with a free intraabdominal perforation with widespread contamination will present with diffuse peritonitis with rebound tenderness and guarding. Signs of sepsis, including fever, tachycardia, and hemodynamic instability, are frequently seen. Imaging can demonstrate free abdominal fluid, signs of peritonitis, and free intraabdominal air. In very few carefully selected, completely stable patients with diverticular perforation and distant pneumoperitoneum, nonoperative management with IV antibiotics, bowel rest, and possible percutaneous abscess drainage may be an option. This approach requires exceptionally careful selection and very close skilled monitoring to try to avoid complications, such as worsening peritonitis and sepsis, necessitating emergency surgery. The ability to distinguish between purulent and fecal diverticulitis before surgery is limited. Hinchey grades 3 and 4 are considered a surgical emergency. After initial resuscitation, patients are taken to the operating room, with the goal of controlling the source of infection by resection and washing out the abdominal contamination.

The mainstay of treatment in these cases has traditionally been Hartmann's procedure,[30] which removes the involved colon and exteriorizes an end colostomy. Reversing the colostomy, however, requires a second major surgical procedure with its own significant morbidity and mortality. Practically, up to 50% of patients will never be reversed, with even higher rates in the elderly. Given these implications, several studies have investigated alternatives to Hartmann's procedure.

Laparoscopic lavage. Laparoscopic lavage[31] is an MIS procedure for which there was some initial enthusiasm to treat perforated diverticulitis, generally presenting as purulent peritonitis (Hinchey grade 3). The technique involves cleaning the peritoneal cavity laparoscopically without removing the diseased colon segment. This aims to control the immediate infection, minimize surgical stress, and potentially allow for a more planned, less morbid procedure later if needed.

Several randomized controlled trials, including the DILALA and the LOLA arm of the LADIES trials, have investigated laparoscopic lavage's effectiveness and safety. The DILALA trial indicated that lavage was linked to a shorter initial hospital stay and fewer stoma formations compared with sigmoidectomy, with no significant difference in major morbidity and mortality rates in patients with Hinchey III disease. The LADIES trial (LOLA arm), however, was prematurely terminated because of high postoperative complications and surgical reinterventions in the lavage group.[32,33] A recent meta-analysis investigating long-term outcomes of different treatment methods for diverticulitis underscored several significant benefits of laparoscopic lavage. As opposed to resection procedures, lavage notably decreased the chances of long-term stoma by 87% and reduced the odds of subsequent operations by 42%, largely by obviating complications linked to Hartmann's procedure that may culminate in permanent colostomies. However, lavage isn't without its problems: It is associated with a nearly sixfold increase in the risk of disease recurrence because it is a damage control strategy that leaves the disease-riddled colon segment intact. Despite this, the long-term complications and mortality rates were on par between lavage and resection, vouching for the enduring safety of the laparoscopic lavage procedure.[34]

Primary resection and anastomosis (with/without proximal diversion). Primary resection and anastomosis have emerged as a promising alternative to the traditional Hartmann's procedure in the management of perforated diverticulitis. Early studies indicated a notable reduction in morbidity rates after ostomy reversal when primary anastomosis with a covering loop ileostomy was used compared with Hartmann's reversal. Furthermore, primary anastomosis saw significantly higher rates of ostomy closure.

Confirming these results, long-term outcome reports from the French DIVERTI trial and the Dutch LADIES trial's DIVA arm showed superior outcomes for resection and primary anastomosis over Hartmann's procedure. The analyses from these trials suggested that primary anastomosis could decrease the chance of a long-term ostomy by a remarkable 98%, reduce long-term complications and the need for reoperation by 80%, and lower incisional hernia rates by 82% when compared with Hartmann's procedure. The data imply that, for hemodynamically stable patients with perforated diverticulitis and peritonitis, primary anastomosis may offer superior long-term outcomes and be the preferred surgical approach.[34] However, these results must be viewed carefully, as recruitment issues and selection bias of these trials raised some concern for nonapplicability.

Damage control strategy. The "damage control" strategy, a concept borrowed from trauma surgery, has also emerged as an alternative approach in managing patients presenting with generalized peritonitis resulting from perforated diverticulitis who require urgent surgical intervention. This strategy, described by Kafka-Ritsch et al., involves an initial surgery that includes abdominal washout and resection without restoring bowel continuity, leaving closed intestinal stumps with an open or temporarily closed abdomen.[35] The decision of whether to anastomose is then deferred to a second-look intervention, typically 24 to 48 hours after the initial surgery. Although this approach still requires large-scale validation studies, it is seen as a positive step toward individualized surgical intervention based on the patient's clinical characteristics and operative findings.

Surgical decision-making in complex septic patients resulting from diverticular perforation involves considering multiple patient-related factors, such as hemodynamic stability, symptom severity, and the extent of perforation, along with factors related to the caregiver, such as surgical capability, experience level, and available resources. With these considerations in mind, it is suggested that fit and hemodynamically stable patients be considered for resection with primary anastomosis or laparosopic lavage in Hinchey 3 perforations and considered for primary resection and anastomosis with a diverting loop ileostomy in Hinchey 4 perforations. Hartmann's procedure should be mainly reserved for unstable patients or cases where a colostomy could significantly improve quality of life, such as in bedridden patients or those suffering from fecal incontinence. Damage control strategy might be appropriate in unstable patients; however, further research is needed to evaluate the safety of this surgical approach. A suggested treatment algorithm can be seen in Fig. 95.26.

Special Populations

Right-Sided Diverticulitis

Right-sided diverticulitis is common in Asian countries but rare in Western populations. This typically affects younger patients and may be challenging to diagnose because signs and symptoms are very similar to those of acute appendicitis. Other differential diagnoses to be considered include Meckel diverticulitis, cholecystitis, ischemic colitis, mesenteric adenitis, pyelonephritis, and pelvic inflammatory disease. The recommended approach should generally be similar to that for diverticulitis in other sites. Patients who have recurrent episodes or complicated disease and patients with an uncertain diagnosis should be considered for resection with a right hemicolectomy.

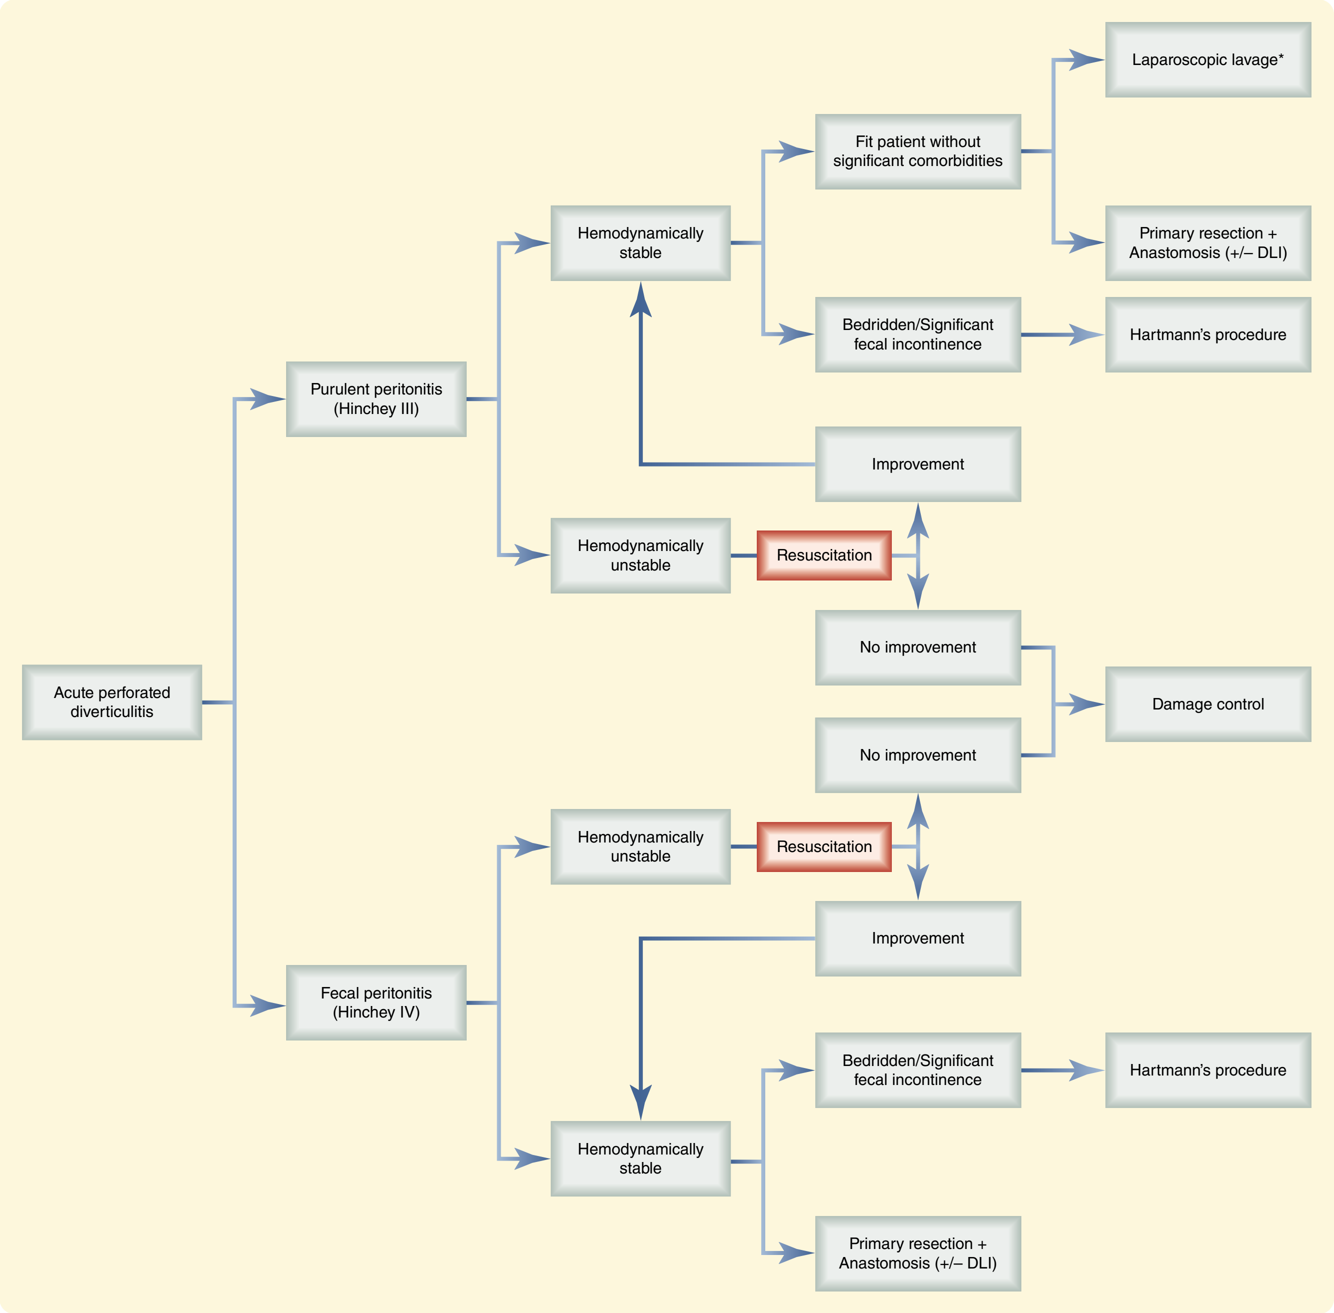
Immunocompromised Patients

Immunocompromised patients include transplant patients; patients with diabetes mellitus, renal failure, or cirrhosis; and patients being treated with systemic steroids and/or chemotherapy. The most updated recommendation from the most recent ASCRS guidelines states that after recovery from uncomplicated acute diverticulitis in immunosuppressed patients, the decision to perform elective surgery needs to be individualized. Immunosuppressed patients constitute a unique cohort that requires careful consideration when it comes to recommending elective surgery after medical treatment for diverticulitis. A review of the NSQIP database revealed comparable mortality rates between immunosuppressed and immunocompetent patients who underwent elective sigmoidectomy. However, the rates of major morbidity and wound dehiscence were significantly higher in the immunosuppressed group. Therefore, the decision to proceed with colectomy in this setting should consider these increased risks.

Different studies presented varying viewpoints regarding the recurrence rates of diverticulitis in immunosuppressed patients, challenging the recommendation for interval elective sigmoidectomy in this group. Although one study found that immunosuppressed patients who experienced a severe initial episode were more likely to have a recurrence, the necessity for emergency surgery was similar to the incidence in immunocompetent patients. A review of patients who underwent renal transplant found high recurrence rates but claimed that nonoperative management is safe for this group. It should be noted that the literature advocating for elective resection after a single episode of uncomplicated diverticulitis in immunosuppressed patients is not universally convincing, and the specific cause of immunosuppression might need to be considered when making treatment recommendations.[29]

Young Patients

Historically, patients younger than 50 years of age were considered to have a more virulent form of diverticulitis and were recommended to



Acute perforated diverticulitis
Purulent peritonitis (Hinchey III)
Fecal peritonitis (Hinchey IV)
Hemodynamically stable
Hemodynamically unstable
Resuscitation
Improvement
No improvement
Fit patient without significant comorbidities
Bedridden/Significant fecal incontinence
Laparoscopic lavage*
Primary resection + Anastomosis (+/– DLI)
Hartmann's procedure
Damage control
No improvement
Resuscitation
Hemodynamically unstable
Improvement
Bedridden/Significant fecal incontinence
Hartmann's procedure
Hemodynamically stable
Primary resection + Anastomosis (+/– DLI)

undergo resection after one episode of uncomplicated disease. Although current evidence does demonstrate higher rates of recurrence, young patients do not have a higher rate of emergency surgical intervention. Current guidelines do not support treating young patients differently than others.

LARGE BOWEL OBSTRUCTION

Large bowel obstruction, defined as bowel obstruction distal to the ileocecal valve, can occur as a result of a variety of etiologies. Broadly, it is classified into mechanical (dynamic) obstruction and functional (adynamic or pseudoobstruction). Mechanical obstruction can be further characterized into endoluminal, mural, and extraluminal causes (Box 95.3).

The most common etiology of mechanical obstruction in the United States is CRC, whereas colonic volvulus is more common in Russia, Eastern Europe, Africa, the Middle East, and India. Presentation and symptoms depend on whether it is an acute obstruction or a more chronic progressive change, as well as partial obstruction, in which some gas/fecal contents are able to pass, versus complete obstruction, in which nothing passes distally. It is thought that, worldwide, volvulus is responsible for roughly one-third of the cases

BOX 95.3 Large Bowel Obstruction Common Etiologies

Mechanical

Intraluminal

Intrinsic mass—neoplasm
Foreign body
Bezoar
Fecal impaction

Mural

Diverticular stricture
Crohn disease stricture
Ischemic stricture
Radiation stricture
Infectious (including lymphogranuloma venereum, tuberculosis, schistosomiasis)
Hirschsprung disease

Extraluminal

Sigmoid volvulus
Cecal volvulus
Hernia (inguinal, ventral, internal)
Metastatic/intraabdominal tumor
Abdominal abscess
Retroperitoneal fibrosis
Adhesions (rare in large bowel)

Functional

Colonic pseudoobstruction (Ogilvie)
Toxic megacolon
Paralytic ileus

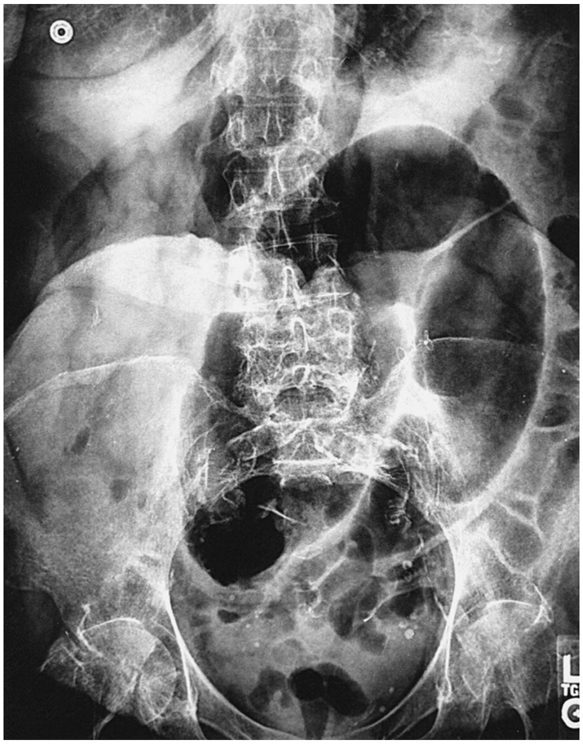

FIGURE 95.27 Plain film of sigmoid volvulus. Note bent inner-tube appearance.

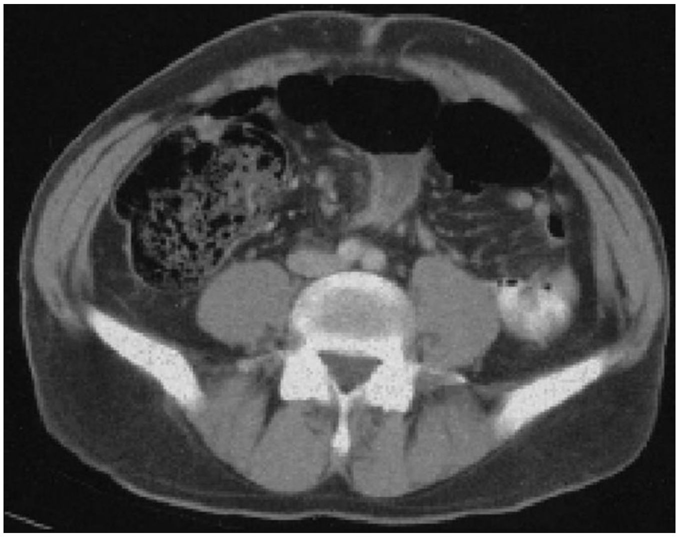

FIGURE 95.28 Computed tomography scan of the abdomen in a patient with sigmoid volvulus. Note characteristic whorl in mesentery.

of large bowel obstruction. The most common site of volvulus is the sigmoid colon; however, cecal volvulus can also occur. Any portion of the colon that is not fixed to the retroperitoneum and that has an elongated mesentery has the potential for volvulus. In these cases, there is an axial twisting of the colon around the mesentery, resulting in an obstruction.

Mechanical obstruction will generally present with increased peristalsis and low-grade colicky pain, but late, long-lasting obstruction may have decreased bowel sounds. In addition, patients will fail to pass stool and flatus and demonstrate increasing abdominal distention. Acute obstructions tend to present more dramatically, with rapid onset of pain, distention, and abdominal tenderness, whereas patients with progressive obstruction may present with increasing constipation, pencil-thin stools, and intermittent abdominal pain. Functional obstruction usually presents with distention, vague abdominal pain, and weak or absent bowel sounds.

Patients with a closed-loop obstruction in which both the proximal and distal parts of a segment of bowel are blocked must be promptly recognized and treated because they have the potential for ischemia and perforation with rapid deterioration. Closed-loop obstruction is commonly encountered in cases such as volvulus and strangulated hernias. Fig. 95.27 shows a plain film of a patient with a sigmoid volvulus. Note the bent, inner-tube appearance of the colon. A plain abdominal x-ray of colonic volvulus typically reveals a large, gas-filled loop of colon, often termed the *coffee-bean sign* because to its distinctive shape. This image suggests a significantly distended loop of colon twisted on its mesentery. The volvulus has resulted in a closed-loop obstruction. In these situations, the colon becomes progressively distended, with pressure increasing to the point of ischemic necrosis and perforation. Fig. 95.28 shows a CT scan illustrating the characteristic mesenteric whorl seen in patients with a volvulus.

In patients with competent ileocecal valves, obstructing colon cancers can lead to a closed-loop obstruction because the valve does not permit the backflow of intestinal contents. This condition usually results in a more acute presentation. However, when the ileocecal valve is incompetent, the presentation tends to be less severe and immediate because intestinal contents can flow back into the small bowel. This scenario often manifests as a progressively bloating abdomen accompanied by feculent nausea and vomiting, with a decreased risk of perforation. It is worth noting that most obstructions tend to occur in the left colon, where tumors typically grow circumferentially. This is in contrast to right-sided colon tumors, which are generally more polypoid in nature. Distention of the colon occurs as a result of gas and stool that gather proximal to the obstruction. The gas originates both from swallowed air (around two-thirds) and bacterial fermentation. In segments that undergo increasing distention, the pressure within the bowel wall can rise above the capillary pressure, diminishing adequate oxygenation, leading to ischemic necrosis and perforation. Although most malignant obstructions occur in the distal parts of the colon, the necrosis and perforation usually occur in the cecum because it has the largest diameter and, in accordance with the law of Laplace, will distend more under lower pressures and develop higher wall stress.

In cases such as incarcerated hernias and volvulus, pressure on the mesentery can compromise the blood supply, initially obstructing venous return and, with increasing edema and inflammation, eventually occluding the arterial blood supply. The resultant ischemia can also lead to early necrosis and perforation. In closed-loop obstructions, distention initially involves the trapped or incarcerated segment, but with time, the proximal bowel will also distend as a result of ongoing accumulation of gas and stool.

Diagnosis and Assessment

A thorough history and physical examination are critical in the diagnosis of large bowel obstruction. The onset and progression of symptoms, background illnesses, medications, and recent endoscopic evaluations can provide important clues. The abdomen should be palpated for masses, tenderness, and previous incisions; the groin should be examined for hernias; and a digital rectal examination should be performed to inspect for neoplasia and the presence of fecal impaction (Fig. 95.29).

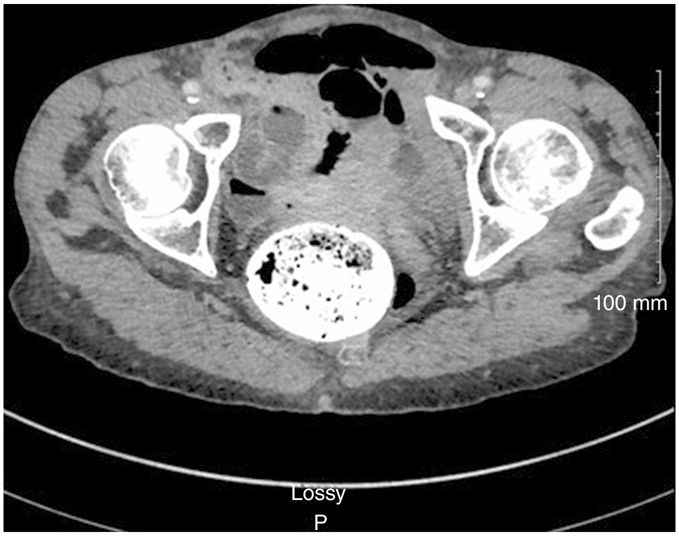

FIGURE 95.29 Computed tomography scan of the pelvis showing a sizable barium impaction after a barium enema resulting in a large bowel obstruction. This patient required disimpaction in the operating room.

Plain films of the abdomen can help in localizing the obstruction, demonstrating the degree of distention and the status of the ileocecal valve (competent vs. incompetent), and in some cases, provide the diagnosis. Water-soluble and IV contrast-enhanced CT scans provide significant information revealing the location and etiology of the obstruction, such as diverticulitis, IBD, and extraluminal causes (e.g., abscesses and inflammation) (Fig. 95.30). CT can also provide clues regarding tissue ischemia and impending perforation. CT with rectal contrast is often preferred in suspected colonic obstruction because of its ability to provide detailed, quick, and safe imaging of

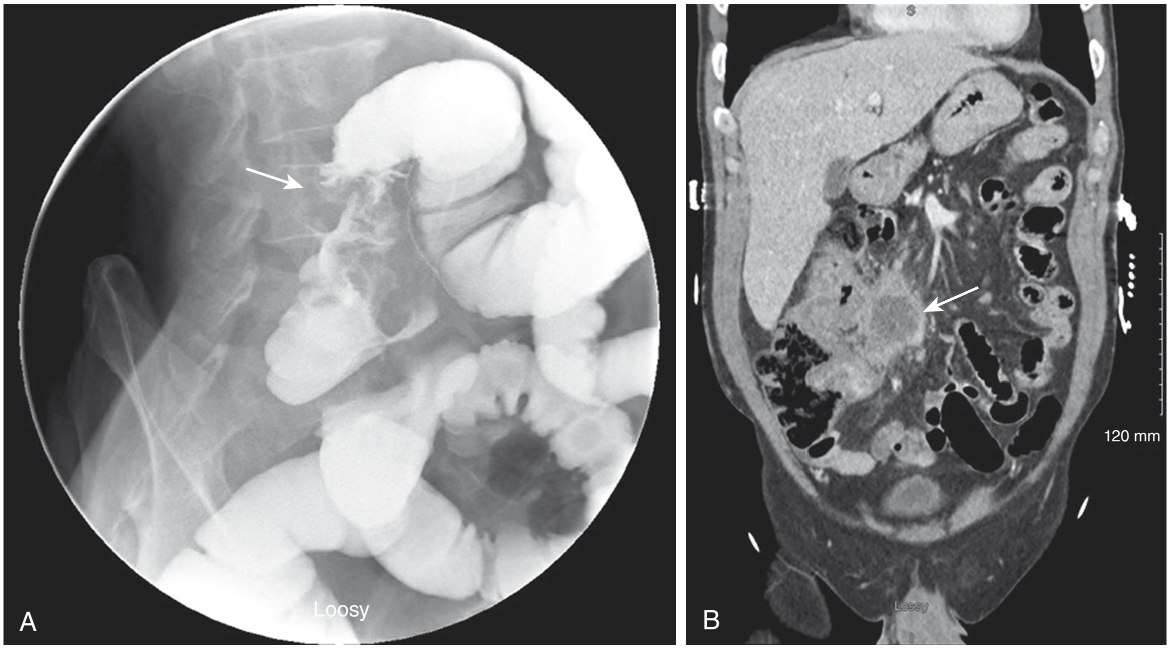

FIGURE 95.30 (A) Gastrografin enema in a patient presenting with obstructing symptoms revealing an "apple-core"–type lesion in the vicinity of the hepatic flexure *(arrow).* (B) Computed tomography scan of the abdomen and pelvis in the same patient showing a large hepatic flexure carcinoma with perforation into the mesentery and associated mesenteric abscess *(arrow).* Computed tomography–guided abscess drainage was not possible. This patient underwent extended right hemicolectomy with exteriorization of his ileocolic anastomosis as a loop ileostomy.

the obstruction site and cause as well as evaluate the competence of the ileocecal valve. A standard water-soluble contrast enema is another option for both diagnostic and occasionally even therapeutic purposes. Flexible endoscopy can assist in the diagnosis of the obstruction and permit biopsies to be collected for further investigation. Endoscopy can also allow for treatment such as detorsion of a sigmoid volvulus and insertion of stents in cases of malignant or benign obstruction. Basic blood analyses are also important in the initial workup. Electrolyte abnormalities can be diagnosed, which are important both as a cause for adynamic nonfunction and a consideration in the operative and perioperative care. Increased white blood cell counts and CRP, as well as increased lactate, base excess, and decreased pH, are all generally associated with a more severe state and can help guide the aggressiveness of treatment.

Treatment

The treatment of large bowel obstruction is tailored to the etiology of the obstruction, several of which are discussed in detail later in the chapter. Treatment options vary considerably depending on the cause of obstruction, suspicion of bowel ischemia, and impending perforation, as well as the patient's general condition and comorbidities. Patients who present with peritonitis, signs of perforation, or ischemic bowel should be taken immediately to surgery.

It is imperative to promptly relieve mechanical obstructions, particularly those with complete and closed-loop obstructions, before compromise of the blood supply results in necrosis and perforation. Patients who do not present with immediate, ominous signs can be managed according to the cause of obstruction. In patients with sigmoid volvulus, endoscopic decompression is often successful using either a rigid or flexible sigmoidoscope with placement of a rectal tube proximal to the point of torsion. If this is unsuccessful, patients require surgery with resection, colostomy, and Hartmann's procedure. If decompression is successful, elective sigmoid resection with primary anastomosis should be performed because of the high rate of recurrence. With cecal volvulus, primary resection and anastomosis can typically be performed unless the patient is at increased risk of anastomotic leak (e.g., nonviable bowel, sepsis, hypotension, and other conditions). Patients with obstruction as a result of active IBD will commonly respond initially to steroids. Paracolic abscesses can be drained percutaneously. Foreign bodies can usually be removed endoscopically. Fecal impaction is commonly relieved with a combination of stool softeners and laxatives from above and manual disimpaction at the bedside or in the operating room under anesthesia. Hernias causing mechanical large bowel obstruction usually require surgery. Adult colonic intussusceptions, in contrast to pediatric intussusceptions, are almost always associated with a pathologic lead point, such as a polyp, cancer, or Meckel or colonic diverticulum. A recent meta-analysis found malignancy as the causative factor in 36.9% of ileocolonic and 46.5% of colonic intussusceptions.[14,36] Most authors recommend surgical resection adhering to oncologic principles without reduction.

Patients with malignant obstruction of the low and midrectum usually require an initial diverting stoma to allow for neoadjuvant chemoradiation before definitive surgery. Colonic stents offer a nonsurgical intervention to manage obstructing colon cancer, enabling symptom relief and providing time for patient optimization and preoperative chemotherapy if needed. Particularly beneficial for high-risk surgical candidates, unfit patients, or those requiring palliation, they may also serve as a bridge to surgery, potentially enabling single-stage operations and stoma avoidance. However, complications such as stent migration, perforation, and reobstruction can occur. Trials and meta-analyses provide mixed results on morbidity, mortality, stoma rates, and long-term survival, indicating the need for case-by-case evaluation considering patient health, tumor location and stage, and available resources and expertise.[2] Surgical options include segmental resection with Hartmann's operation (end colostomy with internal closure of the rectal stump) or primary anastomosis with or without a diverting stoma. If the cecum is ischemic or nonviable, a subtotal colectomy is performed. In cases of right-sided obstruction, a right hemicolectomy is typically performed with primary anastomosis. Patients who are unstable with a high risk for anastomotic failure should undergo creation of a temporary diverting stoma or exteriorization of the anastomosis as a loop ileostomy.

COLONIC PSEUDOOBSTRUCTION

Acute colonic pseudoobstruction, also termed *Ogilvie syndrome,* was initially described by Sir William Heneage Ogilvie in 1948. It is characterized by acute colonic dilatation in the absence of a mechanical obstruction. Ogilvie syndrome is rare, with an estimated incidence of 100/100,000 admissions.[37] Dysregulation of the colonic autonomic innervation is hypothesized to play an important part. Several mechanisms have been implicated, including autonomic imbalance with a relative excess of sympathetic over parasympathetic activity, disrupted colonic reflex arcs, chronic disease, and medications.[37]

It is most commonly encountered among elderly and comorbid patients, classically after an acute illness on a background of neurologic, cardiac, or respiratory diseases. Common associated conditions are depicted in Table 95.2.

Diagnosis

The typical patient is elderly, has multiple comorbidities, and is hospitalized for an acute medical event or has undergone recent surgery (abdominal or nonabdominal). The presenting symptoms of the condition commonly include abdominal distention, pain, nausea, and vomiting. Obstipation is common, but some patients will have diarrhea as a result of hypersecretion of water. Lack of intestinal contractility is often associated with decreased or absent bowel sounds, but high-pitched, tinkling bowel sounds may also be encountered. Systemic toxicity and peritoneal signs

TABLE 95.2 **Conditions Associated With Pseudoobstruction**

CATEGORY	RISK FACTORS
Postsurgical	After major orthopedic and/or spinal surgery, solid organ transplants, cardiac procedures
Neurologic disease	Parkinson disease, Alzheimer disease, stroke, spinal cord injury
Cardiac	Congestive heart failure, myocardial infarction
Pulmonary	Chronic obstructive pulmonary disease
Trauma	Major trauma, shock, burns
Metabolic	Diabetes mellitus, renal failure, electrolyte disturbances
Infectious	Cytomegalovirus, varicella-zoster virus
Obstetric/ gynecologic	Cesarean section, normal and instrumental delivery
Miscellaneous	Lupus, scleroderma
Drugs	Opiates, chemotherapy, anti-Parkinson drugs, anticholinergics, antipsychotic drugs, clonidine

are uncommon and should raise suspicion of ischemia and perforation. Initial evaluation should include a complete blood count, serum electrolytes, renal function assessment, and diagnostic imaging. Plain abdominal radiographs typically demonstrate a distended colon, with the largest diameter usually encountered in the cecum and right colon, which can reach 10 to 12 cm in diameter (Fig. 95.31). Dilation and gas continuing all the way down to the distal rectum support the suspicion of pseudoobstruction in contrast to a mechanical obstruction, in which a paucity of gas is commonly encountered distal to the obstruction. A water-soluble contrast enema can reliably distinguish between a mechanical obstruction and pseudoobstruction. Currently, however, abdominal CT is typically used as the standard confirmatory test; it has the ability to commonly distinguish the type of obstruction and assess for signs of ischemia and impending perforation (Fig. 95.32). Abdominal tenderness, leukocytosis, fever, and cecal dilation of more than 12 cm are signs that may be indicative of colon ischemia, perforation, or impending perforation.

The differential diagnosis includes mechanical obstruction, toxic megacolon due to *C. difficile*, or toxic megacolon resulting from other causes.

Management

The treatment of colonic pseudoobstruction comprises a series of escalating interventions contingent on the degree of distention, risk for perforation, and the patient's response. Treatment options include supportive care, pharmacologic therapy (neostigmine), endoscopic decompression (colonoscopy), and surgery. A rectal tube can be used as an initial step to decompress the dilated colon, providing temporary relief while addressing the underlying cause. The insertion of a rectal tube can be done at the bedside, but it must be very carefully inserted to try to avoid injury to the rectal mucosa.

Nonoperative, supportive care is initiated for patients with a cecal diameter that is less than 12 cm without evidence of ischemia or perforation. This includes nothing by mouth (NPO); correction of electrolyte disturbances; and discontinuation of medications that may be contributing, such as opiates, anticholinergics, anti-Parkinson agents, antidepressants, neuroleptics, clonidine, atropines, and antihypertensives. Insertion of a nasogastric tube and rectal tube for decompression may be of help. Osmotic and stimulant laxatives should be avoided because they can worsen colonic dilation. Ambulation, prone positioning, and knee-chest position to encourage passage of flatus can assist. Patients should be monitored with serial physical exams and abdominal x-rays to assess for response or deterioration. Ischemia or perforation of the colon is the most feared complication and has been reported in the range of 3% to 15% of cases, leading to an associated mortality rate of close to 50%. In cases that do not improve with supportive care or with a cecal diameter of more than 12 cm but without systemic toxicity and abdominal tenderness, colonic decompression is indicated.

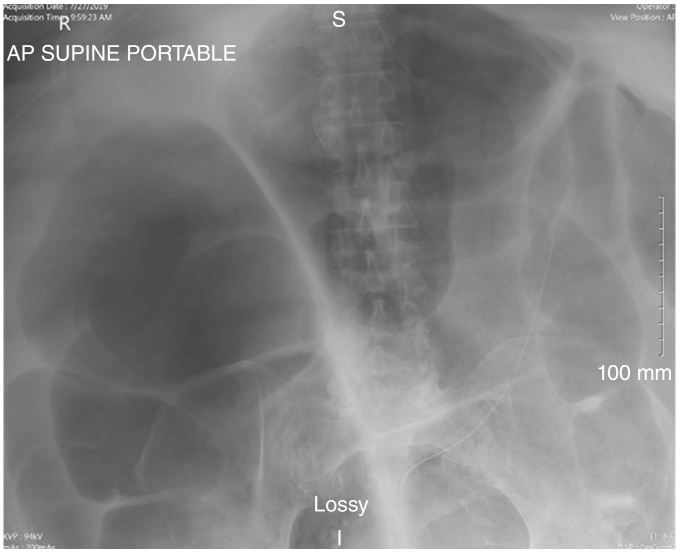

FIGURE 95.31 Massive transverse colon distention due to Ogilvie syndrome in a female with multiple comorbidities, including a body mass index of 69, severe pulmonary hypertension, and cardiac disease.

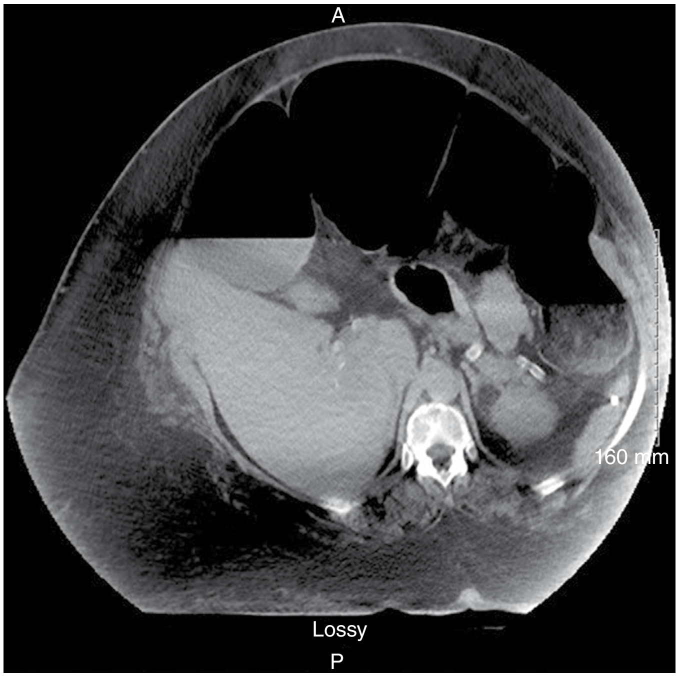

FIGURE 95.32 Computed tomography scan showing massively distended colon without sign of ischemic change.

Neostigmine is the keystone of pharmacologic decompression therapy. It is an acetylcholinesterase inhibitor that stimulates the muscarinic receptors and enhances colonic motor activity. Neostigmine is given as a 2- to 2.5-mg IV bolus injected over 3 to 5 minutes and results in significant parasympathetic stimulation, causing strong colonic peristalsis that usually leads to subsequent flatus and bowel movements. It has been found to be a safe and effective option for patients with acute colonic pseudoobstruction who have failed conservative management. Success rates for neostigmine treatment range from 60% to 94%, with recurrences observed in up to 31% of patients, with some patients requiring multiple drug administrations. Neostigmine is contraindicated in mechanical bowel obstruction and in patients with signs of ischemia or perforation. It should be used with caution among patients with asthma, chronic obstructive lung disease, bradycardia, and recent acute coronary syndrome and in those with renal failure. Neostigmine should be given in a monitored setting with atropine immediately available. Common side effects include vomiting, crampy abdominal pain, excessive salivation, and bradycardia. Colonoscopic decompression should be considered in patients with contraindications to neostigmine or for those who are unresponsive to it. The aim of endoscopic decompression is to advance the scope to the right colon with minimal insufflation and use of narcotics and place a colonic decompression tube while removing as much gas as possible from the colon. Endoscopic decompression has a high success rate of 61% to 95% for initial decompression and 70% to 90% for sustained decompression. Colonoscopic perforation rates after decompression for pseudoobstruction are in the range of 1% to 3%.

Patients who do not respond to other lines of treatment or those who demonstrate signs of systemic toxicity, ischemia, or perforation require surgery. Surgical options are determined according to the condition of the colon and the patient. If the colon is viable, tube cecostomy or cecostomy can be performed, with high rates of success. For patients with signs of ischemia or perforation, a resection, usually with a diverting stoma, is recommended.

INFLAMMATORY BOWEL DISEASE

Epidemiology and Etiology

IBD, which includes both UC and Crohn disease, is largely a disease of the Western world. As Asian countries are adopting a more Western diet, the incidence of these disorders is increasing in these countries as well. The prevalence of IBD in Western countries is approximately 0.5% of the general population.[38] In the United States, over 1 million individuals are estimated to have IBD, with over 200,000 Canadians affected and 2.5 to 3 million individuals in Europe having these disorders.[38] The highest incidence of UC has been reported in Europe, followed by the United States, whereas for Crohn disease, the highest incidence was observed in the United States, followed by Europe. Europe was noted to have the highest prevalence of IBD. Over time, the incidence of both disorders appears to be increasing. Both disorders appear to have a genetic predisposition, with many contributing environmental factors. Over 10% of patients with IBD have a family history of IBD. To date, genome-wide association studies have linked to over 230 IBD susceptibility loci.[39] Cigarette smoking is the most studied environmental factor, having opposite effects in UC and Crohn disease. In UC, smoking tends to suppress symptoms, whereas in Crohn disease, smoking tends to exacerbate symptoms. Antibiotic use in early life has also been thought to predispose to IBD, as has NSAID use.

Disease Distribution and Classification

The extent of UC can also be graded with respect to the extent of inflammation within the colon. It can be limited only to the rectum and sigmoid colon (proctitis or proctosigmoiditis), restricted to the left side of the colon, or extended to involve the entire colon (pancolitis).

There are many classification schemes for Crohn disease. However, one of the most popular was initially the Vienna Classification, which was later updated to the Montreal Classification. With these classification schemes, patients are classified according to age of onset of disease, bowel location of their Crohn disease, and type of disease behavior. In addition to the different ages of onset, the Vienna Classification divided patients into whether or not they develop inflammatory Crohn disease at the age of 40 or later. The Montreal Classification subdivides this into less than 20 or greater than 20 years old. In addition, the Montreal Classification adds a further subdivision of whether the patients have perianal Crohn disease. The three different types of behavior classifications for Crohn disease that are possible include inflammatory Crohn disease, fibrostenotic Crohn disease, and fistulizing Crohn disease. Many people feel that these three types of disease behaviors represent different time points in the progression of disease. In other words, a patient is initially diagnosed with inflammatory Crohn disease, which, over time, progresses to fibrostenotic Crohn disease. This, in turn, will frequently progress to an obstruction, with perforation proximal to the obstruction and abscess formation. When this abscess spontaneously drains into an adjacent structure or organ, fistula formation ensues. In this manner, there is a progression from inflammatory to fibrostenosing to fistulizing Crohn disease. It is with this thought in mind that the progression to "top-down" medical therapy has evolved (see the section "Medications for Treatment of IBD"). The goal is to interrupt this natural progression or cycle in the course of Crohn disease to prevent the progressive fibrosis that results in many of the complications leading to surgery.

Clinical Presentation and Disease Diagnosis

Clinical Presentation

Clinical presentation of both diseases can be similar. Diarrhea can be a presenting symptom in both diseases; however, this is typically more prevalent and severe in UC, where the diarrhea is characteristically bloody. Significant hemorrhage is much more common with UC than with Crohn disease. Typical UC symptoms also include tenesmus and urgency as well as associated anemia. In Crohn disease, symptoms of abdominal pain may predominate. In any patient initially presenting with diarrhea, stool cultures should first be obtained to exclude the presence of infectious causes of diarrhea, such as *Salmonella, Giardia,* or community-acquired *C. difficile,* which is now increasingly seen. Patients with Crohn's disease may present with a palpable abdominal mass resulting from an intraabdominal abscess or have an external fistula. Roughly 25% of patients with Crohn disease will have associated perianal disease. This can include a variety of problems, including anal fissure, which, in contrast to patients without Crohn, is often not painful and may be multiple and/or in atypical locations (lateral and not posterior/anterior location). In addition, these patients can present with large anal skin tags (Fig. 95.33), which are not true external hemorrhoids. As a rule, these should not be excised because they may lead to very delayed wound healing. These patients may also present with anorectal abscesses, fistula(s) (Fig. 95.34), and anal stenosis. Digital rectal examination should always be performed.

Extraintestinal manifestations. Extraintestinal manifestations can occur in many IBD patients, and it is estimated that up to half of IBD patients will have one or more extraintestinal manifestations. Data suggest the prevalence of at least one joint, ocular, or skin extraintestinal manifestation to be 24% in all cases of IBD, 27% in UC, and 35% in Crohn disease. Arthritis is by far the most common extraintestinal manifestation. One of the most common manifestations is sacroiliitis. One of the most serious joint manifestations is ankylosing spondylitis, which runs a course independent of the bowel disease. These patients are HLA-B27 positive and may present in advanced cases with decreased cervical flexion, which has important anesthetic implications for intubation. These patients may require fiberoptic intubation and will require specific preoperative anesthesia evaluation.

Cutaneous extraintestinal manifestations include erythema nodosum and pyoderma gangrenosum. From the long experience of treating surgical patients with IBD, pyoderma is much more frequent than erythema nodosum. Erythema nodosum (Fig. 95.35) is characterized by red, painful, swollen nodules that can occur and

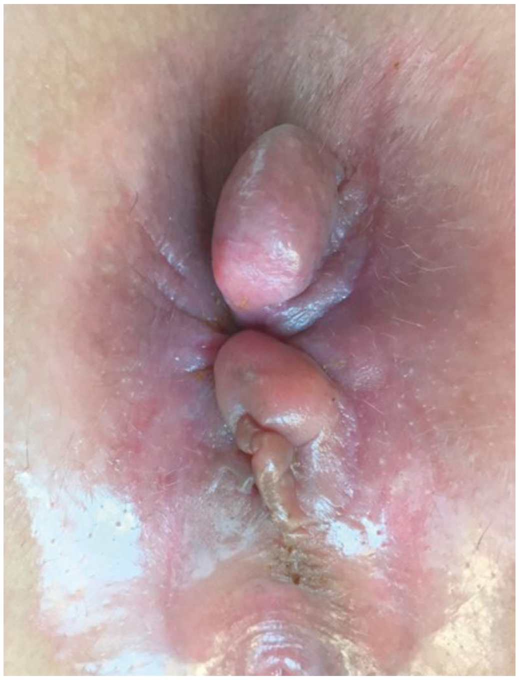

FIGURE 95.33 Large anal Crohn tags. Note the bluish coloring and waxy appearance of the perianal skin.

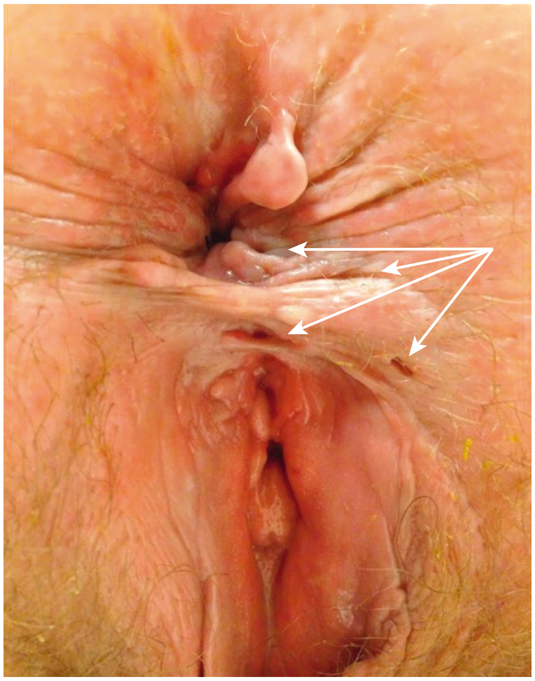

FIGURE 95.34 A female with significant fistulizing perianal Crohn disease. Note the multiple external fistula openings shown by the *white arrows*. These all had a common internal opening in the anterior midline, which was also associated with a rectovaginal fistula. This patient ultimately elected to undergo ileostomy diversion.

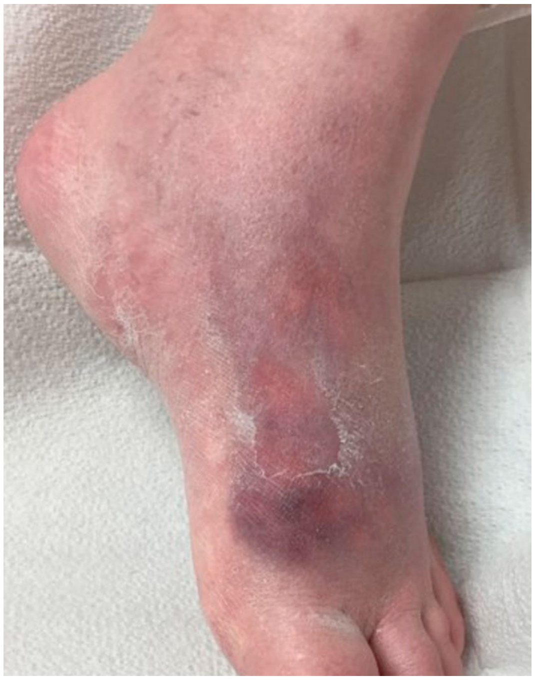

FIGURE 95.35 A patient with a Crohn disease flare and active erythema nodosum. Note the red-purplish nodule on the dorsum of the foot.

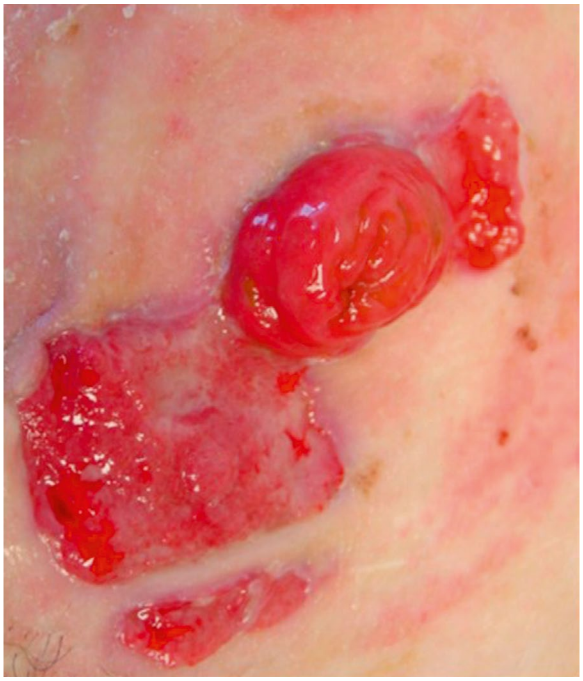

FIGURE 95.36 Pyoderma gangrenosum adjacent to an end ileostomy in a patient with Crohn disease. Here, the lesions have started to heal with granulation tissue.

usually will respond to systemic steroid administration, whereas pyoderma gangrenosum is characterized by typically extremely painful ulcerating lesions that frequently occur at sites of repeated trauma, such as in the vicinity of surgical incisions or, more frequently, around intestinal stomas (Fig. 95.36). There is a phenomenon called *pathergy*, which refers to a worsening of the pyoderma with any type of surgical manipulation or debridement. These lesions are therefore best treated by nonoperative means, which can include intralesional steroid injections (e.g., triamcinolone), topical (tacrolimus 0.1%), or systemic biologic therapy (anti–tumor necrosis factor

[TNF] antibodies or similar agents). Such treatment will typically result in symptom resolution.

Ocular manifestations of UC can include uveitis, iritis, and episcleritis. Some of these can lead to significant irritation and require referral to an ophthalmologist.

Sclerosing cholangitis is estimated to affect approximately 2.16% of patients with IBD. Pooled prevalence in patients with UC, Crohn disease, and IBD-unclassified is 2.47%, 0.96%, and 5%, respectively.[40] It has a course that is curiously independent of the IBD. At its worst, it can progress to cirrhosis, result in liver failure, and require hepatic transplantation. Patients with sclerosing cholangitis are at higher risk for developing colorectal neoplasia, as will be discussed later, and are also at higher risk of developing pouchitis, as will be discussed in the section on IPAA and surgical treatment.

Disease Diagnosis

Endoscopy. The diagnosis of IBD is usually made by endoscopy. This can be accomplished by either rigid proctoscopy, flexible sigmoidoscopy, or colonoscopy. Generally, a complete evaluation of the colon with colonoscopy is performed to both evaluate the extent of the disease and examine the terminal ileum.

With UC, inflammation begins at the level of the dentate line and extends proximally, whereas in Crohn disease, in many cases, the inflammation is patchier, and there can be discontinuous inflammation (skip areas), with areas of intervening normal-appearing mucosa. In some cases, differentiation between the two diseases can be difficult, both endoscopically and histologically. A typical endoscopic view of UC is shown in Fig. 95.37. Note the more roughened or granular appearance of the colonic mucosa. One of the most common scoring systems for endoscopic assessment of UC is the Mayo Clinic Scoring System, which grades the endoscopic findings based on the severity of the mucosal ulceration or the absence thereof. Grade 1 refers to a normal endoscopic appearance, grade 2 refers to slightly more erythematous, grade 3 refers to even more erythematous area with touch bleeding, and grade 4 refers to significant bleeding and friability. As the disease becomes more severe, there is an increasingly erythematous appearance of the mucosa with progressive mucosal ulceration.

With respect to endoscopy, Crohn disease is more characterized by deeper, punched-out-appearing ulcerations. In these cases, there are often longer serpiginous ulcerations covered with fibrin. These can oftentimes extend longitudinally along the lumen of the bowel, in which case they are sometimes referred to as *bear claw* ulcerations (Fig. 95.38). In many cases, Crohn disease ulcers are worse on the mesenteric side of the bowel. Regarding the distribution of Crohn disease, the most common site of involvement in nearly half of patients is ileocolic, followed by colonic involvement. Crohn disease can also affect the small bowel or upper GI tract.

Histologic evaluation. In UC, colonic mucosal biopsies will typically show significant inflammation with the presence of multiple polymorphonuclear leukocytes within the lamina propria. There may be depletion of mucin in goblet cells. One can also identify crypt abscesses, although this is somewhat of a nonspecific finding. As a rule, inflammation in UC is restricted to the surface epithelium (Fig. 95.39). The disease process is limited to the large intestine. Proximal colonic disease occurs in continuity with an involved rectum (no gross or histologic skip lesions). The inflammation is characterized by the absence of mural sinus tracts, deep fissural ulcers, and granulomas, as well as by the absence of transmural lymphoid aggregates in an area not deeply ulcerated.

In contrast, in patients with Crohn disease, there is often transmural inflammation, which is seen in histologic evaluation of resected specimens. In approximately one-third of patients, there are noncaseating granulomas (Fig. 95.40). In biopsy specimens, the diagnosis of Crohn disease is made in the presence of nonnecrotizing granulomas or the presence of transmural lymphoid aggregates in an area not deeply ulcerated. In patients with Crohn disease, just as one can macroscopically see “skip” disease with patchy inflammation, the same is true on microscopic evaluation. The term *focal active enteritis* is used. The differential diagnosis frequently includes infectious colitis or drug-induced colitis, and pathology reports often include this differential diagnosis when areas are biopsied during GI endoscopy. In patients who are suspected of having Crohn disease, it is important to make an effort to intubate the terminal ileum because this is a common site of disease involvement.

IBD undetermined refers to a subset of patients who have overlapping characteristics of both Crohn disease and UC on endoscopic biopsy. It is thought that up to 10% to 15% of patients fall into this category. The diagnosis of **indeterminate colitis** is made in patients in whom there is uncertainty of the diagnosis on evaluation of the colectomy specimen because histologic features of both Crohn and UC are seen. Overall, this diagnosis is more likely in patients with fulminant disease, where the significant amount of inflammation interferes with precise disease diagnosis.

Medical Treatment

Changing medical treatment philosophy. The past two decades have seen a tremendous change in medical treatment for IBD. There has been a gradual evolution from a *bottom-up* approach to what is termed a *top-down* approach. The bottom-up approach begins with the safest, least expensive medications first and only proceeds to the more potent, more expensive medications with a higher side-effect profile once these have failed. This treatment approach has been largely replaced by the top-down approach, whereby patients are initially treated with the stronger, more potent medications, which may, in turn, have a greater side-effect profile and are associated with higher costs. Many of these drugs have been implicated in the higher rate of postoperative complications in patients undergoing surgery, and their use has also been associated with reactivation of certain remote infections. It is important for the surgeon to be aware of these medications and knowledgeable about their mechanism of action. Table 95.3 lists some of the medications more commonly used in the treatment of IBD. The surgeon will find that these medications are being used increasingly not only in patients with IBD but also in patients with rheumatoid arthritis and psoriasis. Medical therapy formerly was based largely on medications such as sulfasalazine and steroids. However, the past 25 years have seen a revolution with the introduction of "biologic therapy," based largely on treatment with antibodies directed against TNF-α (anti–TNF-α). This began with the US Food and Drug Administration (FDA) approval for infliximab (chimeric anti-TNF antibody) for Crohn disease in 1998; followed by adalimumab (humanized anti-TNF antibody) in 2007; certolizumab pegol (a PEGylated Fab' fragment of a humanized TNF antibody) and natalizumab (humanized monoclonal antibody to α4-integrin), both in 2008; golimumab (human monoclonal anti-TNF) approval for UC in 2013; vedolizumab (monoclonal antibody to integrin α4β7) in 2014; ustekinumab (human monoclonal antibody to p40 protein subunit used by interleukin [IL]-12 and IL-23) in 2016; and tofacitinib (Janus kinase [JAK] inhibitor) approval for UC in 2018, ozanimod (sphingosine 1-phosphate [S1P] receptor modulator) in 2021, upadacitinib (JAK inhibitior) in 2023 and risankizumab (human monoclonal antibody binding the p19 subunit of IL-23) in 2024. Currently, there is a wide assortment of drugs to

TABLE 95.3 **Different Types of Medical Treatment Used for Inflammatory Bowel Disease**

DRUG CLASS	EXAMPLES	INDICATION	ADMINISTRATION
Biologics	Infliximab	UC, CD	IV
	Adalimumab	UC, CD	SC
	Cetrolizumab	CD	SC
	Golimumab	UC	IV
	Natalizumab	UC, CD	IV
	Risankisumab	UC	SC
	Upadacitinib	UC	PO
	Ozanimod	UC	PO
	Vedolizumab	UC, CD	IV
	Ustekinumab	UC, CD	IV, SC
Antiinflammatory	Sulfasalazine	UC, CD	PO
	Mesalamine	UC, CD	PO, enema, suppository
Immunosuppressives	Conventional steroids	UC, CD	PO, IV, suppository
	Budesonide	UC, CD	PO, rectal foam
	Antimetabolites	UC, CD	PO
	Tofacitinib	UC	PO
Probiotics	*Lactobacillus* *Bifidobacterium*	UC, CD	Food, tablets, capsules, powders
Antibiotics	Ciprofloxacin	UC, CD	PO, IV
	Metronidazole	UC, CD	PO, IV
	Rifaximin	Off-label	PO

CD, Crohn disease; *IV*, intravenous; *PO*, per os; *SC*, subcutaneous; *UC*, ulcerative colitis.

choose from. There has also been a change in the philosophy of treatment with respect to IBD.

Medications for treatment of IBD

Aminosalicylates. Sulfasalazine has long been used for the treatment of colonic IBD. Originally used as a treatment for arthritis, it was noted that many arthritis patients with coexisting IBD noted an improvement in the latter when taking this medication. Use of this drug was limited by its sulfapyridine ring, which excludes use in patients with sulfa allergies. When this medication is used, patients require folic acid supplementation. Eventually, the sulfapyridine ring is cleaved, leaving the active 5-aminosalicylate (5-ASA) moiety. Pharmacologists rapidly realized that depending on how this drug was formulated, its delivery could be targeted to different portions of the GI tract. For example, mesalamine (Pentasa) begins to dissolve in the stomach and releases drug throughout the GI tract, whereas Asacol begins to be released in the terminal ileum by means of a pH-dependent mechanism and coats the entire colon. Drugs manufactured with an "MMX technology" are designed as once-a-day preparations and formulated so that they slowly dissolve, thus releasing medication throughout the colon. For this reason, they are thought to have greater patient compliance. There are also topical formulations of these medications for distal disease. Suppository formulations are administered at bedtime. While the patient sleeps, the suppositories melt and coat the rectum with mesalamine, which has a very potent antiinflammatory effect. The most popular brand of suppository is Canasa. The same medication in small-volume enema form (Rowasa enemas) can also be administered at bedtime. The patient is advised to lie on their left side, allowing the small volume of fluid to be delivered not only to the rectum but also the sigmoid and, in some cases, the left colon. These medications are most effective for mild to moderate disease.

Corticosteroids. If the patient has severe disease, steroids still play a prominent role in the treatment of IBD. Although they have numerous side effects, they are inexpensive, act quickly, and are readily available, not requiring lengthy insurance preauthorizations as with the more expensive biologic medication alternatives. The recognized side effects of steroids include:

- Cushingoid appearance that is very unpopular, particularly among young patients
- Feared complication of aseptic necrosis of the hips
- Hypertension
- Mood changes that can escalate up to actual psychiatric conditions
- Hyperglycemia
- Increased risk of infectious complications after surgery
- Cataract formation
- Striae and others

Because of these complications, as well as the growth retardation seen when these drugs are used for prolonged periods in children, these medications should be used sparingly for as short a period as possible. Steroids are usually started at a high dose and then tapered quickly. Their main uses are either in the outpatient setting in the form of pulse therapy, as high doses that are tapered quickly, or intravenously in patients who are hospitalized with flares of their disease. In the outpatient setting, pulse therapy is usually given in the form of prednisone at doses starting at 40 to 60 mg/day, tapering by 5 to 10 mg at 2-week intervals until 10 mg/day is reached and then tapering by 5 mg every 2 weeks, at which time the drug is discontinued. In the hospital setting, 100 mg of hydrocortisone can be given intravenously every 6 to 8 hours, depending on disease severity.

Immunomodulators

Thiopurines. Thiopurines are a "steroid-sparing" class of medication that are usually begun once patients are placed on steroids and perhaps have been unsuccessful in weaning off steroids after one or two attempts at pulse therapy. Thiopurines have been used for many decades in the treatment of Crohn disease and have long been used in the organ transplant population. Two drugs fall into this category: azathioprine and its metabolite 6-mercaptopurine. The side effects of this therapy include leukopenia and pancreatitis. These side effects are largely seen in individuals who are homozygous for a variant of the enzyme thiopurine methyltransferase, which is responsible for metabolizing these drugs poorly. For this reason, many physicians now routinely perform thiopurine methyltransferase genotyping of patients to see whether they will be able to metabolize these drugs properly before initiating thiopurine treatment. These drugs have several advantages in that they are readily available and are an oral medication taken once a day, and dosing is based on body weight. On the downside, once a patient begins therapy, there is usually a 3- to 4-month lag time until these medications exert their therapeutic effect. For this reason, these medications cannot be used to treat a flare. Long-term thiopurine use is also associated with a higher risk of developing non-Hodgkin lymphoma compared with the general population.

Methotrexate. Methotrexate is another commonly used immunosuppressive for the treatment of IBD. This medication, which has long been used, particularly in the treatment of patients with arthritis, can be dosed either orally or intramuscularly. Intramuscular dosing is particularly convenient in patients who have problems with significant diarrhea or absorption issues (e.g., short bowel syndrome). The side effects of methotrexate include elevations in liver function tests, as well as pulmonary fibrosis. When methotrexate is given, patients require folic acid supplementation.

Biologics in the Treatment of Inflammatory Bowel Disease

The term *biologics* as it pertains to drugs used for IBD initially referred to monoclonal antibodies.[41] The first such agent, infliximab, a targeted therapy against TNF-alpha, was approved by the FDA for use in 1998. Since then, there has been a continued increase in both the number and type (based on mechanism of action) of medications that have been approved (see Table 95.3). The side effects of these drugs include reactivation of infections, including tuberculosis, histoplasmosis, actinomycosis, and hepatitis. For this reason, a careful patient history regarding these infections should be taken before consideration of treatment. In addition, before starting these drugs, the patient should either have a tuberculin skin test or undergo testing with QuantiFERON gold assay, and a hepatitis profile should be obtained. There is currently no accurate test for past exposure to histoplasmosis. In addition, these types of agents, similar to the thiopurines, can be associated with a higher risk of developing non-Hodgkin lymphoma compared with the general population. In addition, anti–TNF-α antibody has been associated with a low risk of hepatosplenic T-cell lymphomas, particularly in young males who have been taking anti-TNF antibody therapy in combination with other immunosuppressive therapy, such as a thiopurine.

In the past decade, new therapies have emerged as alternatives to traditional anti-TNF medications, including (JAK inhibitors, anti-α4 integrins, and anti-ILs). Commonly known JAK inhibitors include tofacitinib and upadacitinib. These drugs target the JAK-STAT signaling pathway, which plays a pivotal role in immune cell function and inflammatory responses. By inhibiting JAK enzymes, these medications modulate the immune response, offering relief from inflammation. Another class of drugs, the anti-α4 integrins, such as vedolizumab, specifically target cell adhesion molecules involved in leukocyte migration to the inflamed gut tissue, thereby reducing gut-specific inflammation without compromising systemic immunity. Lastly, anti-IL agents, which include such drugs as ustekinumab and risankizumab, target specific interleukins, namely, IL-12 and IL-23. These cytokines are involved in cell signaling of immune responses, and by inhibiting their action, anti-IL agents help modulate the immune response and reduce inflammation in IBD.

Assessment of Symptom Severity

The Truelove and Witts is a popular classification scheme that characterizes patients by the severity of their diarrhea and the presence of blood in stool, fever, tachycardia, anemia, or an elevated erythrocyte sedimentation rate. Many similar classification schemes are used, in addition to analyzing stool samples for either fecal calprotectin or lactoferrin, which can be used as an inflammatory marker to assess disease activity. With Crohn disease, both the Crohn's Disease Activity Index (CDAI) and the Harvey Bradshaw Index have been used to quantitate symptoms.[42] The CDAI is made up of eight clinical and laboratory variables, including the number of bowel movements per day, the presence of abdominal pain, hematocrit, and weight loss. A score of less than 150 indicates clinical remission, and a score of more than 450 denotes severe disease. Because the CDAI requires a 7-day patient symptom diary, the Harvey-Bradshaw Index was proposed as a modification of this scheme that only uses clinical data.

Indications for Surgery for Ulcerative Colitis

There are several indications for surgery for UC, the foremost of which is failure to respond to maximum medical therapy. The frequency of surgery for UC has actually decreased over the last several decades with the improvement in efficacy and the number of new and more effective medical options, such as the entire class of biologic therapies. However, despite these new therapies, patients still present with a failure to respond. Patients falling into this category include those patients who have severe disease, namely, those patients with multiple bowel movements, poor nutritional status, "failure to thrive," and a need for surgery in order to regain their good physical health. These patients have a very poor quality of life with urgency, tenesmus, and low body weight; surgery represents a significant improvement in the quality of life. The second group of patients failing to respond to maximum medical therapy includes patients with fulminant colitis. These patients have such severe disease that they need to be hospitalized and placed on IV steroids. In some cases, they have received in-hospital biologic therapy; in rare cases, these patients may be receiving IV cyclosporine as an attempt to avert colectomy. In these patients with fulminant colitis, toxic megacolon may be present (Fig. 95.41). Fulminant colitis has been arbitrarily defined as having three or more of the following criteria present: tachycardia greater than 100, leukocytosis greater than 12,000/dL^3, hypoalbuminemia less than 3 g/dL^3, a temperature greater than 38°C, or a diameter of the transverse colon greater than 5 cm on a plain abdominal radiograph. Three or more of these criteria meet the definition of toxic megacolon; note that a "megacolon" does not need to be present in order to meet this definition. Thus, the definition of toxic megacolon merely refers to a patient who is septic as a result of very severe colitis. Toxic megacolon can be present not only from severe UC but also from severe Crohn colitis or severe infectious or ischemic colitis. When the colitis is severe enough, it is associated with a significant colonic ileus, and in these cases, the colon becomes dilated, and there is a significant risk of colonic perforation. The next category of indication for surgery occurs in patients in whom there is significant GI bleeding. Recalling basic anatomy, the vessels located underneath the colonic vessels are located underneath the mucosa. If the mucosa

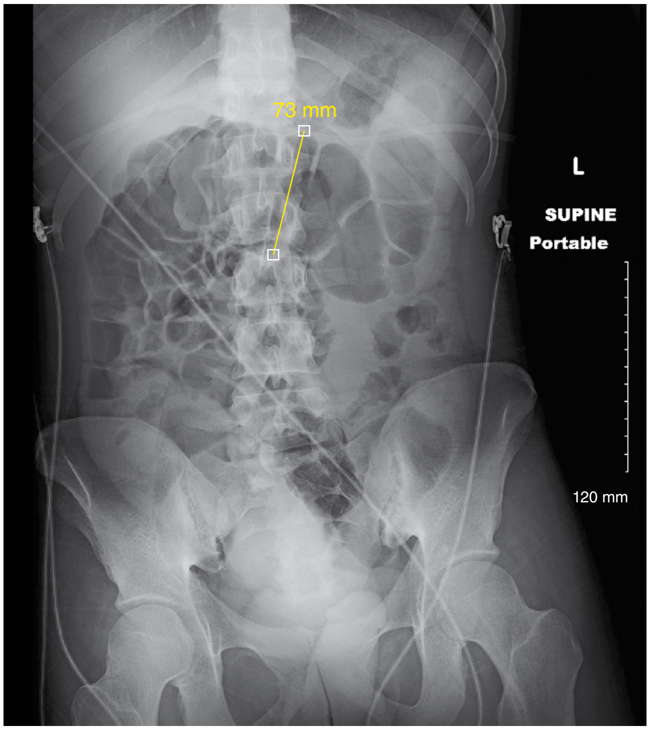

FIGURE 95.41 Toxic megacolon. Abdominal film shows significant distention of the transverse colon in a 20-year-old male with toxic megacolon. (From Rojas-Khalil Y, Galandiuk S. Management of chronic ulcerative colitis. In: Cameron JL, Cameron A, eds. *Current Surgical Therapy*. 13th ed. Philadelphia: Elsevier; in press.)

sloughs, this will, in effect, expose the underlying blood vessels of the colon and can result in massive GI hemorrhage if an ulcer erodes into these vessels. Significant hemorrhage can be one of the reasons for urgent surgery with UC, although the frequency of this complication has decreased over time. Another indication for surgery in children with UC is failure to grow, which is also an indication for surgery in patients with Crohn disease. The presence of dysplasia or cancer is also an indication for surgery. Patients with longstanding UC (>8 years) have a high risk of developing dysplasia or cancer, as do those who have sclerosing cholangitis. Once the disease has been present longer than 8 years, patients are advised to undergo regular (yearly) colonoscopic surveillance with or without chromoendoscopy. If multiple areas of low-grade dysplasia or areas of high-grade dysplasia (Fig. 95.42) are found, a colectomy is recommended to prevent the development of invasive adenocarcinoma. The finding of colonic dysplasia in patients with longstanding UC is an indication for surgery that has undergone significant change over the last 20 years. Whereas past reports estimated a 2%, 8%, and 18% cumulative risk of CRC at 10, 20, and 30 years post-UC diagnosis, respectively, recent meta-analyses suggest a reduced cumulative risk of 1%, 3%, and 7%, respectively, at the same intervals.[43] There is currently somewhat of a controversy as to exactly who requires surgery and who requires continued observation with close surveillance. The current guidelines from the ASCRS published in 2021 state that patients with visible polypoid or nonpolypoid dysplasia that is completely excised endoscopically should undergo endoscopic surveillance. Patients with visible dysplasia not amenable to endoscopic excision, invisible dysplasia in the flat mucosa surrounding a visible dysplastic lesion, or colorectal adenocarcinoma should typically undergo total proctocolectomy with or without IPAA. The changes in the management strategy for dysplasia in UC patients depend on the visibility of the dysplasia and the complete excision of visible lesions. Endoscopic excision is preferred when expertise is available, with en bloc removal favored for thorough histologic evaluation. After dysplasia identification, patients face a heightened risk of recurrent dysplasia, necessitating close endoscopic surveillance. In certain scenarios, total proctocolectomy is recommended because of the increased risk of CRC.

The current guidelines recommend referral of patients with invisible dysplasia (detected with random biopsies) to an experienced endoscopist for repeat endoscopy using high-definition

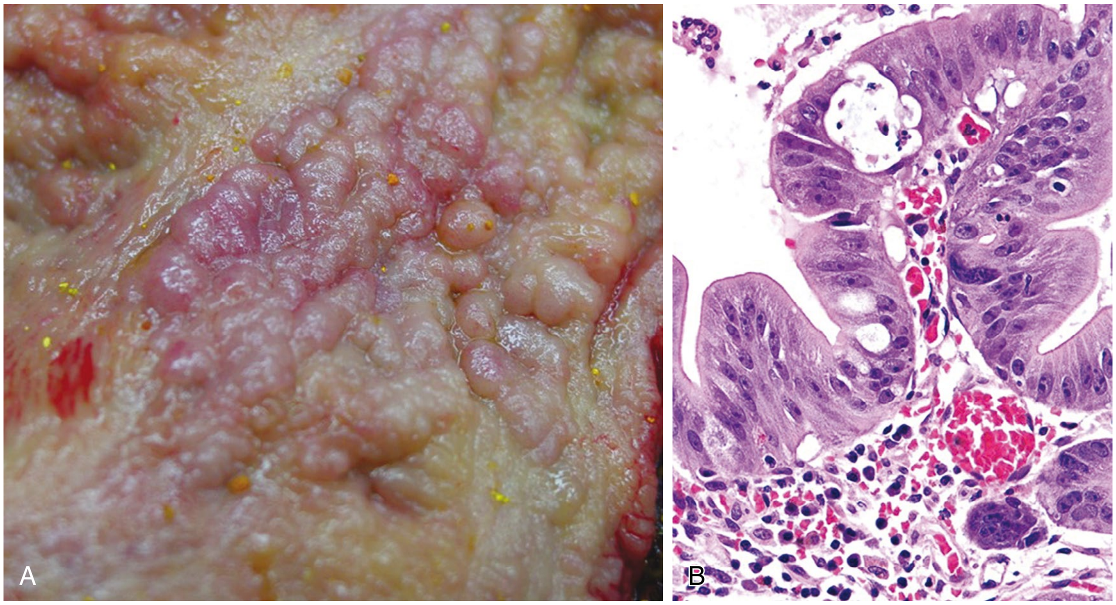

FIGURE 95.42 (A) A dysplasia-associated lesion or mass (DALM) in a patient with long-standing ulcerative colitis and sclerosing cholangitis. (B) High-grade dysplasia within a DALM in a patient with long-standing ulcerative colitis and sclerosing cholangitis.

colonoscopy with chromoendoscopy, with targeted and repeat random biopsies within 3 to 6 months. Patients confirmed to have invisible multifocal, low-grade dysplasia or any invisible high-grade dysplasia should typically be considered for total proctocolectomy.[44] Much of this has arisen as a result of the development of high-definition colonoscopy, as well as the development of techniques of surveillance such as chromoendoscopy. Chromoendoscopy involves the performance of colonoscopy with the spraying of dyes, such as methylene blue or indigo carmine, onto the colonic mucosa at the time of colonoscopy to highlight areas suspicious for dysplasia to permit targeted biopsies rather than just performing the random biopsies that were previously the standard of care. In addition to this, there has been recognition that there are different types of dysplasia. The flat dysplasia that is difficult to detect and blends in with the surrounding mucosa is very different from the “polypoid” dysplasia that is apparent and can be treated in many cases like a polyp and removed using techniques similar to those used for removal of a conventional polyp during colonoscopy. In some studies, patients with UC have undergone “polypectomy” removal of dysplastic lesions and have been followed long term without interval development of cancer.[45] What is important to stress is that patients must have very close follow-up colonoscopy and that meticulous colonoscopy and pathology expertise are vital to this process, as is excellent patient compliance. If any one of these three factors is lacking, this is clearly not a viable treatment alternative. There is, however, still agreement that if there are multiple areas of flat dysplasia within the colon, colectomy is indicated. There is still much to be learned regarding the actual risk of cancer in patients with IBD. Overall, it is felt that approximately one-fifth of the world’s cancers arise in the setting of chronic inflammation. This mirrors the problem with hepatitis, anal cancer, gastric cancer, and many others. With the advent of better medications and interruption in this chronic cycle of inflammation, it will be interesting to see whether the incidence of cancer and IBD begins to decline compared with historical data. The same is true regarding the indication for failure to grow in children. As more effective medications are identified and are able to be instituted at earlier ages, it is anticipated that there will be less of an indication to operate in these young patients.

Similarly, if an adenocarcinoma is identified, colectomy is indicated. In certain patients, the presence of severe extraintestinal disease is also an indication for surgery. In some cases, severe extraintestinal disease will respond to surgery; however, there are some cases in which the extraintestinal disease has a course relatively independent of the colon.

Indications for Surgery for Crohn Disease

Unlike indications for surgery for UC, indications for surgery for Crohn disease are generally reserved for complications of the disease. Similar to UC, surgery is also performed in children with Crohn disease when they show failure to grow. In addition, surgery is frequently performed for symptoms of obstruction secondary to fibrostenosing Crohn disease (Fig. 95.43). In addition, if patients have a perforating Crohn disease associated with abscess or fistula, surgery may be indicated. The presence of many types of fistulas is also a relative indication for surgery. For example, the presence of a symptomatic ileal sigmoid fistula resulting in significant diarrhea bypassing the entire colon can be an indication for surgery. The occurrence of enterocutaneous fistulas is an indication for surgery. Enteroenteric fistulae are not an indication for surgery unless they are associated with significant symptoms of obstruction or discomfort. The presence of significant abdominal pain associated with obstruction is considered an indication for surgery. Patients with Crohn disease who have associated cancer or dysplasia, as with patients with UC, are an indication for surgery. In patients with UC, areas of dysplasia in the colon can be multifocal, and for this reason, if this occurs in the colon, a total proctocolectomy is considered preferable to a segmental resection.

Optimizing patients with Crohn disease before surgery plays a pivotal role in enhancing postoperative results. Antibiotics are often administered to control any active infection or abscess, as well as to decrease intestinal bacterial load, leading to a reduction in postoperative infection rates. In the event of an abscess formation, percutaneous drainage under radiologic guidance typically acts as the first-line treatment, helping manage the infection and bolstering the patient’s condition presurgery, thereby minimizing the potential for septic complications.

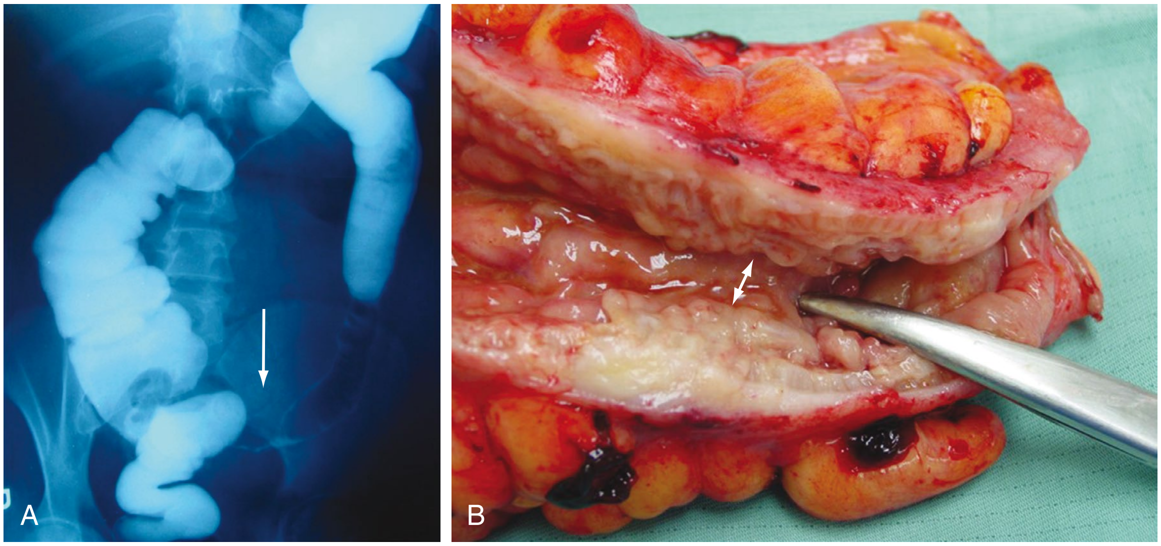

FIGURE 95.43 (A) Gastrografin enema showing significant stricture *(arrow)* of sigmoid colon secondary to Crohn disease. (B) Segmental colonic resection for fibrostenotic disease. Note the significant wall thickening and narrowed lumen *(arrow)* and its size compared with the tip of the scissors.

Malnutrition, a frequent issue with Crohn disease resulting from malabsorption and active disease, necessitates preoperative nutritional support. Both enteral and parenteral nutrition can boost nutritional status presurgery, promoting wound healing, immune function, and overall patient outcomes. Biologic agents and corticosteroids often used for Crohn disease management may increase postoperative complication risks, necessitating careful preoperative management. Biologics usually need to be discontinued for a period before surgery, whereas a gradual tapering is recommended for corticosteroids to avoid adrenal insufficiency. Lastly, patients with Crohn disease, and even more so in patients with UC, as a result of inflammation-induced hypercoagulability, are at elevated risk for DVT. Hence, DVT prophylaxis should be started before surgery to mitigate this risk. This multifaceted preoperative care requires careful management tailored to the patient's specific clinical scenario, involving a multidisciplinary team encompassing gastroenterologists, surgeons, radiologists, and dietitians.[46]

Surgical Options for Ulcerative Colitis

There are several operations that are currently performed for UC. These possibilities include subtotal colectomy, ileostomy, and Hartmann's procedure, frequently performed for fulminant disease. Total proctocolectomy with end ileostomy and proctocolectomy with either stapled or hand-sewn IPAA are commonly performed in the elective setting. Subtotal colectomy and ileal rectal anastomosis and total proctocolectomy with continent ileostomy are less commonly performed procedures. We discuss these in order next.

Subtotal/Total Colectomy With End Ileostomy

Subtotal/total colectomy and ileostomy and Hartmann's procedure is the treatment for patients with fulminant colitis not responding to maximal medical therapy. The term *toxic megacolon* has long been used to refer to a condition arising when patients become toxic from colitis irrespective of its etiology (e.g., whether this be UC, Crohn colitis, infectious, or ischemic). In any of these conditions, as the mucosa sloughs, the endotoxins within the bowel lumen are absorbed, leading to a septic state characterized by leukocytosis, tachycardia, fever, and in severe cases, hemodynamic instability. Many of these patients have protein-losing enteropathy and have associated hypoalbuminemia. If the colitis is severe enough to have an associated colonic ileus, this is apparent on an abdominal film with an increased diameter of the transverse colon (>5 cm). The definition of toxic megacolon is made when any three of these five factors are present. It is important to realize that a patient can have toxic megacolon without having a "megacolon" (specifically, patients can be "toxic" or septic from their colitis). When patients begin exhibiting symptoms of toxic megacolon, prompt surgery is indicated in order to prevent colonic perforation. With the improved medical therapy, this clinical scenario is becoming less common. In performing this operation, whether performed open or in a minimally invasive fashion, it is important to be gentle with the colon because ordinary manipulation can result in perforation. If the colon is very dilated and there is loss of domain, the procedure may not be able to be safely performed in a minimally invasive fashion. One of the common complications of this procedure postoperatively is a "blowout" of the Hartmann stump, resulting in a pelvic abscess. This complication can often be avoided simply by leaving a long Hartmann stump and incorporating this into the fascial closure of the midline abdominal laparotomy wound or the specimen extraction site, depending on whether it is an open or minimally invasive procedure, and closing the incision over this. In this manner, if the stump dehisces and a wound infection develops, the wound is opened, and there is a controlled mucous fistula rather than a deep pelvic infection. Once the patient has stabilized and been weaned off immunosuppressant medications, usually after a period of 3 months, another procedure for restoration of intestinal continuity can be performed. It is important to realize that although the mid- and distal sigmoid colon may be delivered as a mucus fistula, the rectum cannot, for anatomic reasons, be extracorporealized and matured in this fashion.

Total Colectomy and Ileorectal Anastomosis

The option of ileal rectal anastomosis for the treatment of UC avoids complications of pelvic dissection, such as disturbances of sexual function in males and reduced fertility seen in females, because there is no pelvic dissection. The key to good function after this operation is proper patient selection. Patients with limited rectal involvement do best; however, that is uncommon in UC, where the worst disease is usually located distally. In addition, because the patient retains the rectum with this procedure, these patients need to undergo continued surveillance for dysplasia because they have an increased risk of cancer in the retained rectum over time.

Ileal Pouch–Anal Anastomosis

IPAA has become the most popular procedure for UC not responding to medical therapy as well as for patients requiring colectomy for the presence of dysplasia. It has several advantages over ileal-rectal anastomosis in that it removes the entire colon as well as the majority of the at-risk mucosa, depending on how the operation is performed (including stapled or hand-sewn anastomosis). IPAA was described in the mid- to late-1970s and involves removing the entire colon and the majority of the rectum. It has two essential components: proctocolectomy and creation of a small bowel reservoir using the terminal ileum. This reservoir is then either sewn or sutured to the anal canal or lower rectum. Many different configurations of pouches or reservoirs have been proposed in the past, including S pouches, W pouches, and H pouches, all with relative advantages and disadvantages. However, by far, the simplest and easiest pouch and the one with the least complications is the J pouch, which has withstood the test of time. This is created using 15-cm limbs of terminal ileum and two firings of a GIA stapler, preferably with a large caliber of 100 mm (Fig. 95.44). The apex of this J pouch is then either stapled to the distal rectum, leaving a very short rectal cuff (Fig. 95.45), or hand-sewn to the distal rectum after a 2-cm mucosectomy is performed (Fig. 95.46). Currently, the stapled approach is preferred simply because it provides superior continence and is much quicker to perform. However, in cases of dysplasia or cancer, hand-sewn approaches may still be warranted.

IPAA generally yields good functional results in patients with UC. Because many patients who are undergoing this operation are on immunosuppressives at the time of surgery or in a poor nutritional state, this operation is commonly performed with temporary fecal diversion (temporary loop ileostomy). This is in place for 2 to 3 months, during which these immunosuppressant medications are weaned and the patient regains their normal nutritional state. The temporary ileostomy can then be closed, typically without requiring a laparotomy. In patients who are *not* on immune suppression and in a good nutritional state (this usually

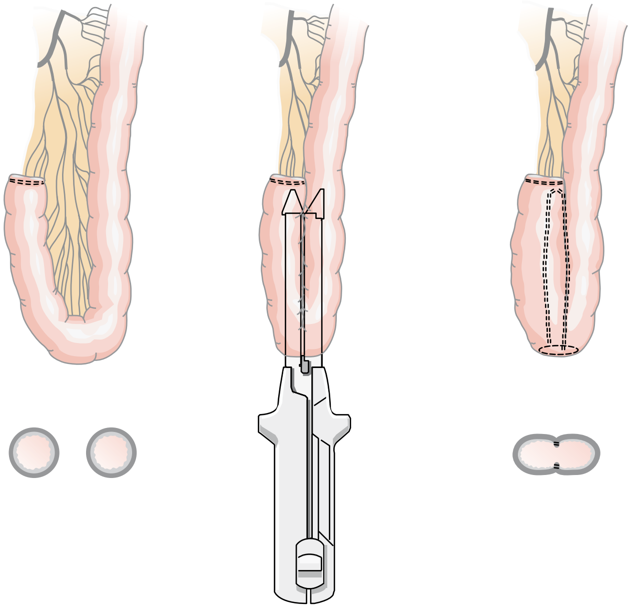

FIGURE 95.44 Creation of an ileal J pouch using a cutting linear stapler. For replacement of the rectum, a reservoir is created from the distal ileum. The stapler joins two limbs of intestine with staples while dividing the intervening wall. The diameter of the pouch is created twice as large as the original diameter of the ileum. The limbs of the J pouch should be 15 cm in length. Two fires of a linear stapler are required; either a 75- or 100-mm stapler can be used.

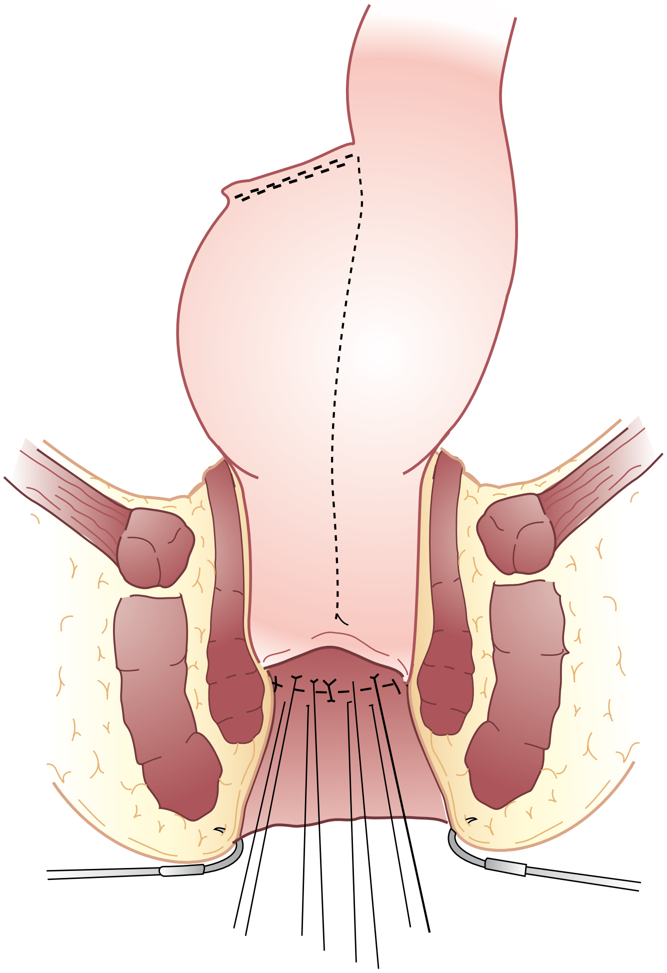

FIGURE 95.46 Hand-sewn ileal pouch–anal anastomosis after anorectal mucosectomy.

refers to patients undergoing surgery for the findings of colonic dysplasia), the operation can safely be done in one stage *without* fecal diversion, provided that there is no tension on the IPAA. Several technical maneuvers can be performed to lessen the tension on the IPAA, including mobilization of the small bowel mesentery to the level of the pancreas (Fig. 95.47). When dividing the right colon mesentery, the ileocolic vessels should be preserved in their entirety. If distal traction is placed on the apex of

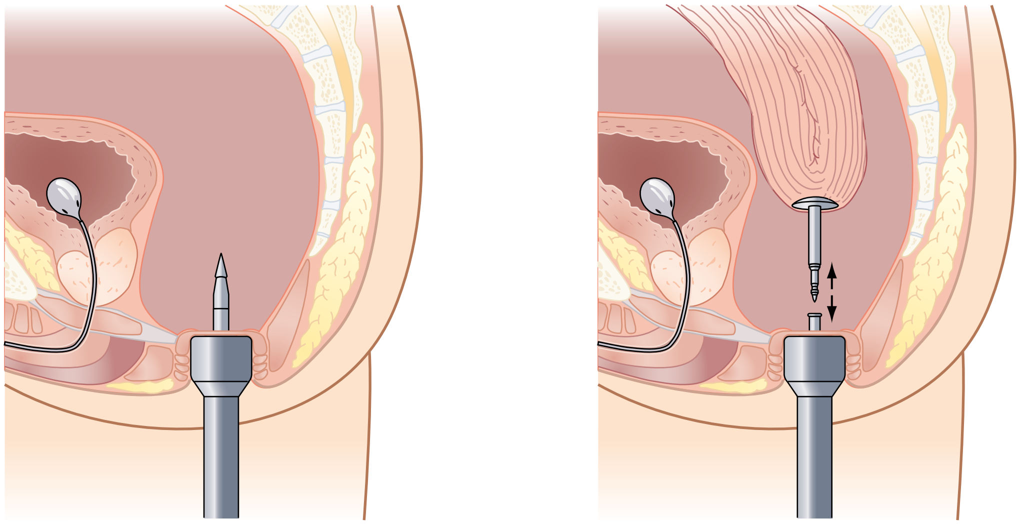

FIGURE 95.45 Fashioning of stapled ileal pouch–anal anastomosis. A circular stapler is used; typically a 29-mm stapler is selected. A common error is to leave too long a segment of rectum, resulting in the persistent symptoms from this retained segment of mucosa affected with inflammatory bowel disease (cuffitis).

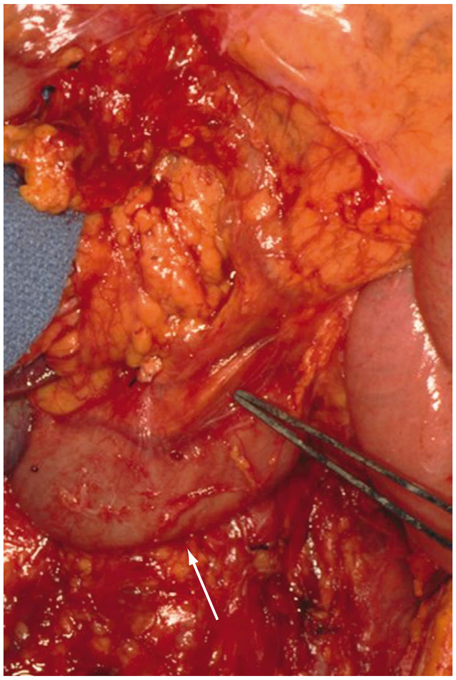

FIGURE 95.47 Mobilization of the small bowel mesentery to the third portion of the duodenum. Here the small bowel mesentery has been retracted cephalad, exposing the third portion of the duodenum *(arrow)*.

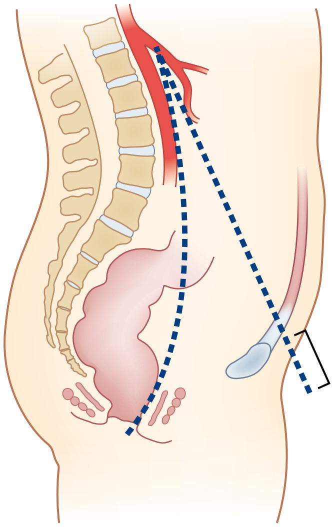

FIGURE 95.48 Estimation of J-pouch length. The apex of the J pouch should be able to be brought down below the level of the symphysis pubis. This is a good estimate of a tension-free reach to the anal canal.

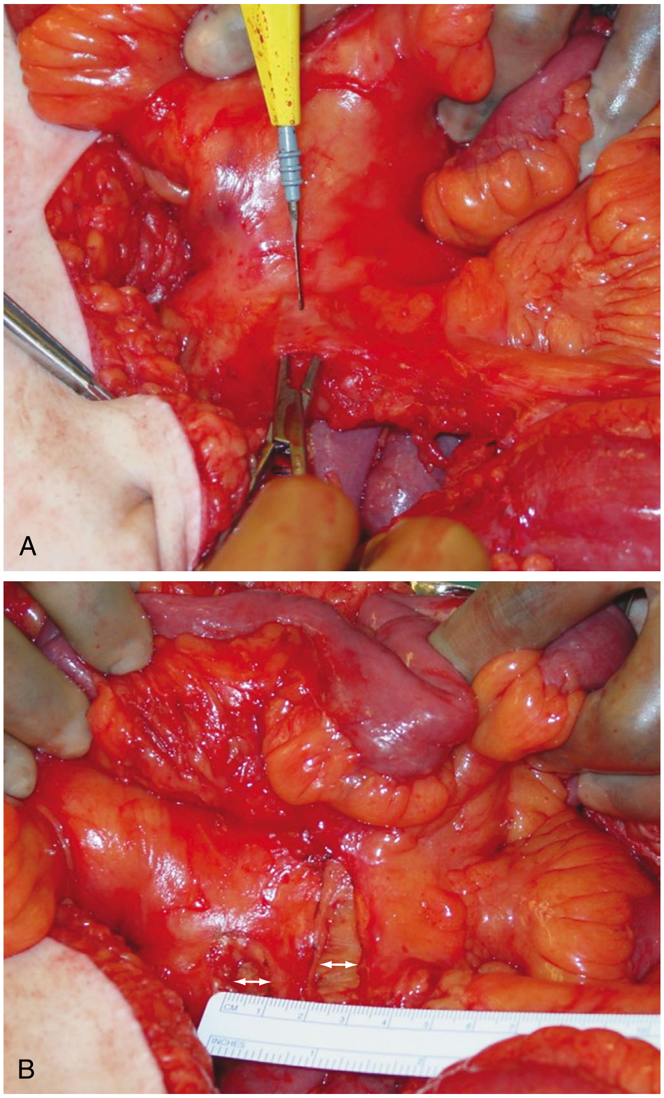

FIGURE 95.49 Peritoneal windowing. (A) The mesenteric peritoneum is lifted away from the superior mesenteric artery by lifting it up with a hemostat and then divided using the electrocautery. (B) The mesenteric peritoneum has been divided perpendicular to the axis of the superior mesenteric artery. Note that at each area where the peritoneum has been divided, an additional 1 cm of mesenteric length has been obtained.

the J pouch, it should easily reach just below the symphysis pubis (Fig. 95.48). When this maneuver is performed, one can either feel or visualize which small bowel mesenteric vessel is under more tension—the superior mesentery vessels or the ileocolic vessels. The vessel with the greater amount of tension can be divided, allowing greater length on the small bowel mesentery. “Peritoneal windowing” can also provide mesenteric length. This is a maneuver whereby small slits are created in the anterior and posterior peritoneum covering the mesenteric vessels. These horizontal slits in the peritoneum, in most cases, provide for 1 or 2 extra centimeters of mesenteric length (Fig. 95.49). Needless to say, the more obese an individual is, the more difficult it can be to obtain sufficient mesenteric length for the small bowel to reach tension-free to the pelvis. In addition to this, with very tall individuals and those with a long torso, tension can also be an issue.

There are a few ongoing debates on the surgical practice of creating an IPAA. First, when considering the creation of an ileoanal pouch, surgeons have several strategic options, each tailored to specific patient conditions and potential risks. The one-stage procedure offers efficiency by condensing the process into a single surgery. However, this approach has an elevated risk of anastomotic leakage because of the absence of a temporary ostomy diversion, which can aid in healing. The more prevalent two-stage procedure is favored for elective cases, particularly for patients without pronounced inflammation. This method involves a total proctocolectomy paired with pouch creation, subsequently followed by a temporary ileostomy diversion. In contrast, the three-stage procedure adopts a phased approach, commencing with a total abdominal colectomy. The subsequent stages involve a completion proctectomy, IPAA creation with a temporary diversion, and ultimately, closure of the ileostomy. This strategy is especially reserved for patients in dire need of surgery for acute UC symptoms, such as severe inflammation or bleeding. By postponing the elective IPAA creation, it offers these patients a safer and more staggered surgical experience, allowing for periods of recovery between each stage. Second, there are two predominant types of anastomosis debated: mucosectomy with hand-sutured anastomosis and the double-stapled method. The former involves complete rectal mucosa removal, aiming to reduce disease recurrence, but can affect anorectal physiology, leading to increased stool frequency. The double-stapled technique, although faster and technically simpler, raises concerns about incomplete mucosectomy and potential disease recurrence. Modified two-stage IPAA involves subtotal colectomy with end ileostomy, followed by completion proctectomy and pouch creation without diverting ileostomy. The modified two-stage IPAA was associated with a significantly lower rate of anastomotic leak compared with the traditional two-stage procedure.[47] A three-stage IPAA has been described in patients with acute colitis and high-risk patients with malnutrition or under steroid therapy (Fig. 95.50).

Common early complications of IPAA include those associated with nonhealing of the IPAA: pelvic sepsis, ileal pouch–anal anastomotic fistulae, ileal pouch–vaginal fistulae, ileal pouch–anal anastomotic sinuses, and IPAA strictures (often a reflection of anastomotic tension). Late complications include the diagnosis of Crohn disease, which is more common in patients who undergo emergent colectomy and in those patients who have a diagnosis of indeterminate colitis.

With a "good" result, patients with IPAA will have up to six bowel movements within a 24-hour period, usually including one nocturnal bowel movement. In the majority of patients, at about 6 months, there will be significant enlargement of the ileal pouch, allowing patients to reduce the amount of antidiarrheal medication they take to control their output.

Redo/revision of the IPAA surgery often stems from technical challenges encountered during the initial surgery or results from inflammatory conditions, mainly pelvic sepsis. A long-term study after the results of redo IPAA surgery demonstrated that 41% of patients required the formation of a new pouch, whereas 59% underwent revisions to their original pouch. Although the postoperative period was generally safe, some patients experienced significant complications, including anastomotic leaks. Over time, around 21% of patients experienced failures of the redo IPAA. Despite these hurdles, many patients reported improved functional outcomes and a better quality of life after the redo surgery.[48] Redo pouch surgery may be successfully undertaken as a laparoscopic operation, with the caveat that the surgeon must be extensively experienced in laparoscopic pouch surgery.[49]

Surgery for Crohn Disease

Ileocolic Resection

Ileocolic resection is one of the most common operations performed for patients with Crohn disease because it is estimated that the ileocecal area is the site of involvement in nearly half of patients. Indications for surgery in these patients are usually either fibrostenosing disease with obstruction or associated fistulizing disease/mass/abscess or phlegmon. Because the terminal ileum lies in the pelvis in close proximity to a number of pelvic structures, if there is a significant obstruction and a proximal perforation occurs, the resulting abscess can perforate into the sigmoid colon or bladder. The sigmoid colon is by far the more common, and the resulting ileosigmoid fistula fairly frequently occurs in these patients. When performing an ileocolic resection, one must always be alert to any "adhesions" and ensure that these are not enteroenteric fistulas. Ileocolic resection lends itself well to the laparoscopic approach. Exceptions are cases in which there is extensive fistulizing disease or a significant phlegmon in which there is difficulty separating the right colon mesentery/terminal ileum away from the retroperitoneal structures. In deciding on margins of resection, one should select areas of bowel that feel normal, are not thickened, and have

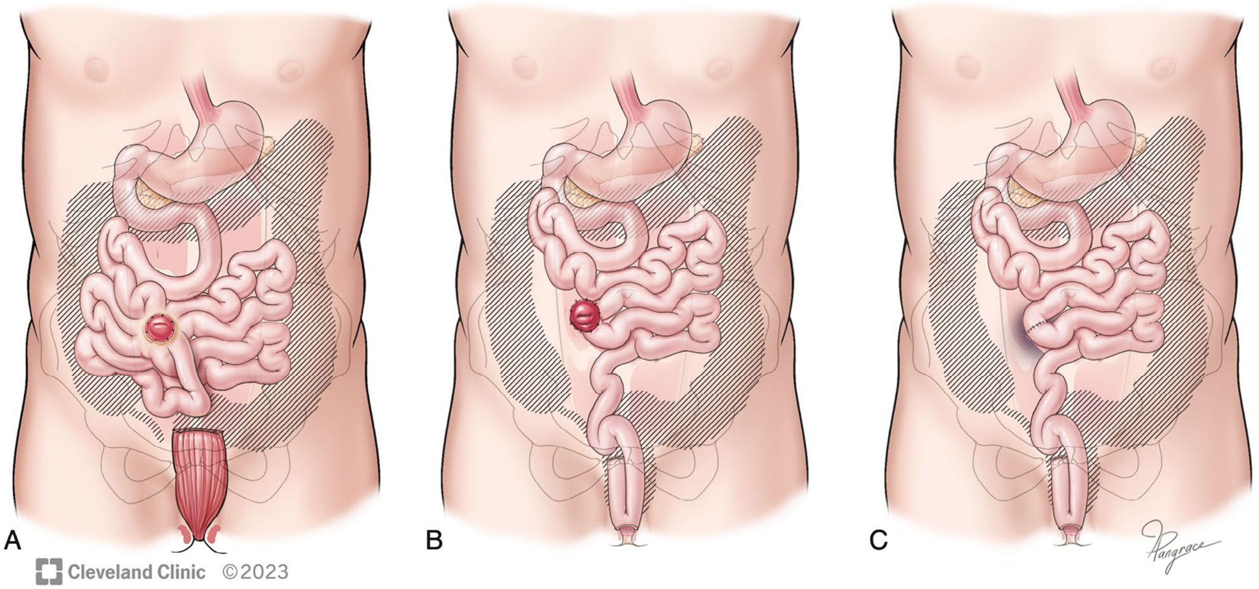

FIGURE 95.50 Three-stage ileal pouch anal anastomosis. (A) Total colectomy with ileostomy creation. (B) Completion proctectomy and creation of the J-pouch. (C) Closure of the ileostomy. (Reprinted with permission, Cleveland Clinic Foundation ©2024. All Rights Reserved.)

a normal thickness of the bowel-mesenteric junction. The ability to palpate a discrete small bowel–mesenteric junction is usually a good indicator that the lumen is free of significant Crohn inflammation. Documenting the residual bowel length in Crohn disease patients is vital for surgeons, given that up to 50% of these patients may require additional surgery within a decade. This information significantly informs future clinical decisions.[50] Although there are many ways to construct the ileocolic anastomosis, a stapled side-to-side anastomosis seems to be the most popular anastomosis. Recently, there has been increased interest in the Kono-S anastomosis, where the diseased bowel is resected and then the surgeon performs a functional end-to-end, side-to-side, hand-sewn anastomosis using a noncutting linear stapler to avoid narrowing at the anastomotic site (Fig. 95.51). This type of anastomosis creates a wide, antitension, antiangulation connection that enhances flow and prevents stasis of fecal content. The first randomized controlled study about the Kono S anastomosis (SUPREME CD trial) showed that this anastomosis significantly reduced both endoscopic and clinical recurrence rates compared with conventional side-to-side anastomosis in Crohn disease, without posing any safety issues.[51] However, a larger scale study published recently found comparable rates of endoscopic recurrence rates between the Kono S and the traditional side-to-side functional end anastomosis.[52] One possible advantage of the Kono S anastomosis is that, postoperatively, these anastomoses are very easy to evaluate endoscopically and to dilate in the event of recurrent disease, which is not true of side-to-side stapled anastomoses. Further studies are ongoing, but in any case, it is paramount that however the anastomosis is constructed, it is made fairly wide.

Segmental Colon Resection

Segmental colonic resection has increasingly been used in the treatment of Crohn disease over the last two decades. This has been performed for two reasons: (1) recognition of the important role of water absorption (see section on colonic physiology) performed by the colon and recognition that many of these patients will undergo repeated operations and (2) availability of newer and more potent medications for Crohn disease allowing more effective suppression of recurrent disease. Segmental resection for colonic Crohn disease can be performed in patients who have isolated areas of colonic stricture with relatively normal areas of "skipped" normal-appearing colon with normal colonic distensibility. In these patients, performing a segmental resection is associated with a much higher risk of recurrence, so this should always be accompanied by some type of postoperative chemoprophylaxis to reduce the risk of recurrence of the disease.

Subtotal Colectomy and Ileorectal Anastomosis

This is an operation that is well suited to patients with Crohn disease if they have a relative rectal-sparing and an otherwise diseased colon. Segmental resection is preferable if there are areas of normal intervening colon. However, this operation also, as with segmental colectomy, is associated with a much higher rate of recurrence. Options for this, if there is a smaller amount of retained rectum, are to perform an ileal pouch–rectal anastomosis in order to lessen the number of bowel movements that the patient has after surgery. Depending on the height of the anastomosis and the circumstances of the surgery (redo, associated immunosuppression, patient's nutritional state), this may require temporary fecal diversion (temporary loop ileostomy) to facilitate healing.

Proctocolectomy and Ileal Pouch–Anal Anastomosis

In previous editions of the Sabiston textbook, there perhaps was only a passing mention of this procedure; however, every year, this is more frequently considered a possibility for patients with Crohn disease, provided that they do not have obvious perianal disease. With the advent of newer and more potent immunosuppressive drugs, this procedure is considered an option in an educated patient who is aware of the increased risk of morbidity and the less favorable functional results (including a greater number of bowel movements) as compared with when this operation is performed for patients with UC. In addition, there is, of course, a higher risk of fistulizing disease and the need to convert to an end ileostomy. However, in the motivated patient who recognizes and accepts these risks, this procedure can be performed. See the section on IPAA for UC for technical details regarding this procedure.

Cancer Risk

As with UC, there is an increased risk of colon cancer in patients with longstanding Crohn disease, although it is thought to be somewhat less than with UC. However, in patients in whom there has been a cancer identified, total colectomy should be performed because there have been studies showing colonic procarcinogenic mutations tracking along the colon, and the risk of a subsequent cancer in other areas of the colon is high. Small bowel cancer is a rare but serious complication of Crohn disease, with patients having an increased risk due to the chronic inflammation and immune system dysregulation associated with the condition. This risk is particularly heightened in those with long-standing disease, especially in individuals with extensive small bowel involvement, a history of surgical resections, or a family history of colorectal cancer. Regular monitoring and early detection are essential for managing this risk effectively.[53]

Postoperative Complications

Many patients with IBD who undergo surgery are on immunosuppressive medications, and in addition, many of these patients are hypoalbuminemic because they have protein-losing enteropathy from their disease. Because of this, they are at increased risk for infectious postoperative complications. There are differing opinions as to the relative risk (RR) of complications with these different medications. However, overall, it is thought that steroids pose an increased risk for infectious complications. Perioperative use of biologics in Crohn disease is a nuanced issue. Although there were initial concerns about the increased risk of postoperative complications because of their immunosuppressive effects, large-scale studies and meta-analyses have indicated that there is no significant increase in such risks. Timing for discontinuation and resumption of therapy should be personalized, considering disease severity and individual patient recovery. The latest guidelines from the European Crohn and Colitis Organization (ECCO) suggest that preoperative treatment with anti-TNF therapy, vedolizumab, or ustekinumab does not increase the risk of postoperative complications in patients with Crohn disease having abdominal surgery. Small scale studies showed lower risks of postoperative complications in patients undergoing re-do surgery while treated with biologic therapy.[54] Cessation of these medications before surgery is not mandatory.[55] IBD patients are at a notably increased risk of venous thromboembolism (VTE) after surgery, with the RR nearly doubled compared with non-IBD individuals. Even after adjusting for factors such as smoking and BMI, the elevated risk persists, signaling a critical need for vigilant postoperative VTE prophylaxis.[56]

Postoperative Recurrence

Surveillance and preventative measures are pivotal in the postoperative management of patients with Crohn disease.[57] Clinical follow-ups, fecal calprotectin monitoring, and endoscopic investigations form the backbone of surveillance strategy. Regular assessments are essential for early detection of recurrent disease because endoscopic recurrence often precedes clinical manifestations. It is recommended to perform ileocolonoscopy within 6 to 12 months after surgery to spot any signs of endoscopic recurrence. Fecal calprotectin, a noninvasive biomarker of intestinal inflammation, can potentially predict this recurrence. The Rutgeerts score, a grading system used to quantify endoscopic recurrence, plays a vital role in adjusting therapeutic strategies. A score of i2 or higher indicates the need for more aggressive treatment (Box 95.4).

For prevention, lifestyle changes, especially quitting smoking, are advised because smoking has been associated with increased postoperative recurrence. Postoperative prophylactic therapy now often includes first-line use of biologic agents, especially in high-risk patients who have experienced multiple surgeries or recurrent disease exacerbations or those with a penetrating disease phenotype. This represents a shift from the traditional use of immunomodulators, such as thiopurines or methotrexate. Alongside this medical intervention, nutritional support continues to be an integral component of preventative care.

Perianal Crohn Disease

Anorectal fistula in Crohn disease is a significant concern, affecting approximately 40% of patients at some point during their disease course. Because of the complex nature of this disease manifestation, the latest ASCRS guidelines recommend that perianal fistulizing Crohn disease necessitates a multidisciplinary approach, combining both surgical and medical interventions, with the primary goal of controlling infection and managing the

BOX 95.4 **Rutgeerts Score**

Grade	Endoscopic findings
i_0	No lesions in the distal ileum
i_1	<5 aphthous lesions
i_2	>5 aphthous lesions with normal mucosa between the lesions, or skip areas of larger lesions or lesions confined to ileocolonic anastomosis
i_3	Diffuse aphthous ileitis with diffusely inflamed mucosa
i_4	Diffuse inflammation with already larger ulcers, nodules, and/or narrowing

underlying Crohn disease effectively.[58] As with most conditions, the use of a scoring system is useful to quantify the severity of disease and monitor the response to therapy. The Perianal Disease Activity Index (PDAI) is a tool designed to measure the severity of perianal disease in patients with Crohn disease. It considers various clinical parameters, such as the number and type of active fistulas, the intensity of pain, the degree to which daily activities are restricted, and the patient's overall well-being. Each component is scored individually, and the total PDAI score is the sum of these, with higher values indicating increased disease severity. This index is crucial for monitoring disease progression in individuals and evaluating the effectiveness of treatments in research settings (Box 95.5).[59]

Over the past decade, biologic therapy has become the mainstay of medical management. Although immunosuppressants like azathioprine and cyclosporine have shown some efficacy, with a success rate of around 30%, infliximab, a type of biologic, has demonstrated fistula healing rates of up to 60% in randomized controlled trials. Other biologics, such as adalimumab and certolizumab, have also been tested, with success rates ranging from 50% to 55%.

A draining seton is often employed, especially during the initial stages of treatment, with a success rate of about 70% in controlling infection and promoting healing. The approach to definitive fistula surgery is highly individualized, considering such factors as the severity of symptoms, fistula tract anatomy, and the overall status of Crohn disease. Postsurgical challenges are frequent, with nearly 25% of Crohn disease patients requiring additional interventions because of complications such as nonhealing wounds or recurrent fistula.

In cases where drainage is not the primary concern, antibiotics, especially metronidazole and fluoroquinolones, have shown symptom improvement in 80% of patients. Interestingly, not all fistulas in Crohn disease patients are symptomatic. Asymptomatic fistulas, accounting for about 15% of all cases, can remain dormant for years. Surgical intervention in such cases might introduce unnecessary risks, so a conservative approach is often recommended.

For severe, refractory cases, proctectomy and permanent fecal diversion might be the only options. These drastic measures are considered for less than 5% of patients but can be lifesaving. Recent advancements have introduced the local administration of mesenchymal stem cells (MSCs) as a potential treatment. Preliminary clinical trials have shown that MSCs have a success rate of 65% in treating refractory fistulizing anorectal Crohn disease, but long-term outcomes were lower. The recently published ADMIRE-CD phase 3 randomized trial found that 56% of patients treated with MSC for complex perianal Crohn disease were in clinical remission for two years following treatment.[60] Although still in the early stages, the potential of MSCs offers hope for those who have exhausted other treatment options. However, these treatments often require multiple applications and are assoicated with significantly increased costs compared to traditional theraputic measures.

INFECTIOUS COLITIS

Infectious colitis may be diagnosed among patients with acute diarrhea and colonic inflammation. Its importance for the surgeon arises from its capacity to mimic surgical conditions such as an acute abdomen or IBD and, in some cases, to deteriorate to the point where it requires surgical treatment.

Clostridioides difficile Infection

C. difficile infection (CDI) is a common inhabitant of the GI tract that can manifest in a spectrum of symptoms ranging from that of an asymptomatic carrier to fulminant colitis.

Epidemiology

C. difficile is the most common cause of healthcare-associated diarrhea and is considered to be a major source of healthcare-associated

morbidity, occurring in 2% of all hospital discharges for all diseases. The prevalence of asymptomatic colonization of *C. difficile* among adult hospitalized patients ranges from 3% to 26% in different studies. Around 453,000 new cases of CDI are diagnosed annually in the United States, of which 83,000 are recurrent cases, with 29,300 attributed deaths.[61] Interestingly, after plateauing at historically high rates, some regions have begun to show a decline in incidence attributed to specific prevention and treatment programs. In participating Canadian hospitals, for example, the incidence of CDI decreased from 7.9/10,000 patient-days in 2011 to 4.3/10,000 patient-days in 2015.[62]

Microbiology and Transmission

C. difficile is an anaerobic, spore-forming, gram-positive bacillus. Transmission routes include person-to-person spread through the fecal-oral route or through exposure to a contaminated environment by ingestion of spores from other patients and transmission via healthcare personnel's hands. Toxicogenic *C. difficile* pathogens can produce A and B toxins, both of which have been associated with colitis. Binding of toxin A or B to colonocyte glycoprotein receptors leads to colonocyte death and release of inflammatory mediators. The emergence of the *C. difficile* Ribotype 027 strain in the mid-2000s resulted in significant outbreaks across the Western world associated with more severe disease outcomes and deaths.

Risk Factors

The most important risk factor for the development of a clinical infection is recent exposure to antibiotics. Antibiotics affect the natural bowel flora, decreasing the natural ability to suppress the growth and spread of *C. difficile*. Virtually all antibiotics have been associated with *C. difficile,* but particularly third- and fourth-generation cephalosporins, fluoroquinolones, clindamycin, and carbapenems have been linked to a higher risk of CDI. Other risk factors include immunodeficiency (including HIV infection); chemotherapy treatment; use of acid-suppressing medications, such as proton pump inhibitors; GI surgery or manipulation of GI tract, including tube feeding; and prolonged hospitalization or lengthy stay in nursing homes or rehabilitation units. Patients with IBD have increased rates of CDI, along with worse outcomes (e.g., HIV) and higher rates of colectomy. These patients are more likely to receive immunosuppressants and antibiotics and have a different intestinal flora compared with healthy subjects. Differentiating between an IBD exacerbation and CDI can be difficult because the symptoms overlap, and a high index of suspicion must be maintained. Patients with an increased risk for death from CDI include those with advanced age, multiple comorbidities, hypoalbuminemia, leukocytosis, or acute renal failure and those infected with Ribotype 027.

Clinical Presentation

Symptoms of CDI commonly begin 4 to 9 days after initiation of antibiotics but can commence 10 weeks or more after antibiotic treatment. Patients presenting with new-onset, unexplained, watery diarrhea (with three or more unformed stools in 24 hours) should be suspected of having CDI. Patients may also have abdominal pain, fever, and an associated ileus. Patients with CDI can be categorized into asymptomatic colonization, nonsevere disease, severe disease, and fulminant disease. Various scores have been used to assess clinical severity and treatment response. Leukocytes of at least 15,000 cells/μL and/or serum creatinine of at least 1.5 cells/μL are predictors of severe disease, according to the Infectious Disease Society of America. Fulminant or severe CDI is diagnosed in patients demonstrating hypotension or shock, ileus, or megacolon. The ATLAS criteria is a simple clinical bedside score that includes age, temperature, leukocytosis, albumin, and systemic antibiotic treatment and has been used to assess response to treatment.[63]

Diagnosis

The diagnosis of CDI is based on typical symptoms in combination with stool testing. Laboratory testing is based on detection of *C. difficile* toxins, *C. difficile* antigen, or the bacteria itself. Various commercial tests are used, including enzyme-linked immunosorbent assay for toxin detection, glutamate dehydrogenase immunoassay for *C. difficile* antigen detection, nucleic acid amplification test, polymerase chain reaction testing, and stool cultures.

Flexible sigmoidoscopy may be helpful as a diagnostic modality for CDI. Although it is not a first-line modality for diagnosis, it can be helpful in cases of inconclusive stool testing or to help exclude other etiologies. Classically, raised, yellowish-white small (2- to 10-mm) plaques (pseudomembranes) can be observed in approximately half of patients with CDI (Fig. 95.52). Nonspecific

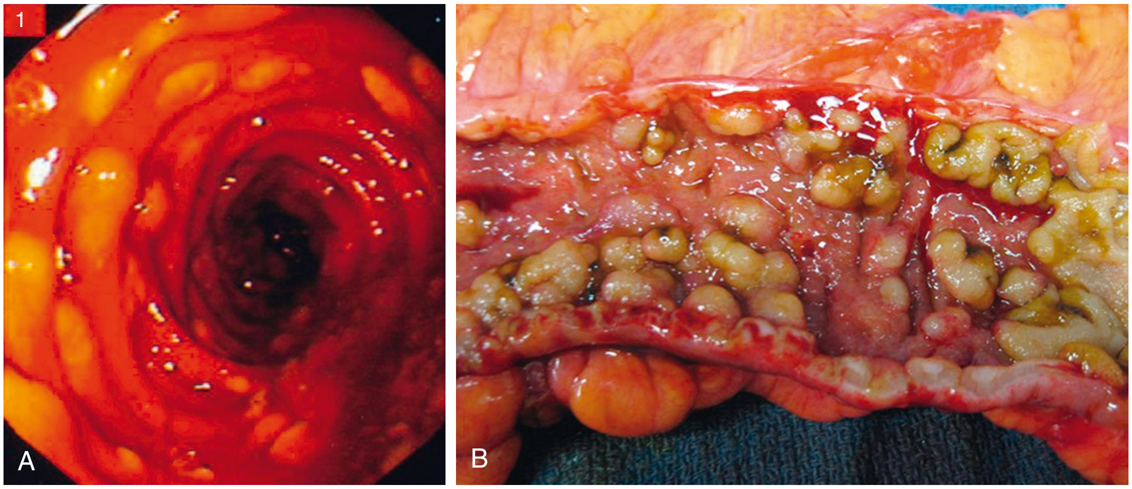

FIGURE 95.52 (A) Endoscopic view of pseudomembranes associated with *Clostridioides difficile.* (B) Pseudomembranes overlying the colon mucosa at the time of colectomy. The patient had active *C. difficile* colitis with coexisting Crohn colitis.

colitis can be found in an additional 25%. Histologic findings from the plaques reveal an inflammatory exudate with mucinous debris, fibrin, necrotic epithelial cells, and polymorphonuclear cells. In fulminant colitis, colonoscopy may increase the risk of perforation and should be considered only when the benefit is higher than the risk of complications.

Imaging is not very useful for diagnosis because it is not specific, but it can assist in assessing disease severity and response to treatment. Typical CT findings include significant colonic wall thickening, bowel dilation, pericolonic fat stranding, high-attenuation oral contrast in the colonic lumen alternating with low-attenuation inflamed mucosa (accordion sign), and ascites. Ultrasound may also be useful, especially among critically ill patients who cannot be transported to the CT scanner in radiology. Ultrasonography may show bowel wall thickening; narrowing of the lumen; and pseudomembranes, which are seen as hyperechoic lines covering the mucosa.

Treatment

Initial treatment includes stopping or minimizing previous antibiotics, parenteral fluids, and correction of electrolytes. The use of antiperistaltic agents for the treatment of CDI should be avoided. Antibiotic treatment of CDI is determined according to the clinical setting and can be divided into the initial episode, recurrent episode, severe disease, and fulminant disease. Table 95.4 summarizes current antibiotic treatment recommendations for initial episodes and for severe and fulminant disease.

Treatment options for recurrent episodes generally include changing antibiotics (from metronidazole to vancomycin or fidaxomicin from vancomycin). In addition, tapered and pulsed regimens are used.

Fecal Microbiota Transplant

Fecal microbiota transplant (FMT) for patients with recurrent episodes of CDI is a relatively new treatment. Patients with CDI lack protective colonic microbiota to resist replication and colonization of *C. difficile*. Reimplantation of normal gut bacteria, particularly bacteria resistant to *C. difficile*, from healthy donors can help restore normal gut biodiversity and correct the imbalance. Different routes of administration have been described in the literature, including nasogastric, oral (frozen fecal microbial capsules), rectal enema, and colonic per colonoscopy. A recent comparison between upper and lower methods of delivery demonstrated the lower approaches being more effective.[64] The efficacy of FMT ranges from 77% to 100%, with multiple FMTs needed to achieve a good clinical response. Current guidelines recommend FMT for patients with multiple recurrences of CDI in whom antibiotic treatment has failed.

Monoclonal Antibodies

Bezlotoxumab and actoxumab are monoclonal antibodies directed against *C. difficile* toxins B and A, respectively. These antibodies limit colonic damage by neutralizing the toxin and blocking the binding to host cells.[65] They can be used as coadjuvant treatment with antimicrobial therapy to help prevent recurrence, especially among patients infected by Ribotype 027, in severe CDI, and in immunocompromised patients.

Surgery

Patients with fulminant CDI who develop signs of systemic toxicity, toxic megacolon, or perforation should be operated on emergently. Emergency colectomy for patients with fulminant colitis provides a survival advantage compared with continuing antibiotics. Among severely ill patients, a total or subtotal abdominal colectomy with preservation of the rectum has traditionally been performed. A newer option with similar results for patients without necrosis or perforation is exteriorization of a diverting loop ileostomy with on-table colonic lavage followed by antegrade vancomycin flushes.[66]

OTHER COLONIC INFECTIONS

Diarrhea and colitis can be caused by other pathogens. Most of these will not require surgery. A careful history can discover the source in many cases, such as polluted drinking or recreational water or consumption of contaminated fruits and vegetables, unpasteurized milk, undercooked meat and fish, shellfish, and eggs. International travel as well as contact with animals and their feces should also be queried. Table 95.5 summarizes the important characteristics of common bacteria causing diarrhea and colitis.

The initial approach includes a careful history, evaluation for dehydration and electrolyte disturbances, and stool testing for ova and parasites and for culture and sensitivity. Patients with signs of sepsis or those who have traveled from enteric fever–endemic

TABLE 95.4 Antibiotic Treatment of *Clostridioides difficile* Infection

CLINICAL CONDITIONS	TREATMENT	TREATMENT DURATION
First episode	1. Oral vancomycin 125 mg 4 times daily OR 2. Fidaxomicin 200 mg twice daily If vancomycin and fidaxomicin are not available, metronidazole 500 mg 3 times daily can be given for nonsevere disease.	10 days
First episode—fulminant (hypotension, shock, ileus, megacolon)	Vancomycin, 500 mg 4 times daily (oral or by nasogastric tube) In case of ileus: 1. Consider adding rectal instillation of vancomycin. 2. Intravenously administered metronidazole (500 mg every 8 hours) should be administered together with oral or rectal vancomycin.	At least 10 days, duration should be individualized

Adopted from McDonald LC, Gerding DN, Johnson S, et al. Clinical practice guidelines for *Clostridium difficile* infection in adults and children: 2017 update by the Infectious Diseases Society of America (IDSA) and Society for Healthcare Epidemiology of America (SHEA). *Clin Infect Dis*. 2018;66:987-994.

TABLE 95.5 **Clinical Characteristics of Common Enteric Infections**

PATHOGEN	CHARACTERISTICS AND CLINICAL PRESENTATION
Campylobacter jejuni	Spiral, microaerophilic gram-positive rod Exposure to improperly prepared chicken or beef Fever, watery diarrhea, and abdominal pain Commonly involves the cecum and terminal ileum May mimic appendicitis or Crohn disease
Yersinia enterocolitica	Gram-negative coccobacillus Exposure to contaminated water or food Abdominal pain and bloody diarrhea, may mimic appendicitis or Crohn disease
Shigella	Gram-negative, facultative anaerobe Common cause for dysentery in developing countries Often affects rectum and sigmoid colon Fever, abdominal pain, watery diarrhea that can progress to bloody diarrhea
Salmonella typhi or *Salmonella enterica* serotypes Paratyphi	Gram-negative, facultatively anaerobic bacilli Recent travel to an endemic area, consumption of foods prepared by a traveler to an endemic area Fever with or without diarrhea, abdominal pain, cramping and vomiting

Adapted from Shane AL, Mody RK, Crump JA, et al. 2017 Infectious Diseases Society of America clinical practice guidelines for the diagnosis and management of infectious diarrhea. *Clin Infect Dis*. 2017;65: 1963-1973.

regions and immunocompromised patients should also have blood cultures obtained.

Initial treatment includes rehydration and correction of electrolyte disturbances. Oral rehydration solution is recommended for mild to moderate disease. Nasogastric administration of oral rehydration solution may be considered for patients who do not tolerate oral intake. Patients with signs of severe dehydration or ileus should be treated with isotonic IV fluids (normal saline or lactated Ringer solution). The majority of patients who present with acute watery diarrhea and those without recent international travel *do not require* antimicrobial therapy. Immunocompromised or septic patients, as well as those suspected of enteric fever, should be treated with empirical, broad-spectrum antimicrobial therapy, usually with fluoroquinolones, such as ciprofloxacin, or macrolides, such as azithromycin, depending on local susceptibility patterns. Surgical intervention is rarely required apart from those cases developing severe fulminant disease that leads to perforation or toxic megacolon.

Viruses can also cause acute diarrhea and colitis. Cytomegalovirus (CMV) is an important etiology to consider in immunocompromised hosts, particularly in advanced HIV infection, transplant patients, patients with IBD, and those receiving chemotherapy. CMV colitis commonly presents with watery or bloody diarrhea, fever, and abdominal pain. Diagnosis is established by serology and by determining viral load in the blood. Endoscopy demonstrates patchy mucosal erythema in the colon. Inclusion bodies seen on biopsy are pathognomonic for CMV. CMV colitis can progress to sepsis, toxic megacolon, and colonic perforation. Treatment is usually supportive with the addition of ganciclovir. Patients with severe, complicated disease may require surgery.

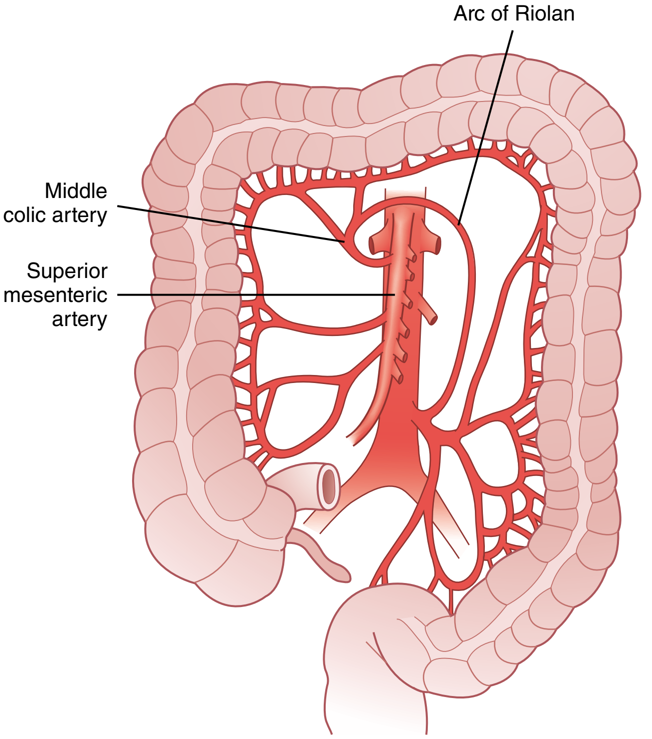
ISCHEMIC COLITIS

Ischemic colitis is a common disorder that develops when the arterial blood supply to the colon is insufficient to support cellular metabolic demands. It is the most common form of GI ischemia, with rates of 7.1 to 22.9/100,000 person-years.[67] Severity varies within a wide spectrum, from mild, self-limiting disease to severe, life-threatening colonic ischemia. Considering the wide range of clinical findings, with most patients presenting with mild, nonspecific symptoms, the true incidence is likely much higher. It is important to differentiate ischemic colitis from situations of acute mesenteric ischemia, in which a major vessel of the bowel is obstructed, wherein patients commonly present with severe pain out of proportion to physical findings and require immediate vascular intervention. Ischemic colitis is considered a disease of small blood vessels and typically presents less dramatically, seldom requiring vascular intervention. Most cases, when recognized and managed promptly, do not require surgery. Delays in diagnosis and treatment, however, can result in the need for emergency colectomy, with high morbidity and mortality.

Anatomic Considerations

The arterial blood supply to the colon is derived from the SMA and the IMA. The SMA gives off the ileocolic, right colic, and middle colic arteries. The IMA gives rise to the left colic and sigmoid arteries and ends as the superior rectal (hemorrhoidal) artery (see Fig. 95.8). There are two well-described collateral networks that aid in preventing colonic ischemia by providing "backup" both within the territories of the two major arteries and between them. The main collateral vessel is the marginal artery of Drummond, which runs parallel and close to the mesenteric margin of the colon from the cecocolic junction to the rectosigmoid junction. The marginal artery was found to be absent at the splenic flexure in up to 18% of people.[68] The colon can receive collateral blood supply through this artery when one of the larger arteries is obstructed. It is important, when resecting a section of colon, to preserve this artery because only the vasa recta are located between it and the colon. When it is compromised, ischemia of that section of colon may result. The second collateral circulation can be found in the proximal region of the large arteries. The "arc of Riolan" (meandering mesenteric artery) is an infrequent finding, traversing close to the mesenteric root and connecting the SMA or middle colic artery to the IMA or left colic artery (Fig. 95.53). It can have a critical role in situations of SMA or IMA occlusion. The presence of a large arc of Riolan commonly indicates an obstruction of one of the major mesenteric arteries.

Watershed areas of the colon are potentially found at the edge of the region supplied by the two main arteries, the SMA and the IMA, zones that are frequently dependent on collateral circulation (Fig. 95.54). There are two well-described watershed areas where the collateral circulation is classically inconsistent and vulnerable to ischemia. The first is the area of the splenic flexure (Griffiths point). In some studies, up to 50% of specimens were found to lack a marginal artery in the region



Arc of Riolan
Middle colic artery
Superior mesenteric artery

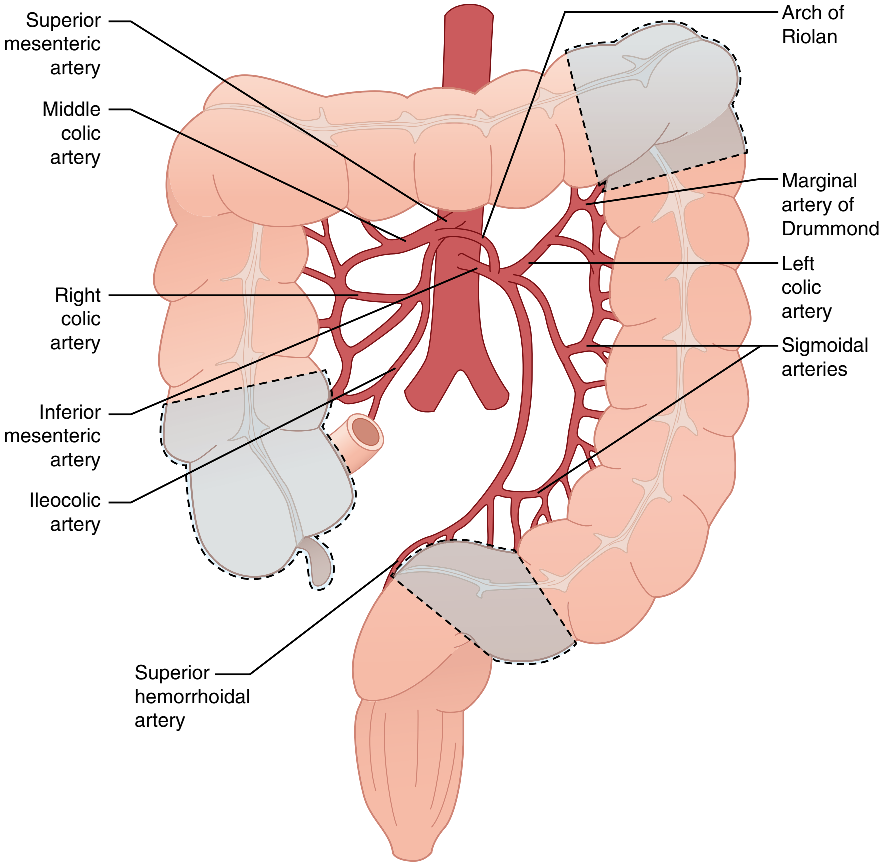
FIGURE 95.53 The arc of Riolan. (From Gordon PH, Nivatvongs S, ed. *Principles and Practice of Surgery for the Colon, Rectum and Anus*. 2nd ed. St. Louis: Quality Medical Publishing; 1999:27.)

where the SMA and IMA circulations meet. Commonly, surgeons avoid making anastomoses in this area for fear that the impaired blood supply will not be sufficient to permit anastomotic healing, leading to anastomotic leaks. A second potential watershed area is the rectosigmoid junction (Sudeck's point). This region receives its blood supply from the superior hemorrhoidal artery and distal sigmoid branches, both terminal branches of the IMA and prone to atherosclerotic changes. The right colon, although not classically considered a watershed area, is also vulnerable to ischemia from embolic occlusion because the ileocolic artery is the terminal branch of the SMA. For this reason, the right colon is also particularly prone to low-flow conditions, such as heart failure, hemorrhage, and sepsis. The rectum, which has a good blood supply from both the IMA and the iliac circulation, as well as a strong collateral network, is rarely the victim of ischemic injury.

Risk Factors

Ischemic colitis may occur in all ages but is significantly more common in elderly patients, in females, and in patients with multiple comorbidities. Several medical conditions and medications have been associated with ischemic colitis (Box 95.6).[69]

Patients with low-flow states, as a result of heart failure or sepsis, are especially prone to develop ischemic colitis. Diabetes mellitus, hypertension, chronic obstructive pulmonary disease, peripheral vascular disease, and renal disease have also been associated with this disorder. Recently, COVID-19 was found to be associated with ischemic colitis in some patients.[70] Patients



Superior mesenteric artery
Middle colic artery
Right colic artery
Inferior mesenteric artery
Ileocolic artery

BOX 95.6 Conditions and Drugs Associated With Ischemic Colitis

Low-Flow State

- Septic shock
- Congestive heart failure
- Hemorrhagic shock
- Hypotension

Atherosclerosis

- Ischemic heart disease
- Cerebrovascular disease
- Peripheral vascular disease

Gastrointestinal

- Constipation
- Diarrhea
- Irritable bowel syndrome

Surgery and Invasive Interventions

- Abdominal surgery
- Aortic surgery (especially abdominal aortic aneurysm repair)
- Cardiovascular surgery
- After endovascular abdominal manipulations (including chemoembolization)
- Postcolonoscopy

Cardiovascular/Pulmonary

- Chronic obstructive pulmonary disease
- Atrial fibrillation
- Hypertension

Metabolic/Rheumatoid

- Diabetes mellitus
- Dyslipidemia
- Systemic lupus erythematosus
- Rheumatoid arthritis

Miscellaneous

- Hypercoagulable states
- Sickle cell disease
- Long-distance running

Drugs

- Constipation-inducing drugs (opioids and nonopioids)
- Cocaine and methamphetamines
- Immunomodulatory drugs (anti–tumor necrosis factor-α, type 1 interferon-α, type 1 interferon-β)
- Chemotherapeutic drugs (including taxanes)
- Female hormones and oral contraceptives
- Decongestants (pseudoephedrine)
- Serotoninergic (including alosetron, sumatriptan)

undergoing aortic reconstructive surgery or abdominal surgery in which the IMA is ligated are also especially predisposed to colonic ischemia. In these patients, if the collateral circulation is not sufficient, acute occlusion of the IMA can result in sigmoid and left colon ischemia.

Several medications have been implicated in ischemic colitis. Constipation-inducing drugs can cause ischemic colitis, most likely as a result of reduced blood flow and increased intraluminal pressure. Immunomodulator drugs such as anti–TNF-α inhibitors can affect thrombogenesis, and illicit drugs such as cocaine and methamphetamines cause ischemia through vasoconstriction, hypercoagulation, and direct endothelial injury.

Presentation and Diagnosis

The majority of patients with partial-thickness ischemia of a localized section of colon present with relatively nonspecific signs and symptoms. A high index of suspicion is needed to make an early diagnosis. Presenting symptoms usually include sudden abdominal pain and cramping, tenesmus, and bloody diarrhea or hematochezia. The combination of these symptoms is present in close to 50% of the patients, with the pain usually beginning before the bleeding. Bleeding associated with ischemic colitis is usually minor and seldom requires blood transfusions. Patients may also experience nausea, vomiting, and a low-grade fever. On physical examination, abdominal distention may be noted, as well as tenderness overlying the involved region. A good medical history is important in establishing the diagnosis, with a focus on associated diseases and medications.

The most common affected region is the left colon (including the splenic flexure), followed by the sigmoid colon, based on the affected blood supply. Pancolitis resulting from ischemia is associated with a worse prognosis. About a quarter of the patients present with isolated right-sided ischemic colitis. These patients are more likely to present with abdominal pain without bleeding and more commonly have atrial fibrillation, coronary artery disease, and/or chronic renal failure. Patients with isolated right-sided ischemic colitis have a higher chance of requiring surgery and have a poorer prognosis. A minority of patients will present with full-thickness ischemia. These patients are sicker and commonly present with high fever, leukocytosis, acidosis, and peritonitis.

Basic laboratory testing is nonspecific but can assist in predicting severity. Severe disease has been associated with an increased white blood cell count, blood urea nitrogen, and lactate dehydrogenase and decreased hemoglobin and albumin levels. Acidosis, decreased bicarbonate, and increased lactate levels are also associated with severe ischemic colitis. It is also recommended to test stool for *C. difficile* toxin, ova and parasites, and culture and sensitivity in order to exclude an infectious etiology.

Abdominal plain films may show bowel distention and “thumbprinting,” which are rounded densities along the sides of a gas-filled colon indicative of submucosal edema. These are nonspecific to ischemic colitis because thumbprinting can be found in other situations of colonic inflammation. Free intraperitoneal air suggests bowel perforation and should prompt immediate operative management. Water-soluble contrast enemas have generally become obsolete in the diagnosis of ischemic colitis but may still be used for the evaluation of chronic ischemic strictures. CT scans of the abdomen have become the primary noninvasive modality for the initial diagnosis of colonic pathology. CT scans, performed using both IV and oral contrast, can assist in determining the location of involved areas to assess the severity, identify complications, and exclude the presence of other diseases. Findings suggestive of ischemic colitis, although relatively nonspecific, include segmental bowel thickening, pericolonic fat stranding, and thumbprinting. Pneumatosis intestinalis (the presence of gas in the colonic wall), portal venous gas, and the absence of large bowel enhancement on contrast-enhanced CT usually indicate severe transmural disease favoring immediate surgical intervention. Vascular imaging is usually not indicated in cases of ischemic colitis because this is usually a disease of small vessels; however, in cases of pain of sudden onset that is out of proportion to physical and laboratory findings and in isolated right colon ischemic colitis, multiphasic CT angiography should be performed to exclude acute proximal mesenteric ischemia. MRI may be used as an alternative to invasive procedures in diagnosis and grading of acute ischemic colitis, enabling the early identification of pathologic changes.[71]

The gold standard for the diagnosis of ischemic colitis is flexible endoscopy. Early colonoscopy should be performed (within 48 hours), except in cases of acute peritonitis or in cases of suspected severe transmural ischemia. In contrast to the expected increased risk of perforation resulting from endoscopy in the evaluation of ischemic colitis, current published literature does not demonstrate a higher rate of perforation compared with other patients. It is recommended, however, to refrain from overinsufflation and avoid advancing the scope beyond the most distal extent of disease. Common endoscopic findings characteristic of ischemic colitis include edematous and friable mucosa, erythema, petechial hemorrhage, and mucosal ulceration. The "single-stripe sign," a single linear ulcer running along the longitudinal axis of the colon, is rare but considered specific for ischemic colitis. Segmental distribution, with abrupt transition between injured and noninjured mucosa, and sparing of the rectum support ischemia over IBD. It is important to note that diagnostic endoscopy usually cannot distinguish between partial-thickness and full-thickness ischemia. Fig. 95.55 depicts a recommended algorithm for diagnosis and treatment of ischemic colitis.

Treatment

The majority of patients, nearly 80%, will respond to conservative nonoperative treatment, with significant improvement within a few days. The mainstay of treatment includes bowel rest, IV fluids, and broad-spectrum antibiotics. A nasogastric tube should be inserted if ileus is present. Medications including phosphodiesterase type 5 inhibitors, pentoxifylline, and prostaglandin E1 may improve blood flow to the ischemic colon and promote mucosal healing.[72]

Efforts should be made to correct low-flow states and hypotension with aggressive fluid resuscitation and optimal treatment of associated conditions, such as heart failure and sepsis. Colonic ischemia can result in failure of the intestinal epithelial barrier with bacterial translocation, leading to overt sepsis. For this reason, empiric broad-spectrum antibiotics against both anaerobic and aerobic coliform bacteria are prescribed in ischemic colitis to cover the normal colonic bacterial flora. Cathartics are not recommended because they may lead to colon perforation. Glucocorticoids should be avoided unless treating a preexisting disorder such as lupus or rheumatoid arthritis.

Most episodes of ischemic colitis are mild and self-limiting. Patients who fail to improve or have worsening symptoms within a few days should raise the concern for the development of full-thickness ischemia and should have repeat imaging or endoscopy to help guide treatment.

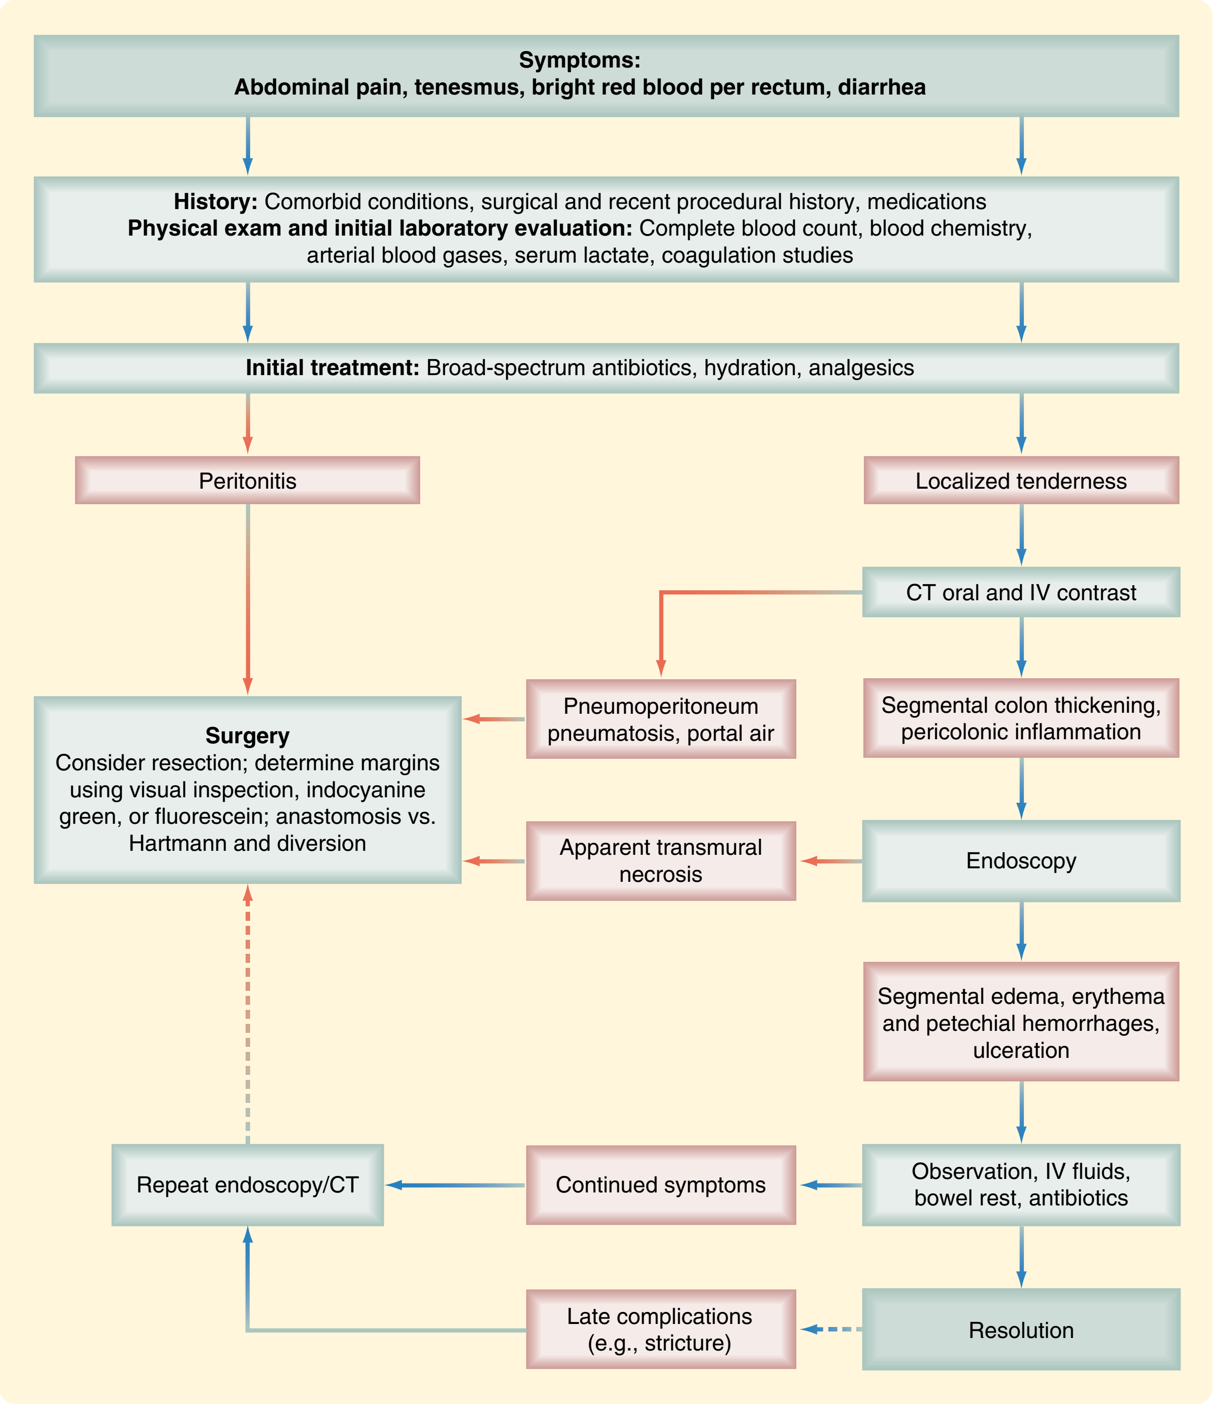
A small proportion of patients with mild to moderate symptoms will develop a chronic colitis, with ongoing or recurrent bouts of symptoms of abdominal pain, bloody diarrhea, and sepsis. These patients have a higher rate of complications and commonly require surgical resection of the involved segment. Some patients who initially recover from partial-thickness ischemic colitis will eventually develop a chronic stricture at the involved segment. These patients may complain of constipation, narrowed stools, and abdominal pain. Diagnosis can be confirmed with a contrast enema, CT, or endoscopy. Symptomatic patients or those in which malignancy cannot be excluded should undergo elective resection.

Patients who present with or develop signs of transmural ischemia and perforation—including peritonitis; hemodynamic instability; free peritoneal air; and ominous signs on CT, as mentioned earlier, such as portal venous gas—require emergent surgical exploration. A recent large database study identified a 25% 30-day postoperative mortality rate for ischemic colitis,[73] with other studies reporting up to 47% mortality after acute surgical intervention. Risk factors independently identified as associated with perioperative mortality after colectomy for ischemic colitis include elderly age, poor functional status, multiple comorbidities, preoperative septic shock, preoperative blood transfusions, preoperative acute renal failure, and delay from hospital admission to surgery.

During surgery, it is important to visualize and assess the entire small and large intestine for signs of ischemia and gangrene. Ischemia commonly affects a recognizable segment of the colon, frequently in watershed areas. In these cases, an anatomic resection should be performed to allow sufficient blood supply to the remaining colon with minimal reliance on stressed collaterals. Deciding how much to resect or whether a specific segment is likely to survive can be difficult. Visual examination tends to be inaccurate, especially when the bowel is ischemic but still viable. Intraoperative infrared angiography is a relatively new technique that has been gaining popularity as an adjunct for determining bowel viability and for determining the integrity of intestinal anastomoses. In this technique, indocyanine green is injected intravenously and distributes throughout the circulation. Then, using a variety of commercially available imaging systems, the indocyanine green undergoes laser excitation, demonstrating real-time tissue perfusion (Fig. 95.56). Creation of an anastomosis is usually not recommended in the acute setting because of the concern for evolving ischemia and the existence of hemodynamic instability and sepsis commonly encountered in these situations. A temporary abdominal closure with a planned second look after 24 hours may be prudent to determine the need for further resection. Staple the ends and leave them in the abdomen, avoiding complications of a stoma, as in very obese patients. Pancolic ischemia is rare, but such cases require total colectomy with ileostomy. In contrast to mesenteric ischemia of the small intestine, there is usually no indication for revascularizing the large bowel in primary colonic ischemia, which is not generally related to large artery obstruction.

PELVIC FLOOR DISORDERS AND CONSTIPATION

Disorders of the pelvic floor include multiple conditions, often involving colorectal, urologic, and gynecologic specialists. Constipation is a dysfunction of colonic motility and of the defecation process. It can be present with several medical and colorectal conditions, including colon obstruction and pelvic floor diseases. Functional constipation is an entity that must be differentiated from distinct anatomic problems during patient evaluation and



Symptoms:
Abdominal pain, tenesmus, bright red blood per rectum, diarrhea
History: Comorbid conditions, surgical and recent procedural history, medications
Physical exam and initial laboratory evaluation: Complete blood count, blood chemistry, arterial blood gases, serum lactate, coagulation studies
Initial treatment: Broad-spectrum antibiotics, hydration, analgesics
Peritonitis
Localized tenderness
CT oral and IV contrast
Surgery
Consider resection; determine margins using visual inspection, indocyanine green, or fluorescein; anastomosis vs. Hartmann and diversion
Pneumoperitoneum pneumatosis, portal air
Segmental colon thickening, pericolonic inflammation
Apparent transmural necrosis
Endoscopy
Segmental edema, erythema and petechial hemorrhages, ulceration
Repeat endoscopy/CT
Continued symptoms
Observation, IV fluids, bowel rest, antibiotics
Late complications (e.g., stricture)
Resolution

FIGURE 95.55 Algorithm for investigation and treatment for ischemic colitis. *CT*, Computed tomography; *IV*, intravenous. (From Netz U, Galandiuk S. Management of ischemic colitis. In: Cameron JL, Cameron A, eds. *Current Surgical Therapy*. 12th ed. Philadelphia: Elsevier; 2017:171-176.)

may be considered for surgical treatment if unresponsive to active medical therapy. The reader is referred to the ASCRS Consensus Statement of Definitions for Anorectal Physiology Testing and Pelvic Floor Terminology, Clinical Practice Guidelines for the Treatment of Rectal Prolapse, and Clinical Practice Guideline for the Evaluation and Management of Constipation.

The pelvic floor disorders that present to the surgeon include:

- Rectal prolapse or procidentia: a circumferential, full-thickness intussusception of the rectum
- Rectocele: a bulging of the rectum into the posterior wall of the vagina
- Cul-de-sac hernia: a protrusion of the peritoneum between the rectum and the vagina, referred to as *enterocele* if it contains the small bowel and as *sigmoidocele* if it contains the sigmoid colon.
- Anismus: the failure of the puborectalis and the external anal sphincter to relax during defecation (simple nonrelaxation or paradoxical contraction)

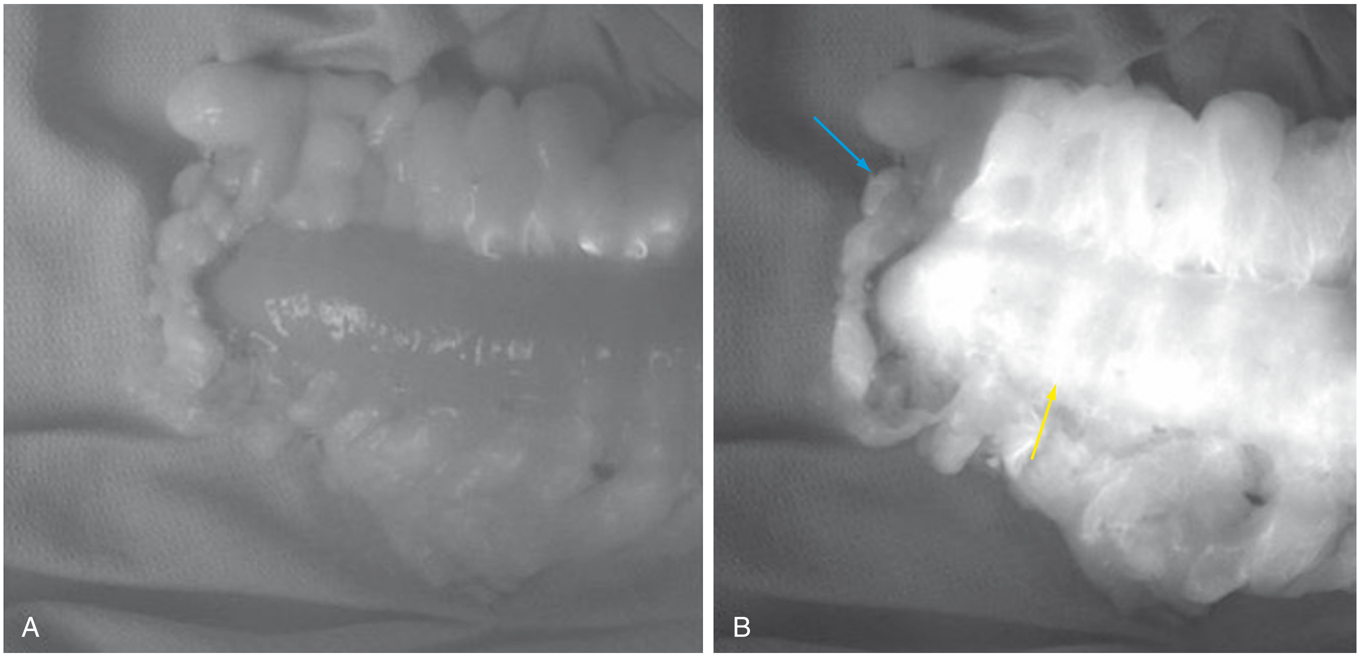


FIGURE 95.56 Indocyanine green–based infrared angiography. (A) Colon before injection. (B) Colon after injection: ischemia of resection margin *(blue arrow);* normal perfusion of colon *(yellow arrow)*. (From Netz U, Galandiuk S. Management of ischemic colitis. In: Cameron JL, Cameron A, eds. *Current Surgical Therapy*. 12th ed. Philadelphia: Elsevier; 2017:171-176.)

Even if functional disorders do not always require surgical operation, the surgeon is almost always involved in the evaluation of these patients and in establishing a treatment plan.

Diagnosis: Testing and Evaluation

Anorectal Physiology Laboratory Tests

Anorectal physiology tests are performed to evaluate anal canal pressures to determine the presence of anal reflexes, anal sensation, and electromyography recruitment.

Anorectal manometry evaluates the high-pressure zone (including the length of the anal canal); the resting pressure, mostly due to the internal sphincter; the maximum voluntary pressure; and the squeeze pressure, due to the external anal sphincter (Fig. 95.57). The test is performed by placing a manometry catheter with a water-filled balloon at its tip in the anal canal so that the balloon at the tip lies within the rectal lumen. Normal resting pressure values are 40 to 80 mm Hg. Anorectal manometry also provides information on intrarectal pressures, reflexes, rectal sensation, and rectal compliance. High-resolution manometry can provide greater physiologic resolution and minimizes motion artifacts.

The balloon expulsion test evaluates the ability of the patient to expel a balloon inflated with 50 to 60 cc of water/gas/air that simulates stool.

Pudendal nerve terminal motor latency measures the conduction of the pudendal nerve from its emergence at the level of the ischial spines to the internal anal sphincter by the use of a transducer. Normal pudendal nerve terminal motor latency times are 2.0 ± 0.2 milliseconds. Prolonged values are seen in traumatic injuries (spinal cord) or with stretch injury from obstetric trauma resulting from prolonged labor, chronic stretch injury as seen in long-standing defecation disorders, sacral nerve root damage, or chronic diseases such as diabetes. This is typically measured with a special electrode taped to the index finger of the examiner, whereby the tip of the finger electrode stimulates the pudendal nerve, and the recording electrode at the base of the finger measures anal sphincter contraction.

Electromyography records the change from basal electrical activity of motor units of the external sphincter and puborectalis muscle during activity. Patients with inappropriate or paradoxical puborectalis contraction fail to show a relaxation of the muscles when asked to push.

Imaging to Evaluate the Pelvic Floor and Colonic Transit

Endoanal ultrasound (Fig. 95.58) can be used to evaluate the integrity, thickness, and possible abnormalities (scars, fistulas) of the internal and external anal sphincter.

Defecography is a dynamic study of the anorectum and the pelvic floor during defecation. It provides information regarding anatomic abnormalities, such as rectocele, rectal prolapse, internal rectal intussusception, and cul-de-sac hernia, as well as about functional disorders, such as nonrelaxation or paradoxical puborectalis contraction, perineal descent, and the degree of rectal emptying. Dynamic images are captured with fluoroscopy, with the rectum and the vagina opacified with radiographic contrast and the patient in the sitting position on a radiolucent commode. If magnetic resonance defecography is performed, the rectum is opacified with a mixture of ultrasonography gel and gadolinium. The advantages of MRI are high-quality images of the pelvic soft tissues and viscera and avoiding use of ionizing radiation. It is, however, limited by the supine position of the patient, which does not reproduce normal conditions of defecation (Fig. 95.59). Furthermore, a recent study showed that magnetic resonance defecography seems equivalent to traditional x-ray video defecography in the assessment of defecation disorders.[74]

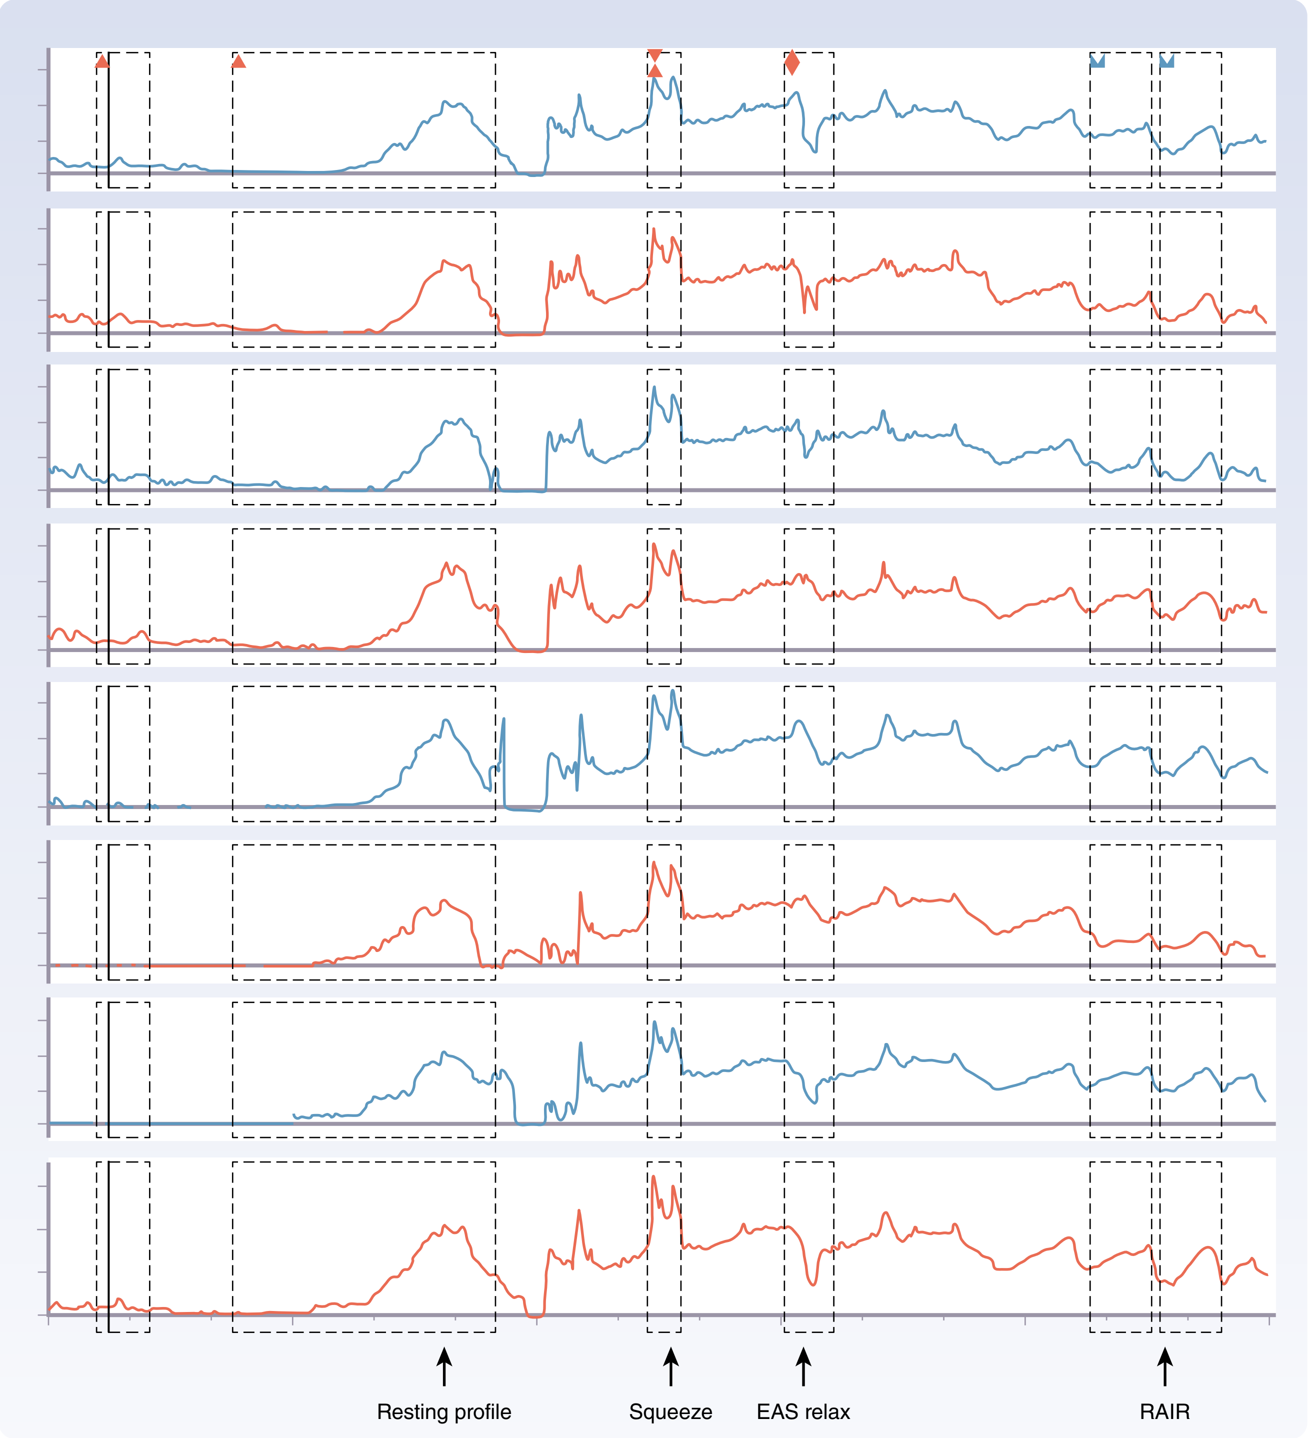

FIGURE 95.57 A normal anorectal manometry: resting and squeeze pressure curves are evident, and the external anal sphincter relaxation when the patient is asked to push. The rectoanal inhibitory reflex is present. *EAS*, External anal sphincter.

Colonic transit time is a test that studies colonic inertia. The patient is asked to ingest 24 radio-opaque markers contained in a capsule (Sitzmarks®) and to refrain from using laxatives and any other mechanical measures that might interfere with colonic function. The progression of the markers through the three areas of the colon (right, left, and rectosigmoid) is studied with plain abdominal films that are taken every other day until day 7. In the healthy population, 80% of the markers should be expelled by day 5. Patients with slow transit constipation or colonic inertia retain a significant portion of the markers during the entire time of the study (Fig. 95.60).

Rectal Prolapse (Procidentia)

Anatomy and Pathophysiology

Rectal prolapse is a circumferential, full-thickness intussusception of the rectal wall. The degree of prolapse can vary from intrarectal

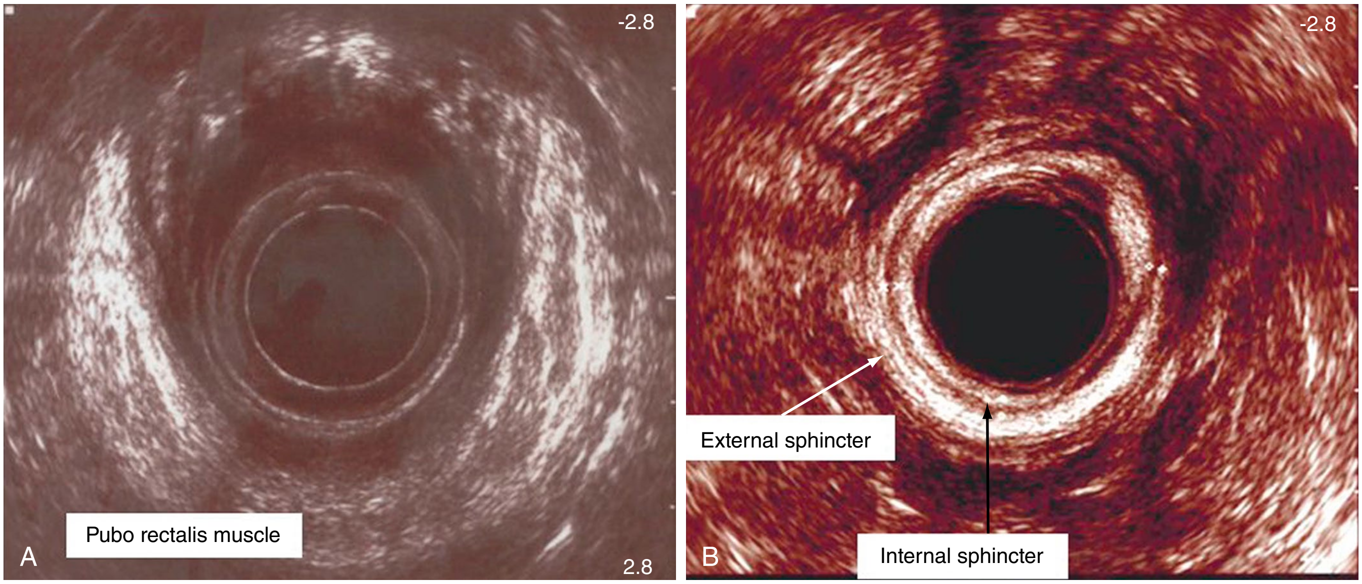

FIGURE 95.58 Endoanal ultrasound. (A) The arch-shaped hyperechoic puborectalis muscle appears as a whitish structure. (B) The hypoechoic internal sphincter *(black arrow)* and the hyperechoic external sphincter *(white arrow)* are shown.

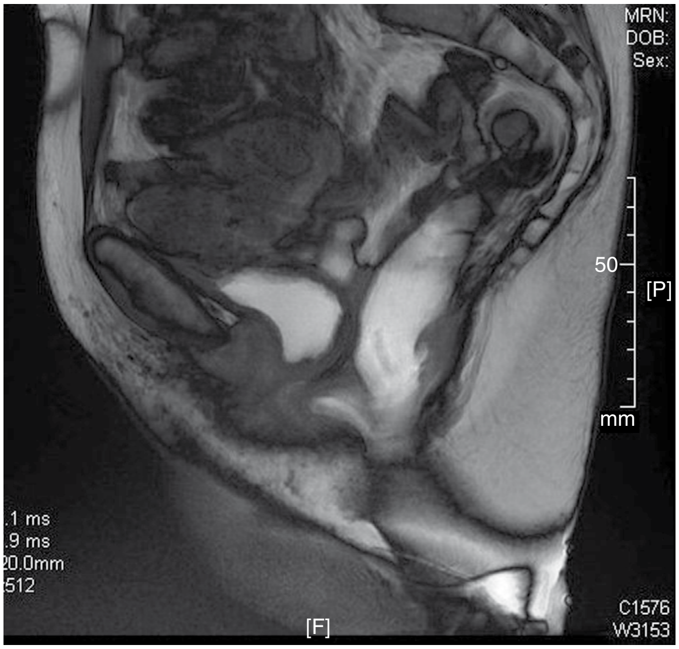

FIGURE 95.59 A magnetic resonance imaging image of rectal prolapse.

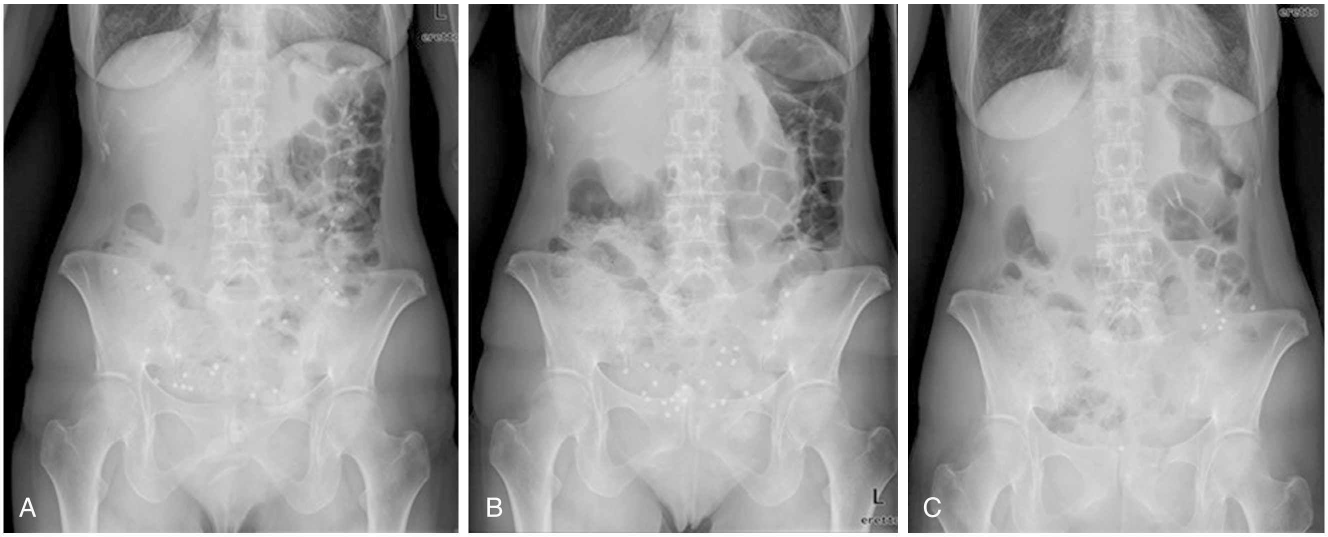
or internal rectal prolapse (Fig. 95.61) to intraanal prolapse to external rectal prolapse (Fig. 95.62). Rectal prolapse is an uncommon condition that occurs in about 0.5% of the general population, with females older than 50 years being six times more likely than males to develop rectal prolapse. The few males who present with rectal prolapse are usually younger than 40 years. Rectal prolapse in young males may have a special geographic predilection because certain countries, including Egypt and India, tend to have a higher incidence of rectal prolapse in young males. Young patients (males and females) with prolapse often suffer from psychiatric diseases, such as autism or developmental delay, and take constipating medications. The cause of rectal prolapse is still unknown, but some anatomic defects are commonly found in patients with total rectal prolapse. These defects include a diastasis of the levator ani muscle, an abnormally deep cul-de-sac, a redundant sigmoid colon, a patulous anus, and a lack of fascial attachments of the rectum against the sacrum. Risk factors of rectal procidentia include age over 40 years, female sex, prior pelvic surgery, chronic straining and constipation, chronic diarrhea, vaginal delivery and multiparity (however, one-third of the female rectal prolapse patients are nulliparous), pelvic floor dysfunction and/or anatomic defects, neurologic diseases/injuries, and psychiatric diseases that require constipating medications. Rectal prolapse usually has a progressive course from transient self-reducing prolapse during defecation to prolapse requiring digital self-reduction, then to stable prolapse that may present with ulceration and even nonreducible, incarcerated prolapse with necrosis in the most advanced and complicated cases.

Symptoms

Symptoms include discomfort from the prolapsed tissue, incontinence with drainage of mucus or blood, and constipation. The majority (50%–75%) of patients with evident rectal prolapse complain of fecal incontinence (passive or urge incontinence) that is caused by the presence of a direct conduit and by the chronic stretching of the sphincter resulting from the prolapse, which may induce an anal sphincter injury graded into four grades by endoanal ultrasound.[75] Also, the persistent stimulation of the rectoanal inhibitory reflex caused by the prolapsed rectum is one of the contributing factors to continence impairment. Up to one-half of patients with incontinence also have pudendal neuropathy, with a prolonged pudendal nerve terminal motor latency. The other 25% to 50% of the patients, and in particular those with intrarectal prolapse, report constipation or obstructed defecation (feeling of an incomplete rectal evacuation during defecation) that results from the "telescoping" of the bowel on itself, creating a functional blockage that worsens with straining (Fig. 95.61), or by the presence of a concomitant rectocele.



Day 3 Day 5 Day 7

FIGURE 95.60 Colonic transit study: plain abdominal films at 3, 5, and 7 days after ingestion of radiopaque markers. Note that at day 5, the majority of the radiopaque markers are within the pelvis; however, by day 7, most markers have passed.

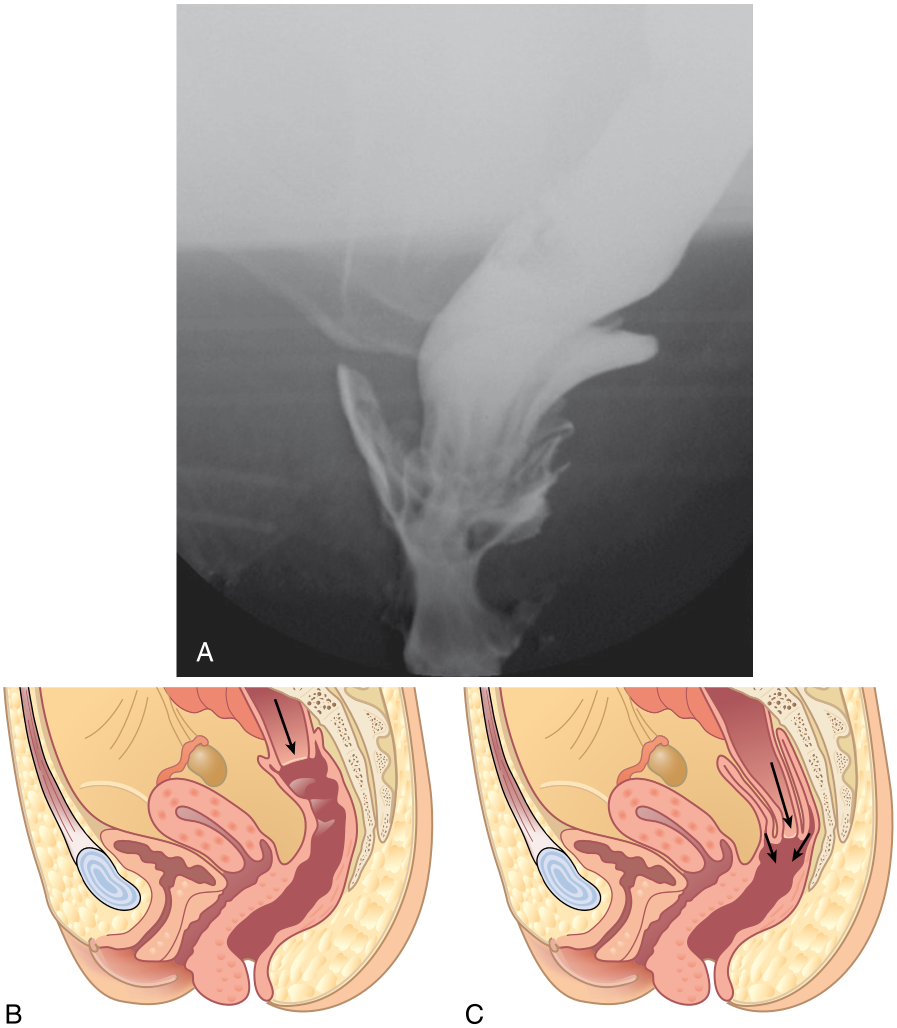


FIGURE 95.61 (A) The internal rectal prolapse of a male patient is nicely demonstrated by defecography. (B–C) Progression of the internal rectal prolapse.

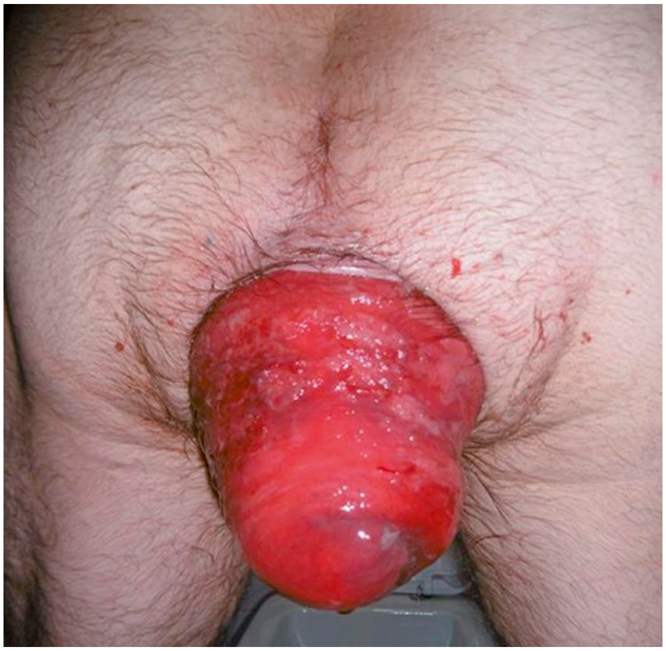

FIGURE 95.62 A patient with a large external rectal prolapse. (Courtesy G. Sarzo, MD, Hospital Sant Antonio, Department of Surgery, Padova Italy.)

Diagnosis and Differential Diagnosis

On physical exam, true rectal prolapse must be differentiated from prolapsed rectal mucosa or prolapsed hemorrhoids: the full-thickness rectal prolapse has concentric folds, whereas prolapsed hemorrhoids or rectal mucosa is characterized by radial folds, with grooves along hemorrhoid cushions. At rest, typical findings include a patulous anus with a lax sphincter. Examination is performed in the office with the patient in standard left lateral decubitus or in the sitting or squatting position during straining. If the prolapse cannot be observed in the office setting, the patient can be asked to take a “selfie” at home to document the prolapse. Proctoscopic examination demonstrates redundant tissue and, in 10% to 15% of patients, an anterior solitary rectal ulcer. Proctoscopy may indicate erythema at 5 to 6 cm, which is the leading edge of the prolapse. Fluoroscopic or MRI defecography is an additional test to confirm the diagnosis of rectal prolapse and provides more information regarding coexisting disorders, such as rectocele, cystocele, vaginal vault prolapse, enterocele, and sigmoidocele (see Figs. 95.62 and 95.63). Colonoscopy should always be performed to exclude the presence of CRC or other colonic pathology. A colonic transit study is performed in patients with a lifelong history of constipation in order to differentiate constipation resulting from obstructed defecation from constipation resulting from slow colonic transit. The two frequently coexist. Endoanal ultrasound usually shows a thickening of the internal anal sphincter.

Nonoperative Management

Prolapse-associated symptoms of constipation and fecal incontinence can be palliated with medical treatment to improve quality of life. Adequate fluid intake, fiber supplements, and stool softeners can treat constipation. Sugar or salt can be used topically to reduce rectal mucosal edema and facilitate reduction of the prolapsed tissue. Enemas and suppositories may be helpful to assist in defecation.

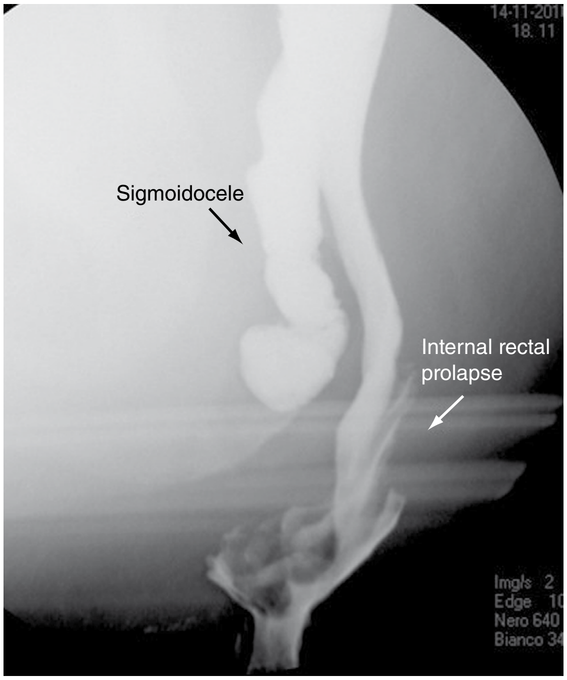

FIGURE 95.63 Defecography of a young male patient who presents with internal rectal prolapse *(white arrow)* and sigmoidocele *(black arrow)*.

Operative Repair

The goals of surgery are to eliminate the prolapse and correct the anatomic and functional abnormalities. The approach can be transabdominal or transperineal. Perineal procedures are followed by a relatively high incidence of recurrence, yet an acceptably low complication rate as compared to the abdominal procedures.[76] The choice of procedure is based on the patient’s comorbidities, the patient’s age and bowel function, and the surgeon’s preference. A network meta-analysis concluded that posterior mesh rectopexy was associated with the lowest recurrence while perineal procedures ranked worst with the highest recurrence rates. There were no significant differences between the abdominal and perineal procedures in complications and improvement in incontinence.[77]

Abdominal procedures. The rationale of the intraabdominal approach is to perform a fixation of the rectum with the goal of providing adequate upward tension to prevent a recurrence but at the same time allowing appropriate evacuatory movements during defecation. The abdominal approach can be performed via open or minimally invasive approaches (laparoscopic or robotic). Both have equivalent clinical and functional results, recurrence rates (4%–8%), and morbidity (10%–33%). Laparoscopy offers benefits in terms of pain control, hospital stay, and recovery time. The advantages offered by robotic rectal prolapse repair are the ease of suturing and tying and improved visualization of the deep pelvis. The rectum must be dissected, retracted intraabdominally, and fixed to the presacral fascia with sutures (posterior rectopexy). In these cases, a simultaneous resection of the redundant sigmoid can be performed in selected patients with coexisting constipation. A mesh can be used to increase scarring and improve fixation of the rectum posteriorly or anteriorly. With the posterior mesh rectopexy, the rectum is mobilized posteriorly and laterally down to the levator ani muscles, and a mesh is fixed to the presacral fascia, below the sacral promontory, and to the rectum laterally (Fig. 95.64). This technique is associated with significant improvement in fecal incontinence in 20% to 60% of patients but has a 20% rate of

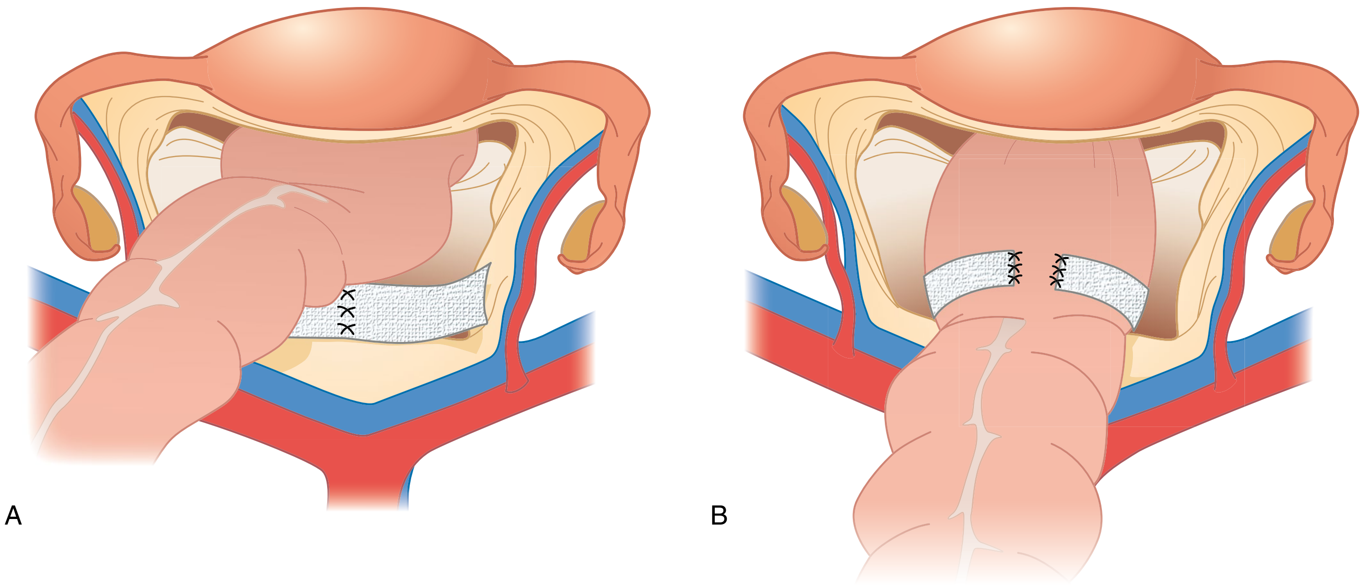

FIGURE 95.64 The posterior mesh rectopexy (modified Ripstein operation). (A) The rectum is mobilized, and the mesh is fixed to the presacral fascia. (B) The mesh is fixed to both sides of the rectum.

postoperative complications and is associated with a 2% to 5% recurrence rate. The more recently described ventral mesh rectopexy is a technique that involves a limited anterior rectal mobilization and a mesh suspension to the sacral promontory. The mesh is fixed to the anterior wall of the rectum and suspended to the sacral promontory (Fig. 95.65). Advantages of this technique are the improvement in postoperative incontinence and constipation, with few cases of de novo postoperative constipation, and low complication and recurrence rates (3%–5%).[78,79] In published series, many different types of mesh and fixation devices are used: nonabsorbable or biologic grafts, tacks, sutures, or staples to fix the mesh. Mesh-related complications include erosion, usually into the vagina; infection and pelvic sepsis; bowel obstruction; and mesh detachment and/or migration. In theory, with the use of biologic mesh, the risk of infection or erosion may be lower, and the risk of recurrence may be higher, but recent literature[78] shows no statistical improvement in recurrence and complication rates between biologic and nonabsorbable mesh. The follow-up for studies using biologic mesh is, however, short. One meta-analysis with a meta-regression analysis showed that male sex and the length of mesh used were significantly associated with full-thickness recurrence of rectal prolapse after ventral mesh rectopexy.[79] Concomitant pelvic organ prolapse (POP) and rectal prolapse repair with isolated apical prolapse repair or rectopexy may offer a comprehensive treatment for patients with multicompartmental prolapse without increasing the risk of postoperative complications.[80]

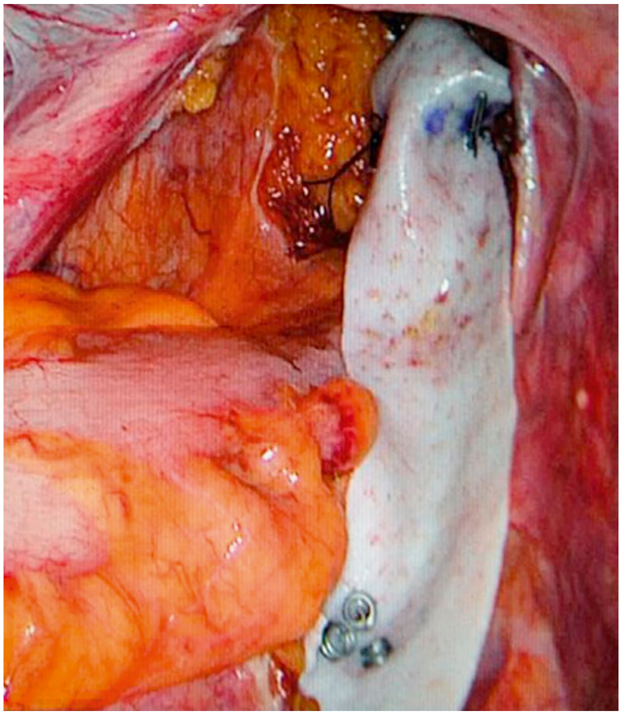

FIGURE 95.65 Ventral mesh rectopexy. The mesh is attached to the anterior rectal wall and the sacral promontory. (Courtesy G. Sarzo, MD, Hospital Sant Antonio, Department of Surgery, Padova, Italy.)

Perineal approach. Perineal procedures allow for the resection of the prolapse without concomitant fixation. They are recommended for the elderly or medically unfit patients and are thought to be associated with lower operative morbidity and mortality but with higher recurrence rates. Recent reviews and trials have, however, concluded that there are no significant differences in recurrence and reoperation rates between perineal and abdominal approaches. Therefore perineal procedures may have to be considered an option for all patients with rectal prolapse. The "Altemeier procedure," or perineal proctectomy or proctosigmoidectomy, is a true rectosigmoidectomy. The prolapse is exteriorized, it is grasped with Allis clamps, and a full-thickness circumferential incision is made through the rectum 1 cm above the dentate line. The peritoneal cavity is entered anteriorly, and the redundant sigmoid colon is extracted transanally (Fig. 95.66). The levator muscles are visualized and can be plicated posteriorly in order to reinforce the pelvic floor and restore the anorectal angle (levatorplasty, or Parks postanal repair). A hand-sewn or stapled coloanal anastomosis is then performed. The operation can be done under epidural anesthesia, with

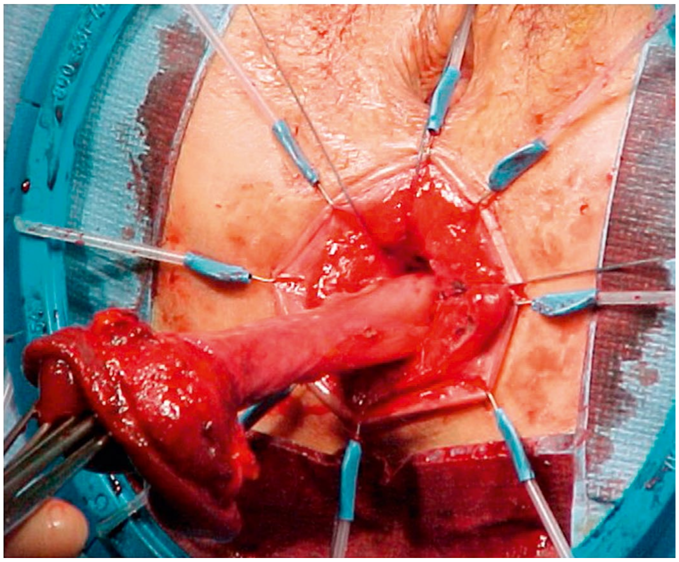

FIGURE 95.66 The Altemeier procedure or perineal proctectomy. The redundant rectosigmoid colon is resected through a transperineal approach, and a hand-sewn coloanal anastomosis is performed.

minimal postoperative pain. This technique allows for the resection of redundant bowel, it has low complication rates, and especially when levator plication is done, it is associated with low recurrence rates (10%). For patients with a short (<5 cm) rectal prolapse, the Delorme procedure can be appropriate. A circumferential incision within the submucosal plane is made 1 cm proximal to the dentate line, and the mucosa is stripped away from the muscularis propria of the rectum to the most proximal portion of prolapse. The stripped mucosa is then excised. A longitudinal suture plication of the muscularis propria is then performed. Finally, an anastomosis is performed between the proximal and distal mucosal edges (Fig. 95.67). This technique is very safe, entails a short hospital stay, and has lower complication rates than the abdominal approach. Incontinence and constipation are improved. Overall recurrence rates range from 7% to 27% and are comparable to the Altemeier or abdominal procedures. For symptomatic intrarectal prolapse, the stapled transanal rectal resection (STARR) has been proposed as an alternative possible technique. It consists of a full-thickness rectal resection, including the internal prolapse, with a circular stapler (STARR) or a specific curved-shape stapler (Transtar). These techniques have initially shown good results in cases of obstructed constipation, but the onset of chronic proctalgia and stool urgency with postoperative incontinence have often been reported. Other complications of transrectal stapled repair are staple-line bleeding and, rarely, staple-line disruption and rectovaginal fistula (overall morbidity rate from 7% to 21%). Because of the high rate of serious complications and poor functional outcome, this is not recommended by the ASCRS Clinical Practice Guidelines.

Solitary Rectal Ulcer

Solitary rectal ulcer syndrome (SRUS) is a rare chronic benign disorder characterized by a combination of symptoms, clinical findings, and histologic abnormalities. Twenty percent of patients have a single ulcer, whereas 40% of patients have multiple ulcers. The remainder have nonspecific lesions such as hyperemic mucosa or pseudopolyps.

SRUS is a disorder of young adults (30–40 years), with a slight female predominance. The cause is multifactorial and includes internal rectal prolapse and abnormal/paradoxical contraction of the puborectalis muscle. These two conditions result in trauma and compression of the anterior rectal wall on the upper anal canal during straining and defecation, with resulting mucosal ischemia and, in some cases, ulceration. Symptoms reported by patients with SRUS include rectal bleeding, prolonged excessive straining, incomplete defecation/tenesmus, mucous discharge, perineal and abdominal pain, and constipation. Up to one-quarter of patients are asymptomatic.

Physical examination and anoscopy demonstrate an intrarectal prolapse and a 1- to 1.5-cm ulcer of the anterior rectal wall 3 to 10 cm from the anal verge that is sometimes difficult to differentiate from a rectal cancer. Histologic examination of biopsies shows characteristic findings: fibromuscular obliteration of the lamina propria, hypertrophied muscularis mucosae with muscular fibers between the crypts, and glandular crypt abnormalities. These specific findings differentiate SRUS from cancer and other inflammatory lesions such as IBD, ischemic colitis, and infectious proctitis.

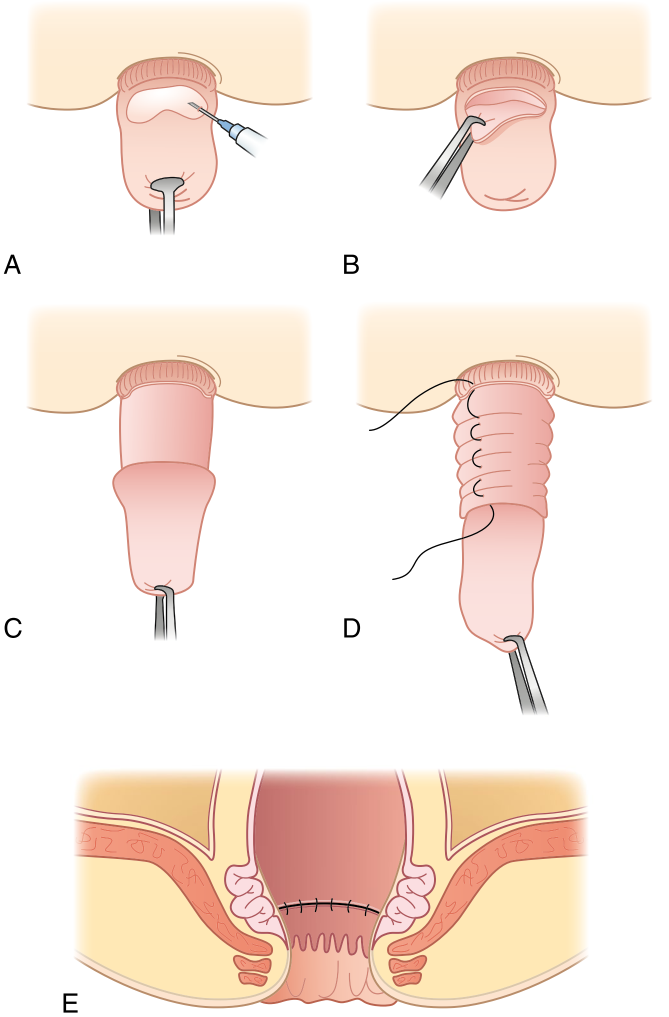

FIGURE 95.67 The Delorme procedure. The mucosal layer is infiltrated with epinephrine-containing solution (A), incised (B), and stripped off the underlying muscularis (C). Plication of the muscularis propria is performed (D). The operation concludes with an anastomosis between the proximal and distal mucosal edges (E).

For patients with mild to moderate symptoms and no significant mucosal prolapse, medical treatment is usually effective. It consists of patient education and behavioral modification: high-fiber diet; stool softeners and bulking laxatives; avoidance of straining and/or anal digitations; minimizing time on the toilet; and the use of sucralfate, corticosteroid, and/or mesalamine enemas. Surgery is rarely indicated and is reserved only for highly symptomatic patients absolutely unresponsive to medical treatment. Surgical options include local excision of the ulcer, treatment of the rectal prolapse, or a defunctioning stoma for patients who have failed other options. Unfortunately, many patients with SRUS continue to have symptoms of anorectal dysfunction regardless of the treatment.

Rectocele

A rectocele is a bulging of the anterior wall of the rectum into the posterior wall of the vagina. The most common risk factors are advanced age, history of pregnancy and vaginal childbirth, increasing BMI, chronically elevated intraabdominal pressure, and a history of hysterectomy. The cause of rectocele is multifactorial and may be explained by muscular and/or neurologic damage to the rectovaginal septum (usually resulting from obstetric trauma) and by the effect of chronic straining on the endopelvic fascia and on the posterior wall of the vagina. It can be associated with other pelvic organ prolapses. Most rectoceles are asymptomatic, but when they become symptomatic, the cardinal symptom is difficulty in rectal emptying and the need to press against the posterior wall of the vagina or against the perineum in order to complete the rectal emptying (obstructed defecation). Other symptoms include the sensation of a vaginal bulge, urinary and/or sexual dysfunction, constipation, and in some cases, fecal incontinence. The mechanism of incontinence is thought to be fecal trapping within the rectal pocket, allowing for postdefecatory leakage; an associated mucosal prolapse that impairs anal closure; or overflow incontinence. The diagnosis of rectocele is mainly clinical and based on physical examination. Digital vaginal and rectal examinations show a bulging in the posterior vaginal wall and in the anterior rectal wall during straining that can be associated with the prolapse of other pelvic organs and with anterior cystocele. Associated stress urinary incontinence is assessed by making the patient cough or perform the Valsalva maneuver with a full bladder.

On defecography, the rectocele appears as a bulging of the rectal wall toward the vagina. A rectocele is graded as small if it is less than 2 cm, moderate if it is between 2 and 4 cm, and large if it is larger than 4 cm in size (Fig. 95.68). This test also gives information about the possible trapping of contrast within the rectocele during defecation and about the possible association with an enterocele or sigmoidocele. It is important to realize that the degree of anatomic distortion often does *not* correlate with the degree of functional impairment and symptoms. Dynamic MRI and MRI defecography are limited by the fact that they are performed with the patient in the supine position (not in the normal upright position for defecation). The balloon expulsion tests can identify the inability to expel an inflated balloon from the rectum after 4 minutes of sitting on a commode. Asymptomatic rectoceles do not need treatment, whereas patients with a symptomatic rectocele are initially managed with a bowel regimen and fiber products in order to improve defecation. Only selected patients with markedly symptomatic rectoceles unresponsive to medical treatment are candidates for surgery. The goal of surgery is to remove the redundant tissue of the rectocele and strengthen the rectovaginal septum.

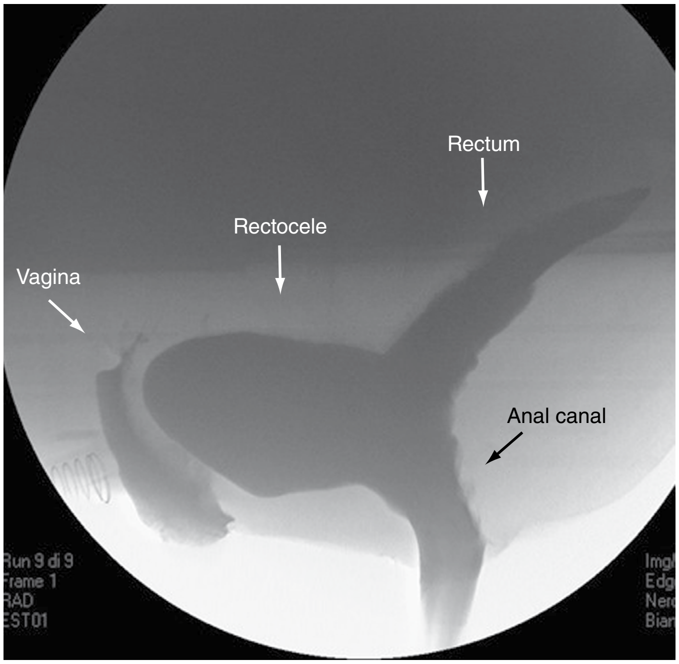

FIGURE 95.68 A defecating proctogram. Both the vagina and the rectum are opacified. The rectocele is clearly evident.

The transvaginal approach, preferred by gynecologists, allows for better visualization of and access to the levator muscles. A local anesthetic with epinephrine or vasopressin is injected below the vaginal mucosa to dissect the tissue and for hemostasis. The vaginal epithelium is opened in the posterior midline to the upper level of the defect; the fibromuscular layer is exposed and plicated in the midline with vertically or transversely placed sutures. The puborectalis can be reapproximated. The surplus vaginal epithelium is cut off if necessary and sutured with absorbable sutures.

An endorectal repair is performed by colorectal surgeons, with the patient in prone jackknife position. A local anesthetic plus epinephrine or vasopressin is injected into the submucosal plane to dissect the tissue and for hemostasis. A T-shaped or midline incision is made in the rectal mucosa just above the dentate line. Two lateral mucosal flaps are developed on either side of the midline to a level proximal to the rectocele. The excess rectal mucosa is excised. The underlying muscularis layer is exposed and plicated with transversely placed absorbable sutures, and the mucosal edges are then approximated with absorbable sutures. The transperineal rectocele repair is performed by a transverse incision across the bulbocavernosus and transverse perineal muscles; the two limbs of the puborectalis muscle are reapproximated. Transvaginal repair of rectocele was found to confer a better improvement in constipation and sexual-related quality of life than transperineal repair, without an increased incidence of dyspareunia.[81] A mesh can be placed in order to reinforce the plasty. This approach is indicated especially in patients with associated fecal incontinence because a concomitant sphincteroplasty or levatorplasty can be performed.

Constipation

Constipation is a frequent condition that can affect more than 50% of the population over age 65, but in a small subset of patients, constipation may present at a younger age. Several medical conditions can contribute to constipation, including metabolic, endocrine, neurologic, and psychiatric disorders. In adults, new-onset constipation is always a worrisome symptom, and the primary cause must be excluded. Hypothyroidism and medication-induced constipation are common causes. The presence of colorectal malignancies and other causes of colonic obstruction must be excluded with colonoscopy. Patients should be counseled to increase fluid intake up to 1.5 to 2 L/day and to increase the fiber content in the diet. Polyethylene-based solutions (e.g., MiraLAX), probiotics, and over-the-counter products may be helpful. Stimulant laxatives such as bisacodyl or senna should not be used long term. A locally acting chloride channel activator (lubiprostone; Amitiza), a guanylate cyclase agonist (Linzess), and/or a serotonin 5-HT4 agonist (Motegrity) can all be used to treat symptoms of constipation. Long-term constipation, resistant to medical treatment and laxatives, should be further investigated. According to Rome IV criteria, functional constipation is diagnosed if (1) there are at least two of the following symptoms, during at least 25% of defecations, for at least 3 months[82]: straining, lumpy or hard stools, a sensation of incomplete evacuation, sensation of anorectal obstruction/blockage, need for manual maneuvers to facilitate defecation (e.g., digital evacuation, support of the pelvic floor), or fewer than three spontaneous bowel movements per week; (2) loose stools are rarely present without the use of laxatives; and (3) there are insufficient criteria for irritable bowel syndrome. In the presence of obstructed defecation symptoms, defecography, anorectal manometry, balloon expulsion testing, and electromyography can exclude the presence of pelvic floor disorders. Measuring the colonic transit time with the use of radiopaque markers (Sitzmark) can establish the diagnosis of slow transit constipation or colonic inertia. Slow transit constipation can have a neuropathic origin, even if a specific histologic change has not yet been demonstrated. The frequency of bowel movements varies in these patients from one to two per week to one per month. Some patients are unable to have a complete bowel movement in the absence of laxatives or colonic enemas. Severe constipation is associated with abdominal distention, abdominal pain, and nausea, and these symptoms can so affect the quality of a patient's life that they can be absolutely miserable. Chronic symptoms can be present from childhood or adolescence. Slow transit constipation can present with a megacolon on plain x-ray (Fig. 95.69); a water-soluble enema or colon CT can show a redundant, hypotonic colon, and colonoscopy similarly demonstrates a dilated hypotonic colon. In a subset of patients, the colon can be normal and not dilated at radiologic examination. In these patients, the diagnosis and the decision to initiate surgical treatment can be challenging. In highly symptomatic patients with slow transit constipation who failed aggressive medical therapy and whose quality of life is severely impaired, surgical treatment is indicated. Abdominal colectomy with IRA (total abdominal colectomy with ileorectal anastomosis or colectomy with ileorectal anastomosis) can be performed with minimally invasive techniques. Despite postoperative diarrhea (5%–15%), abdominal pain (30%–50%), small bowel obstruction (10%–20%), fecal incontinence, and recurrence of constipation (10%–30%) that have been reported in long-term follow-up, single-center series have demonstrated acceptable results. A systematic review concluded that although colectomy may offer benefits for some patients with chronic constipation, it entails considerable short-term and long-term morbidity, highlighting the paucity of current evidence to guide patient or procedural selection.[83]

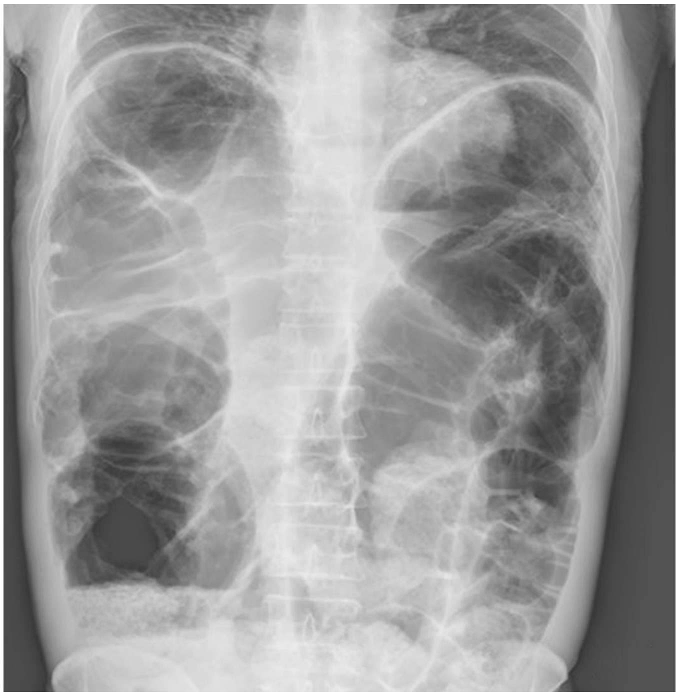

FIGURE 95.69 Plain abdominal film of a patient with slow transit constipation and megacolon.

Segmental colon resections based on transit time measurements are no longer recommended. The extreme therapeutic solution proposed to patients with intractable constipation is a permanent ostomy, usually an ileostomy.

COLORECTAL CANCER

Colorectal Cancer Genetics

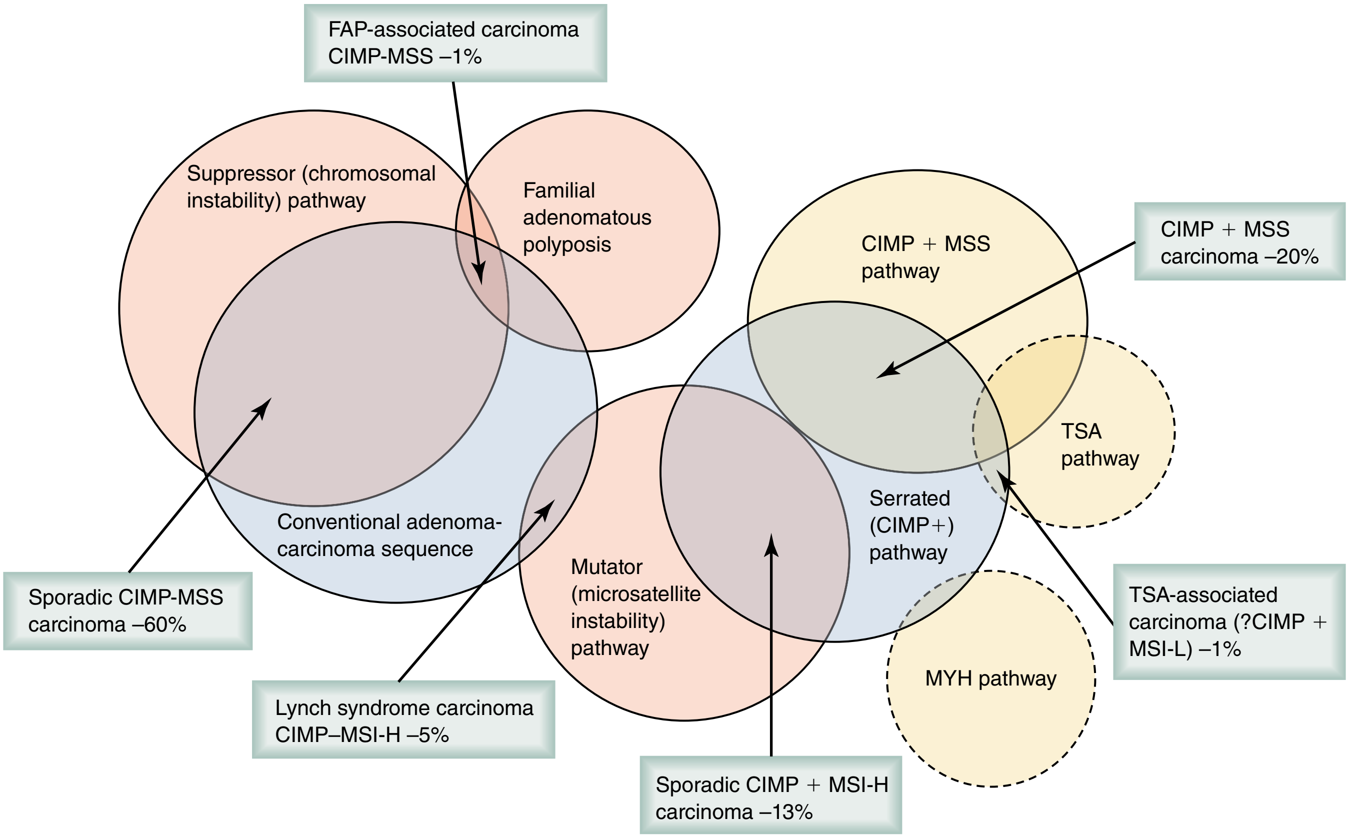
Life requires continual cell division and reproduction, a process that must maintain integrity and has a series of checks and balances. Changes in cellular DNA may occur in a variety of ways and is tightly controlled by oncogenes, tumor suppressors, and DNA repair mechanisms. Multiple genetic and epigenetic events need to happen for normal tissue to become dysplastic, expand, and invade. Defining the genomic landscape and etiologies of colorectal cancer (CRC) provides a better understanding of the varied CRC phenotypes and the differences in the clinical spectrum. Genetic changes may occur via somatic mechanisms and occur within local cells or can exist within the germline and may be inherited, causing an inherent predisposition to developing cancer.

Distinct Colorectal Cancer Pathways

In general, three distinct but potentially overlapping pathways lead to CRC development: chromosomal instability (CIN), methylation, and microsatellite instability (MSI) (Fig. 96.1).

Chromosomal instability pathway. CIN is the most common pathway observed in CRC (65%–70%). It involves a mutation that causes the loss of one allele as a result of insertion, deletion, amplification, aneuploidy, or loss of heterozygosity. Although this can happen in any part of the genome, when it includes a tumor-suppressor gene or driver gene, it provides an initiating event. In the CIN pathway, which was initially described by Fearon and Vogelstein,[1] the first hit includes abnormality in the adenomatous polyposis coli *(APC)* gene and leads to activation of the wnt signaling pathway, which produces accumulation of nuclear β-catenin and resultant proliferation signals. The initial manifestation of this is an accumulation of dysplastic cells, which can form a tubular adenoma. This pathway's activation has been identified in all CIN tumors, and 80% of these tumors have an *APC* mutation.[2–4] A subsequent *KRAS* mutation initiates extension and promotes growth, and then a third genetic change in genes such as *TP53, SMAD4, PIK3CA,* or *FBXW7* promotes invasion of surrounding tissue. The resultant lesions in this pathway include adenomas and follow the classic adenoma-to-carcinoma sequence.

The serrated or methylator pathway. The recognition of serrated polyps as precancerous lesions has led to the elucidation of the serrated or methylator pathway to CRC. Mutations in the *BRAF* gene are often the inciting event in this pathway. Subsequent increased DNA methylation in the promoter region of key tumor-suppressor genes and DNA repair genes leads to silenced expression of these genes and lack of protein transcription. Because the methylation tends to occur in the promoter regions that are rich in cysteine and guanine, these cancers have been termed the *CpG-island methylator phenotype* (CIMP).[5] CpG islands of CG dinucleotides are present in the 5′ region of almost half of human genes, and methylation leads to silencing or loss of gene expression of the downstream genes.[6] Approximately 15% to 20% of all CRCs evolve from serrated preneoplastic lesions. Some



FAP-associated carcinoma
CIMP-MSS –1%

TSA-associated carcinoma (?CIMP + MSI-L) –1%
MYH pathway
Lynch syndrome carcinoma CIMP–MSI-H –5%
Sporadic CIMP + MSI-H carcinoma –13%

FIGURE 96.1 Schematic represents several overlapping ways to describe the development of colorectal carcinoma. The *red circles* represent mechanisms based on suppressor and mutator pathways. The *blue circles* represent mechanisms based on the precursor lesion (the conventional adenoma-carcinoma sequence and serrated pathways). The *yellow circles* represent poorly characterized pathways. *CIMP–,* CpG-island methylator phenotype negative; *CIMP+,* CpG -island methylator phenotype positive; *FAP,* familial adenomatous polyposis; *MSI-H,* high degree of microsatellite instability; *MSI-L,* low degree of microsatellite instability; *MSS,* microsatellite stable; *TSA,* traditional serrated adenoma. (From Snover DC. Update on the serrated pathway to colorectal carcinoma. *Hum Pathol.* 2011;42:1-10.)

authors suggest that most interval cancers (i.e., cancers that are found between routine screening examinations) are a result of the failure to detect serrated lesions during colonoscopy because these lesions can be flat and subtle.[7,8] Methylated CRCs tend to be more common in patients of older age, tend to be located in the right colon, and are more common in females.

Microsatellite instability pathway. The MSI pathway results from a loss of mismatch repair (MMR) function, usually secondary to loss of one of the four MMR genes (mutL homolog 1 *[MLH1],* mutS homolog 2 *[MSH2],* mutS homolog 6 *[MSH6],* or PMS1 homolog 2 *[PMS2]*). There are three main etiologies for the development of MSI tumors[9]: (1) a germline pathogenic variant in one of the MMR genes (i.e., the cause of Lynch syndrome); (2) hypermethylation of the promoter region of *MLH1* with the subsequent loss of MLH1 expression; and (3) double somatic mutation loss of one of the MMR genes in the tumor. Regardless of the cause, loss of MMR function leads to the inability to fix DNA base-pair mismatches during transcription and thus the accumulation of errors in the DNA that can be incorporated and reproduced. Because DNA mismatches tend to occur in repeating areas of DNA sequences called *microsatellites,* these tumors are called *microsatellite instability-high* (MSI-H). MSI-H tumors have distinct pathologic features, such as a Crohnlike reaction, presence of mucin, lymphocytic infiltration, and high tumor mutational burden. Approximately 12% to 15% of CRCs are MMR deficient.

Colorectal Cancer Molecular Subtypes

A significant collaborative effort has been made to establish a common ground for classifying CRC based on molecular features. Four CRC subtypes based on gene expression, signaling pathways, and molecular and transcriptome-wide analysis have been proposed[10,11]:

1. CMS1: Immune, characterized by MSI, high CIN, and *BRAF* mutations.
2. CMS2: Canonical, characterized by CIN and downstream targeting of the wnt and MYC pathways.
3. CM3: Metabolic, characterized by a distinct genomic and epigenomic profile with mixed metabolic reprogramming. This subtype includes dysregulated pathways enriched with *KRAS* mutations, a low mixed state of MSI, and intermediate CIMP.
4. CMS4: Mesenchymal, characterized by overexpression of proteins involved in stromal infiltration and mesenchymal activation.

Understanding these subtypes allows for more uniform classification and the ability to collaborate on prospective clinical trials that could help evolve more precise prognosis and treatment. It has been shown that CMS4 tumors have a twofold increased risk of relapse after curative treatment, and CMS1 MSI-H tumors have a worse prognosis in the metastatic setting.[4,12] Fig. 96.2 provides an overview of the different CRC subtypes.

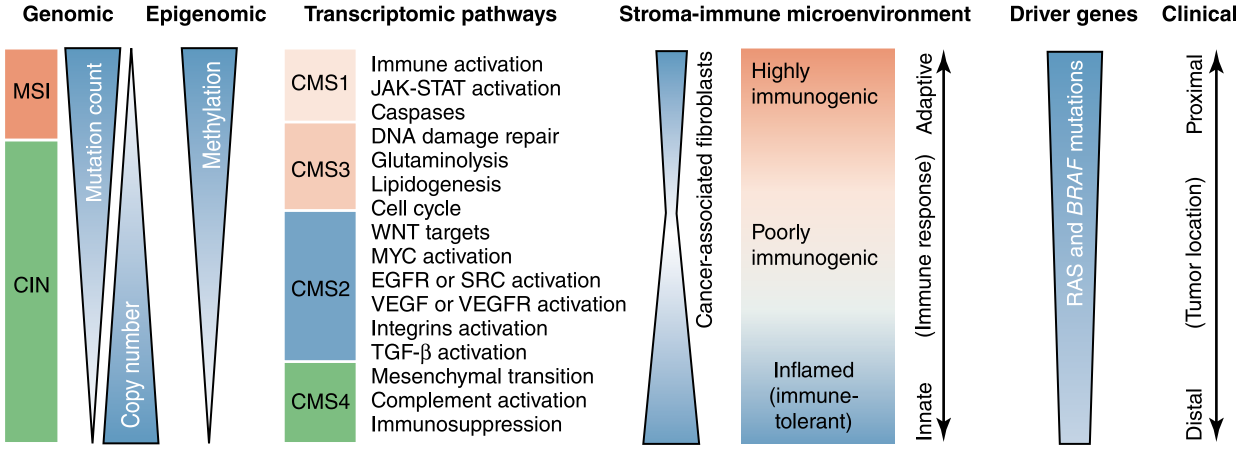
Colorectal Polyps

Most CRCs develop through intermediary lesions called *polyps*. Colorectal polyps are any growth of cells noted in the colorectal lumen, and some may progress to CRC. Polyps can be characterized according to their endoscopic appearance but, more importantly, by their histologic classification. It is important to understand and recognize the different types of polyps in the context of potential advanced neoplasia and the necessary management. Traditionally, nonneoplastic polyps include hamartomas and inflammatory polyps. Hamartomas are accumulations or abnormal growths of normal cells. In the colorectum, hamartomas are rare. They can be sporadic or found in hereditary syndromes (see later). Hamartomas do not have intrinsic malignant potential. Removal is indicated for obstructive symptoms, often as a result of intussusception, or bleeding. Inflammatory polyps are areas of inflamed or healing tissue and are not premalignant. Inflammatory polyps often occur in inflammatory bowel disease and represent areas of normal or healing mucosa in a field of ulcerated or acutely inflamed tissue. The fact that these are usually normal tissue gives them the term *pseudopolyps.*

Polyps with malignant potential include adenomas and serrated polyps. All adenomas have potential for malignant transformation, but only a small percentage actually become cancerous. The risk of cancer depends on size and histology. Patients with an advanced adenoma, defined as size at least 1 cm, high-grade dysplasia, or tubulovillous or villous histology, are at a significantly increased risk of developing CRC. Polyps felt to be adenomas should be removed endoscopically.[13] Serrated polyps are defined histologically by a sawtooth crypt pattern and nuclear atypia. As discussed earlier, recent research has demonstrated a serrated pathway to carcinoma. Sessile serrated lesions include hyperplastic polyps, sessile serrated adenomas (SSAs), and traditional serrated adenomas (TSAs). Hyperplastic polyps are a result of proliferation in the basal portion of the crypts, are composed of standard cellular components, and are not considered to have a risk of cancer. SSAs (also called *sessile serrated polyps* or *sessile serrated lesions*) are usually larger than hyperplastic polyps and have distorted architecture of the serrated crypts. They typically show one of the following histologic features: horizontal growth along the muscularis mucosa, dilation of the crypt base, serrations extending into the crypt base, or asymmetric proliferation. These polyps can harbor or develop dysplasia and thus have the potential to develop into invasive cancer.[14–16] TSAs histologically show distorted villous or tubulovillous architecture, and the villi have bulbous tips in many cases. These polyps can acquire adenoma-like or serrated dysplasia, thus having neoplastic potential.

Hereditary Colorectal Cancer Syndromes

Understanding and characterization of hereditary CRC syndromes have evolved vastly over the past three decades. The initial classification and understanding of these syndromes were based on phenotypic observation of the colorectum during endoscopy, that is, polyposis versus nonpolyposis syndromes. This understanding evolved as the genetic causes of these syndromes were discovered and defined. Timely identification of individuals at risk for hereditary CRC syndromes offers an opportunity for diagnosis and intervention to prevent cancer development. The development of next-generation multigene panel testing has made genetic diagnosis readily and widely available and has allowed for more precise diagnosis of patients. A summary of the different hereditary syndromes and their associated gene variant is provided in Table 96.1.



Genomic
Epigenomic
Transcriptomic pathways

FIGURE 96.2 Schematic representation of colorectal cancer (CRC) subtypes. Microsatellite instability is linked to hypermutation, hypermethylation, immune infiltration, activation of RAS, *BRAF* mutations, and locations in the proximal colon. Tumors with chromosomal instability *(CIN)* are more heterogeneous at the gene-expression level, showing a spectrum of pathway activation ranging from epithelial canonical (consensus molecular subtype 2 *[CMS2]*) to mesenchymal (CMS4). Tumors with CIN are mainly diagnosed in left colon or rectum, and their microenvironment is either poorly immunogenic or inflamed, with marked stromal infiltration. A subset of CRC tumors enriched for RAS mutations has strong metabolic adaptation (CMS3) and intermediate levels of mutation, methylation, and copy number events. *EGFR,* Epidermal growth factor receptor; *JAK,* Janus kinase; *SRC,* steroid receptor coactivator; *STAT,* signal transducer and activator of transcription; *TGF-*β, transforming growth factor-β; *VEGF,* vascular endothelial growth factor; *VEGFR,* VEGF receptor. (From Dienstmann R, Vermeulen L, Guinney J, et al. Consensus molecular subtypes and the evolution of precision medicine in colorectal cancer. *Nat Rev Cancer.* 2017;17:79-92.)

TABLE 96.1 Inherited Colorectal Cancer Syndromes

SYNDROME	GENES	CLINICAL FINDINGS	CRC RISK
Familial adenomatous polyposis	*APC*	Colonic tubular adenomas, duodenal adenomas, gastric fundic gland polyps, desmoid tumors, epidermoid cysts, osteomas	100%
MUTYH-associated polyposis	*MUTYH*	Colonic tubular adenomas, CRC <50 years, gastric fundic gland polyps, duodenal adenomas and carcinomas	80%
NTLH1-associated polyposis	*NTLH1*	Adenomas, skin hemangiomas, seborrheic keratosis, intradermal nevi, ovarian and hepatic cysts, breast papilloma	—
Polymerase proofreading-associated polyposis	*POLD1, POLE*	Adenoma, meningioma, severe cases: café au lait, pediatric brain tumors	—
MSH3-associated polyposis	*MSH3*	Adenomas, scarce data	—
MBD4-associated polyposis	*MBD4*	Adenomas, acute myeloid leukemia, uveal melanoma, schwannoma	—
JPS	*SMAD4, BMPR1A*	≥5 Juvenile polyps; any juvenile polyp and JPS family history	40%
PJS	*STK11*	Peutz-Jeghers polyps (PJPs) Orocutaneous pigmentation Family history of PJP; cancer of small bowel, colon, stomach, pancreas, breast, ovary, testis	40%
PTHS	*PTEN*	Hamartomas, lipomas, fibromas, ganglioneuromas	9%–32%
Lynch syndrome	*MLH1, MSH2, MSH6, PMS2, EPCAM*	Microsatellite-unstable CRC, advanced adenomas, gastric, duodenal, small bowel, transitional cell, gallbladder, pancreas, endometrial, ovarian	60%–80%

AD, Autosomal dominant; *AR*, autosomal recessive; *CRC*, colorectal cancer; *JPS*, juvenile polyposis syndrome; *PJS*, Peutz-Jeghers syndrome; *PTHS*, PTEN hamartoma tumor syndrome.

Polyposis Syndromes

Familial adenomatous polyposis. Familial adenomatous polyposis (FAP) is an autosomal dominant syndrome resulting from a pathogenic variant in the *APC* gene. The incidence of FAP is approximately 1 in 10,000. This syndrome has a 20% reported incidence of de novo mutations, and thus, the absence of family history does not exclude this diagnosis. The known neoplastic features of this syndrome include colorectal polyps and CRC; gastric polyps; duodenal and periampullary polyps and cancer; medulloblastoma; papillary thyroid carcinoma; hepatoblastoma; and nonmalignant features such as congenital hypertrophic retinal pigmented epithelium (CHRPE), osteomas, supernumerary teeth, odontomas, and desmoid tumors. The risk of CRC approaches 100% without prophylactic colectomy. The risk of duodenal or periampullary cancer ranges between 1% and 10%; gastric cancer, between 0.1% and 7.1%; and desmoid tumors, between 10% and 24%.[17] Surveillance includes annual colonoscopy starting at age 10 to 12 years old. Upper endoscopy begins at age 20 to 25 years.[18] Annual thyroid screening by ultrasound should be considered for FAP patients. There is no recommendation for desmoid screening, but one must be aware of the potential for desmoids, especially with a family history. Desmoid disease may arise intraabdominally, in the abdominal wall, and extraabdominally in the limbs or back. Desmoids create morbidity by local extension into surrounding structures, and complications of intraabdominal desmoids include bowel obstruction, enterocutaneous fistula, and ureteric obstruction. Asymptomatic or small desmoids may be observed, whereas growing or symptomatic desmoids may be treated with escalating therapies. Surgical management of desmoid disease should be planned in expert centers to balance the extent of the intervention with maintaining the patient's quality of life.

Judicious operative management of the colon and rectum in FAP patients is critical because those decisions made in the early years define the patient's future risk of cancer and also quality of life. Operative intervention is usually delayed until the late teenage years to allow for normal physical, emotional, and psychosocial development. Several factors to consider regarding the timing of surgery are given in Table 96.2. Indications for surgery include formation of cancer, multifocal high-grade dysplasia, or a rapidly increasing number or size of polyps that cannot be surveyed or managed endoscopically.

There two main surgical options for patients with FAP: (1) total proctocolectomy (TPC) with or without reconnection of the gastrointestinal (GI) tract and (2) total abdominal colectomy (TAC) with an ileorectal anastomosis (IRA). Both options can be accomplished safely using minimally invasive techniques. After a TPC, intestinal continuity is usually reestablished with an ileal

TABLE 96.2 Surgical Decision-Making in Patients With Familial Adenomatous Polyposis

SURGICAL RECOMMENDATION	INDICATION	COMMENT
Total abdominal colectomy	• Colon cancer • Uncontrolled colon polyp burden • Rectum <20 polyps	• Rectum polyp burden has to be manageable endoscopically
Total proctocolectomy	• Profuse polyposis • Rectal cancer • Rectal polyp burden >20	• Stapled anastomosis if the anal transitional zone is clear of polyps, otherwise will need mucosectomy and hand-sewn pouch-anal anastomosis
Pancreas-sparing duodenectomy (PSD)	• Spigelman stage IV on upper endoscopy findings	• Whipple procedure if cancer is present
Thyroidectomy	• Papillary thyroid cancer	—

pouch–anal anastomosis (IPAA). Each option has advantages and disadvantages in terms of cancer risk reduction and quality of life. In general terms, TPC/IPAA is associated with longer surgical times and increased complications, including sexual and urinary dysfunction, decreased fecundity, and more frequent bowel movements and incontinence, compared with a TAC/IRA. However, removing the rectum during TPC removes future rectal cancer risk, which remains after TAC/IRA. The main advantage of TAC/IRA is decreased daily bowel movements and better overall quality of life, but again, this is weighed against cancer risk. The main decision point relies on the rectal polyp burden, and most surgeons use 20 or fewer polyps in the rectum as a threshold to preserve the rectum. Following these guidelines, the risk of rectal cancer is approximately 3% at a median follow-up of 13 years, and the need for completion proctectomy is 8%.[19]

Another consideration regarding choice of TAC/IRA or TPC includes desmoid risk. Because most desmoid disease presents after surgery, patients with desmoid tumor or those at high risk of developing desmoid tumors should defer surgery as long as safely able. When surgery is indicated, these high-risk patients should be considered for TAC/IRA (if safe to survey the rectum), given that TPC/IPAA is more desmoidogenic than IRA.[20] For patients who undergo TPC/IPAA, the extent of the distal dissection is dependent on the extent of the polyposis in the anal transition zone (ATZ). The standard approach is to divide the rectum at the anorectal junction (top of the anal canal) and perform a double-stapled anastomosis, leaving a 2- to 3-cm segment of ATZ that will need to be surveyed. If there is diffuse polyposis or high-grade dysplasia in the ATZ, then mucosectomy should be performed with a hand-sewn IPAA. This decreases future neoplasia risk but also results in worse bowel function. Regardless of what surgery is done, any remaining anorectal mucosa, ATZ, and/or ileal pouch should be surveyed annually for neoplasia.

MUTYH-associated polyposis. MUTYH-associated polyposis (MAP) is an autosomal recessive disease; thus, biallelic pathogenic variants in *MUTYH* are needed for diagnosis. About 1% to 2% of the general population carries a monoallelic *MUTYH* pathogenic variant, and less than 1% of all CRC diagnoses are due to MAP. Patients develop anywhere between 10 and 100 colorectal adenomas by the fifth or sixth decade, and up to 60% of those patients have CRC at presentation.[21,22] Some patients may present only with CRC and not have any other polyps. Duodenal polyps have been reported in patients with MAP and some rare occasions of duodenal cancer.[23] Surveillance includes colonoscopy every 1 to 2 years starting at diagnosis, a baseline upper endoscopy at age 30 to 35 years, and follow-up surveillance based on the Spigelman classification.[18] Surgical management of patients with MAP follows the same general guidelines used for decision-making in FAP. TAC/IRA is recommended if colon cancer develops or if endoscopic management of polyp burden is no longer feasible. Rectal cancer is uncommon in MAP, but patients with rectal cancer should be considered for proctocolectomy and IPAA.

Juvenile polyposis syndrome. Juvenile polyposis syndrome (JPS) is an autosomal dominantly inherited syndrome caused by pathogenic variants in the *SMAD4* or *BMPR1A* genes and characterized clinically by hamartomatous polyps. There is a 25% chance of de novo mutations in JPS patients. The incidence of JPS is 1 per 100,000 in the general population. The clinical criteria of diagnosis have been set for any individual who meets at least one of the following: (1) $\geq$5 juvenile polyps in the colon, (2) multiple juvenile polyps throughout the GI tract, and (3) any number of juvenile polyps in an individual with a family history of JPS.[24] *SMAD4* mutations in JPS are associated with hereditary hemorrhagic telangiectasia (HHT).[25] JPS patients commonly present with GI bleeding or obstruction as a result of prolapsing polyps. Patients with JPS exhibit a 10% to 38% lifetime risk of colon cancer, and the average age at diagnosis is 34 years. For the pediatric population, upper endoscopy and colonoscopy should start at 12 to 15 years and be repeated every 1 to 3 years based on findings or every 5 years if no polyps were found.[26] Colectomy is recommended if a patient develops CRC or the polyp burden prevents adequate surveillance.

Peutz-Jeghers syndrome. Peutz-Jeghers syndrome (PJS) is an autosomal dominant syndrome resulting from a pathogenic mutation in the *STK11 (LKB1)* gene. It is characterized by multiple hamartomatous polyps in the GI tract and mucocutaneous pigmentation and has a prevalence of 1 in 8000 to 200,000 in the general population. PJS has high penetrance by the third decade of life and has a de novo rate of 10% to 20%. Thus, the absence of family history should not exclude the diagnosis or referral to genetic testing. A clinical diagnosis can be made if individuals meet two or more of the following criteria: (1) two or more PJS hamartomatous polyps in the GI tract; (2) mucocutaneous hyperpigmentation of the mouth, lips, nose, eyes, genitalia, or fingers; or (3) family history of PJS.[27] Because of the increased risk of ovarian sex cord tumors and Sertoli cell testicular cancers, an annual physical examination is recommended for observation of precocious puberty in females or feminizing changes in male patients.[17]

Adult surveillance is intensive for this patient population because of the increased risk of breast cancer (32%–54%), colon cancer (39%), gastric cancer (29%), small intestine cancer (13%), pancreatic cancer (11%–36%), cervical and endometrial cancer (9%–10%), ovarian and testicular cancer (9%), and lung cancer (7%–17%). Thus, the following surveillance is recommended[28,29]:

- Mammogram and breast MRI at age 30; repeated every 6 months
- Colonoscopy at age 18; repeated every 2 to 3 years
- Upper endoscopy at age 18; repeated every 2 to 3 years
- Small bowel visualization with either video capsule endoscopy or CT/MRI enterography at age 18; repeated every 2 to 3 years
- Annual pancreatic endoscopic ultrasound (EUS) or magnetic resonance cholangiopancreatography at age 30 to 35
- Annual pelvic examination with pelvic ultrasound or biopsy if any abnormal bleeding, starting at age 18 to 20 years
- Annual testicular examination

Colectomy is recommended for the development of CRC or uncontrolled polyp burden. Small bowel polyps often cause obstruction. Those patients should be referred to expert centers that can focus on bowel preservation and perform a "clean-sweep" procedure with removal of all small and large bowel polyps to decrease future risk of malignancy and obstruction.[30]

PTEN hamartoma tumor syndrome. There are multiple phenotypic variations of syndromes under the PTEN hamartoma tumor syndrome (PTHS) nomenclature. They follow an autosomal dominant inheritance and result from a pathogenic mutation in the *PTEN* gene. Cowden syndrome (CS) is the most thoroughly described phenotype in this syndrome thus far and has a prevalence of 1 in 200,000 to 250,000. There is a 10% to 30% de novo rate. Phenotypically, there are many characteristic findings in patients with CS:

- Mucocutaneous (trichilemmomas, acral keratoses, facial blemishes, and clear cell acanthomas)
- Breast cancer (up to 85% lifetime risk)
- Nonmedullary thyroid cancer

- Genitourinary manifestations, such as uterine fibroids, bilateral hyperechoic testicular lesions, lipomatosis of the testes, endometrial cancer (13%–30%), and renal cell carcinoma (13%–34%)
- Esophageal glycogen acanthosis
- Gastric, duodenal polyps: hyperplastic, hamartomas, ganglioneuromas, adenomas, and inflammatory polyps[31]
- Colorectal polyps: hamartomas, inflammatory, ganglioneuromas, lipoma, leiomyomas, and hyperplastic polyps. CRC has been reported in up to 13% of PTHS patients by the age of 50 years[31]
- Macrocephaly has been described in 21% to 38% of patients with CS, in addition to many other neurologic abnormalities, intellectual disability, developmental delay, and autism

The International Cowden Consortium has set testing criteria for PTHS. A clinical operational diagnosis is established in a family where one individual meets revised PTHS clinical diagnostic criteria or has a *PTEN* mutation.[32] Diagnosis and management of patients with potential PTHS is complex and requires multidisciplinary communication and management, and diagnosis and surveillance should be done in expert centers. National Comprehensive Cancer Network (NCCN) recommendations are to be followed: an annual physical examination; annual breast examination, mammogram, and MRI; colonoscopy starting at age 35 or 5 to 10 years before the earliest CRC in the family; renal ultrasound; psychomotor assessment in children; annual dermatology evaluation; annual thyroid ultrasound; and consideration of transvaginal ultrasound and endometrial biopsy.[33]

TAC/IRA is recommended for CRC patients with PTEN. Other phenotypes in PTHS are Bannayan-Riley-Ruvalcaba syndrome and Proteus syndrome.

Serrated polyposis syndrome. Serrated polyposis syndrome (SPS) is a clinical diagnosis. The World Health Organization has recently updated its diagnostic criteria for SPS as the following[34]:

- At least five serrated lesions or polyps proximal to the rectum >5 mm, with two or more larger than 10 mm
- More than 20 serrated lesions or polyps of any size distributed throughout the colorectum, with at least 5 proximal to the rectum

The lifetime CRC risk has been reported to be approximately 15% to 30% overall but also varies based on the patient's age, the number of polyps present, and the histologic type of polyps.[35,36] The current recommended surveillance is with high-quality colonoscopy and polypectomy of all polyps ≥5 mm and repeated every 1 to 3 years based on the number and size of polyps.[17] Total colectomy is recommended for CRC or high polyp burden that is not able to be effectively managed endoscopically.

Other polyposis syndromes. The advancement and accessibility of genetic testing of patients with polyposis phenotype has facilitated the description of other syndromes with CRC predisposition. The management of these syndromes follows the primary recommendations for oncologic resection and polyp burden management.

- NTLH1-associated polyposis (NAP) is an autosomal recessive inheritance in the *NTLH1* gene.[37]
- Polymerase proofreading-associated polyposis (PPAP) follows a dominant inheritance pattern in the *POLE* or *POLD1* genes.[38]
- MSH3-associated polyposis follows an autosomal recessive inheritance pattern in the *MSH3* gene.[39]

Nonpolyposis Syndromes

Lynch syndrome. Definitions of Lynch syndrome have evolved from phenotypic description and family history criteria to a more complex genetic characterization. Lynch syndrome was previously referred to as *hereditary nonpolyposis colorectal cancer* (HNPCC), a term that was initially established to distinguish the hereditary predisposition from FAP. HNPCC is a clinical diagnosis based on the Amsterdam criteria. For a family to meet Amsterdam II criteria, the following conditions must be met: (1) at least three relatives with an HNPCC-associated cancer (colorectum, endometrium, ovaries, small bowel, stomach, ureter or renal pelvis, pancreas, brain, skin), one of whom is a first-degree relative of the other; (2) two or more successive generations should be affected; and (3) at least one cancer should be diagnosed before age 50. The discovery of the underlying inherited variants in MMR genes led to a more precise definition of Lynch syndrome that is dependent on the presence of a pathogenic variant in a DNA MMR gene.

Lynch syndrome is an autosomal dominant inherited syndrome resulting from a pathogenic mutation in one of the four known MMR genes *(MLH1, MSH2, MSH6, PMS2)* and *EPCAM*. The incidence is 1/279 in the general population[40] and about 3% of all CRCs.[41] Patients with Lynch syndrome are at an increased risk of colorectal, endometrial, ovarian, urothelial, gastric, small bowel, pancreas, biliary tract, prostate, and skin cancer (sebaceous adenocarcinoma). The cumulative risk of cancer varies based on each gene mutation.[17] The cumulative risk of CRC by age 80 is 46% to 61% in patients with *MLH1* mutations, 33% to 52% in *MSH2,* 10% to 44% in *MSH6,* and 8.7% to 20% in patients with *PMS2* mutations.[17] Annual colonoscopy starting at age 20 to 25 is the cornerstone of surveillance and decreases both CRC formation and death from cancer in Lynch syndrome patients. Annual transvaginal ultrasound with endometrial biopsy beginning at age 30 to 35 should be considered, and prophylactic hysterectomy after childbearing is completed should also be discussed. Other screening includes annual physical examination and dermatology examination for detection of sebaceous tumors. Of note, *EPCAM* gene deletions can lead to silencing of the *MSH2* gene; thus, patients with *EPCAM* mutations should follow the same guidelines that patients with *MSH2* mutations follow.

CRC tumor testing for MSI or expression of MMR proteins is a common means of screening for Lynch syndrome. Patients with either a microsatellite-unstable tumor or whose tumor lacks expression of one of the MMR proteins (without *MLH-1* promoter hypermethylation indicating a sporadic tumor) should then be referred for genetic counseling and testing.[42] Historically, family history meeting Amsterdam criteria and tumor histologic characteristics for Bethesda criteria were used to identify and screen individuals for Lynch syndrome.[43] Because next-generation multigene panel testing has demonstrated a higher yield of detecting pathogenic variants than more focused testing, there is consideration for genetic germline testing of all patients with CRC.[42,44]

Surgery for Lynch syndrome is based on therapeutic resection of the tumor as well as prophylactic extended resection to reduce future CRC risk. Future cancer risk should be balanced against quality of life, and decisions should be individualized. The risk of metachronous CRC after segmental resection alone is 12% to 20% at 10 years and as high as 72% at 40 years.[45–49] The American Society of Colon and Rectal Surgeons recommends total colectomy as opposed to segmental colectomy for patients with colon cancer and Lynch syndrome to reduce future cancer risk.[50] The extent of resection for rectal cancer is more challenging and debated. Extended prophylactic resection would include TPC/IPPA, which has more significant functional implications. Based on small retrospective studies, the risk of metachronous colon cancer after proctectomy is 19% at 10 years, 47% at 20 years, and 69% at 30 years.[51,52] The decision for proctectomy alone versus TPC/IPAA should be discussed in the context of risk reduction and quality of life and be individualized after informed discussion. Regardless of the procedure performed, any remaining colon or rectum should be surveilled by endoscopy annually.

Recent advances in neoadjuvant immunotherapy in patients with DNA MMR deficiency (dMMR) rectal cancer are redefining the treatment paradigm for patients with Lynch syndrome. dMMR rectal cancer patients treated with neoadjuvant immunotherapy in a prospective trial have shown a 100% clinical response rate and yielded a nonsurgical approach.[53] Longer follow-up and more patients are needed before to better define these outcomes.

Constitutional mismatch repair deficiency. Constitutional mismatch repair deficiency (CMMRD) is a highly penetrant syndrome resulting from the inheritance of biallelic pathogenic mutations in one of the MMR genes *(MLH1, MSH2, MSH6, PMS2).* The resultant phenotype involves formation of multiple cancers at a young age. Most cases are diagnosed in childhood. The surveillance and management of these patients are complex and done with an experienced center.[54]

Familial colorectal cancer type X. CRC patients from families who meet Amsterdam I criteria but have MMR proficiency are defined as having familial colorectal cancer type X (FCCX).[55] The CRC risk is twice that of the general population but less than those with Lynch syndrome. The mean age of CRC is also between that of the general population and Lynch syndrome, at age 61. Colonoscopy should start at age 45, or 10 years younger than the youngest CRC in that family. If colonoscopy is normal, it should be repeated every 5 years. For FCCX patients who develop CRC, a segmental rather than total colectomy is recommended because the risks of metachronous CRC are not as well defined, and there is an absence of evidence that extended resection reduces cancer risk. Recent data suggested that the risk of extracolonic cancers might also be present in this patient population, such as gastric cancer, urothelial cancer, breast cancer, ocular melanoma, and pancreatic cancer.[56] Surveillance in this patient population should be individualized based on family history and age of cancer presentation in families as well.

COLON CANCER

Incidence and Risk Factors

Colon cancer is among the top three cancers in both males and females in the United States. There are approximately 100,000 new cases nationally each year. The overall incidence has been declining as a result of the widespread adoption of CRC screening, but younger age groups (less than 50 years old) have had an increasing incidence.[57] From the mid-1980s through 2013, there was a 2.4% increase per year in people aged 20 to 29 years, a 1.0% increase in people aged 30 to 39, a 1.3% increase in people aged 40 to 49 years, and a 0.5% increase for people aged 50 to 54 years. In patients above the age of 50 years, 6% to 10% of all CRCs are the result of an inherited gene pathogenic variation, whereas 20% of all CRCs in patients younger than 50 years old have an inherited predisposition.[58–60] In patients with CRC younger than 50 years old, up to 10% of those patients have Lynch syndrome, and this increases to 23% in patients younger than age 35 years.[61]

There is an increased risk of CRC in patients with inflammatory bowel disease.[62] Beyond germline pathogenic mutations and inflammatory bowel disease, many other risk factors are documented to increase the risk of CRC but do not change the screening recommendation regarding age or frequency, such as obesity, diabetes mellitus and insulin resistance, tobacco use, alcohol use, red and processed meat intake, and lack of exercise and sedentary lifestyle.

Clinical Presentation

The most common presenting symptoms of colon cancer include change in bowel habits, blood per rectum, and abdominal pain. Symptoms also vary depending on tumor location. Right-sided tumors present with iron-deficiency anemia, whereas left-sided tumors more commonly present with a change in stool caliber or hematochezia. It is important to note that many colon cancers are asymptomatic, and screening at appropriate times and intervals is indicated.

Evaluation and Clinical Staging

Most colon cancers are diagnosed at colonoscopy. This examination should document the location of the tumor, including relationship to anatomic landmarks, and an endoscopic tattoo should be placed. It should be noted that the entire colon was evaluated for other lesions and that the examination was complete. The lesion should be biopsied because definitive diagnosis is made by histology. The biopsy should also undergo evaluation for MMR deficiency[63] to identify patients who qualify for genetic counseling to diagnose Lynch syndrome or qualify for treatment with checkpoint inhibitor immunotherapy.[64] Laboratory evaluation includes a complete blood count, chemistry, and the tumor marker carcinoembryonic antigen (CEA) testing. Evaluation for distant metastases incudes CT of chest, abdomen, and pelvis with intravenous and oral contrast unless the patient has any contraindications. Positron emission tomography (PET)/CT scan is not routinely recommended and should be used only to evaluate equivocal findings on contrast imaging.

Surgical Technical Principles

The most important surgical principles for primary colon cancer are to ensure negative margins and adequate lymphadenectomy for pathologic staging. The recommended resection margin is 5 to 7 cm proximal and distal to the tumor.[65–67] Regional lymph nodes are located in the mesocolon along the main vascular pedicles, and removal provides staging information and removes potential lymph node metastases. Evaluation of more than 12 lymph nodes harvested is associated with a survival benefit in stage II and III colon cancer,[68] and achieving this lymph node yield is facilitated by high vascular ligation. Evaluation of fewer than 12 lymph nodes is associated with an increased risk of recurrence.[69–71] Recent data from the National Cancer Database (NCDB) showed a survival benefit in patients with T3N0 disease who receive adjuvant chemotherapy when there is an inadequate lymph node harvest.[70] After the resection, the anastomosis must be constructed without tension, using healthy, well-vascularized segments of bowel. It is important to preserve the marginal artery to the segments of reconnected bowel to avoid ischemia and complications.

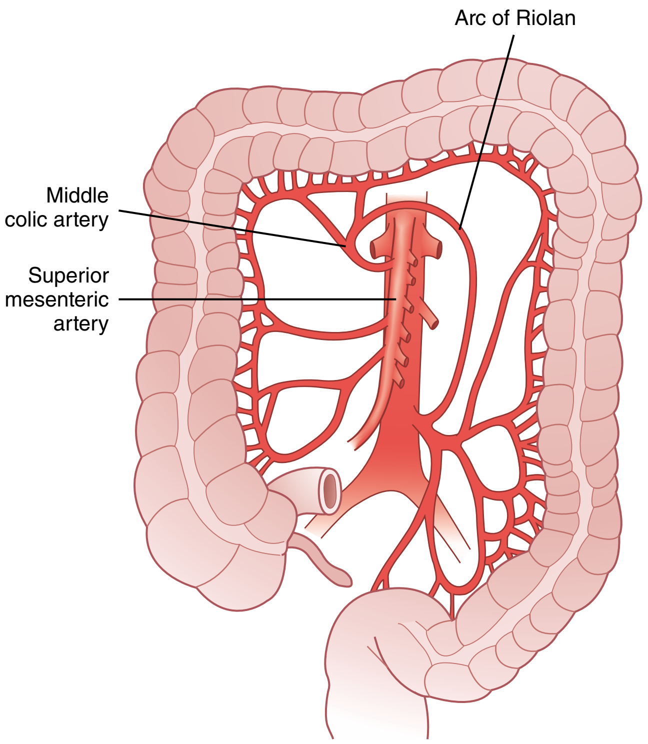

FIGURE 96.3 The arterial blood supply to the colon is from the superior and inferior mesenteric arteries. (From Gordon PH, Nivatvongs S, eds. *Principles and Practice of Surgery for the Colon, Rectum and Anus.* 2nd ed. Quality Medical Publishing; 1999:23.)

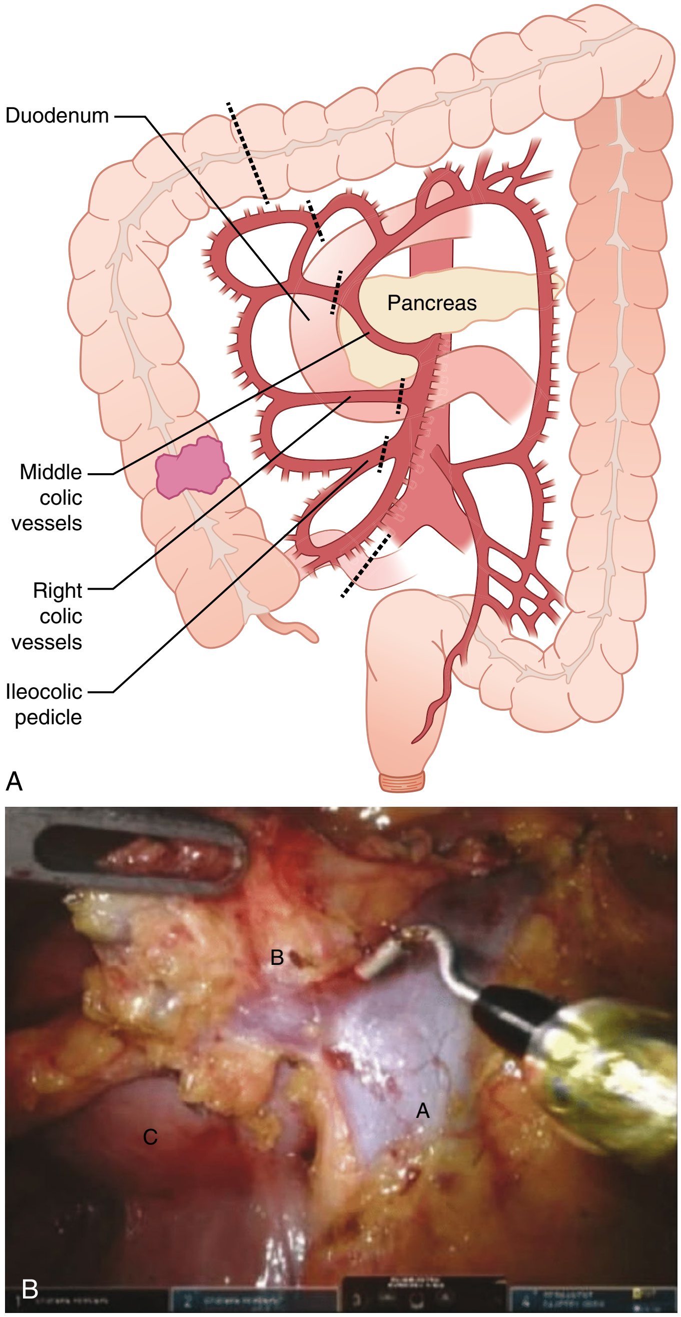

FIGURE 96.4 Resection for a right-sided cancer. The ileocolic, right colic, and right branch of the middle colic vessels are ligated. The terminal ileum and the transverse colon are divided as shown in (A). (B) Lapascopic view of a right-sided colon dissection from a medial approach. The duodenum *(A)*, right colon mesentery *(B)*, and cecum *(C)* are shown.

Surgical Anatomy and Extent of Resection

The extent of resection and name of the operation are usually dictated by the location of the primary tumor and the vascular supply of the resected colon segment. Understanding the vascular anatomy is essential for safe and effective colon cancer resection. The arterial supply to the colon is shown in Fig. 96.3. The main branches from the aorta that supply the colon include the superior mesenteric artery and its branches to the right colon, including the ileocolic artery, right colic artery, and middle colic artery, and the inferior mesenteric artery (IMA) with its branches to the rectum and left colon, including the superior rectal artery, sigmoid artery, and left colic artery. There is an arcade of collateral vascularization via the marginal artery running parallel to and near the colon wall.

Right-Sided Tumors

Tumors of the cecum and ascending colon are treated by right colectomy. This operation includes high ligation of the ileocolic artery, right colic artery (when present), and the right branch of the middle colic artery (Fig. 96.4). The lymph nodes associated with these vessels are harvested en bloc. The operation can be done using a medial-to-lateral or a lateral-to-medial approach. In either approach, the plane between the mesocolon and the duodenum under the ileocolic pedicle is dissected and developed, exposing the head of the pancreas and allowing access to the transverse colon mesentery to ligate the right branch of the middle colic artery. The terminal ileum is divided approximately 5 cm from the ileocecal valve and the transverse colon at its proximal third. The omentum should be resected en bloc with the specimen. An ileocolic anastomosis is performed and may be done using a variety of techniques and configurations, including side-to-side antiperistaltic, side-to-side isoperistaltic, end-to-end, or end-to-side techniques. This can be constructed using staplers or hand-sewn techniques.

Transverse Colon Tumors

Most tumors in the transverse colon are treated with an extended right colectomy, which includes ligation of the ileocolic artery as in a right colectomy but also includes division of the middle colic

artery at its base (Fig. 96.5). An ileocolic anastomosis is constructed in the distal transverse colon according to the same principles as described earlier.

Splenic Flexure Tumors

Some debate exists about the ideal surgical resection of splenic flexure tumors. Options include an extended right colectomy or subtotal colectomy with inclusion of the splenic flexure and ileo–descending colon anastomosis. Blood flow to the anastomosis is dependent on the marginal artery. Segmental resection of the splenic flexure alone has been described (Fig. 96.6). In this surgery, the left colic artery is divided at its origin from the IMA, and the inferior mesenteric vein is divided at the inferior border of the pancreas. The omentum in this region should be resected en bloc with the colon. The colocolonic anastomosis is often best suited for an end-to-end or isoperistaltic side-to-side configuration. Recent data suggest segmental resections have similar oncologic and survival outcomes to extended resections.[72]

Left-Sided Tumors

Tumors of the descending colon are generally treated with left colectomy, which includes high ligation of the IMA. The base of the inferior mesenteric is surrounded by the mesenteric and hypogastric nervous plexus and should be avoided during dissection (Fig. 96.7). The inferior mesenteric vein is also ligated lateral to the ligament of Treitz (Fig. 96.8), which increases lymph node harvest and also allows for increased mobilization of the colon for the anastomosis. The splenic flexure must be fully mobilized with detachment of the mesocolon of the splenic flexure and distal

transverse colon from the pancreas and left abdominal gutter detachment to create an anastomosis without tension. Other techniques that might be needed to gain appropriate length for the colon conduit to reach for the anastomosis include ligation of the middle colic artery, creating a retroileal path of the colon, total mobilization of the right colon, and counterclockwise mobilization of the right colon. Reconstruction is usually done with end-to-end stapled anastomosis. Tumors of the sigmoid colon, particularly the distal sigmoid colon, may be resected as a segmental sigmoid resection following oncologic principles (Fig. 96.9). The distal dissection and transection on the bowel are done at the upper rectum, and the proximal resection point is the distal descending colon.

Colon resections can be approached via laparotomy or by minimally invasive techniques, such as laparoscopy or robotic surgery. Minimally invasive techniques provide short-term benefits, such as less postoperative pain, shorter postoperative hospital stay, faster recovery of bowel function, and a lower rate of wound infection, when compared with standard open colectomy. Laparoscopic versus open surgery for colon cancer has been compared in the Clinical Outcomes of Surgical Therapy (COST) trial, which demonstrated that oncologic outcomes after laparoscopic resections are noninferior, with no significant difference in 5-year disease-free survival (DFS).[73,74] Although no clinical trials have compared laparoscopic versus robotic or open approach for colon cancer, a systematic review comparing robotic versus laparoscopic left colectomy showed fewer conversions using a robotic approach and no difference in other postoperative outcomes.[75]

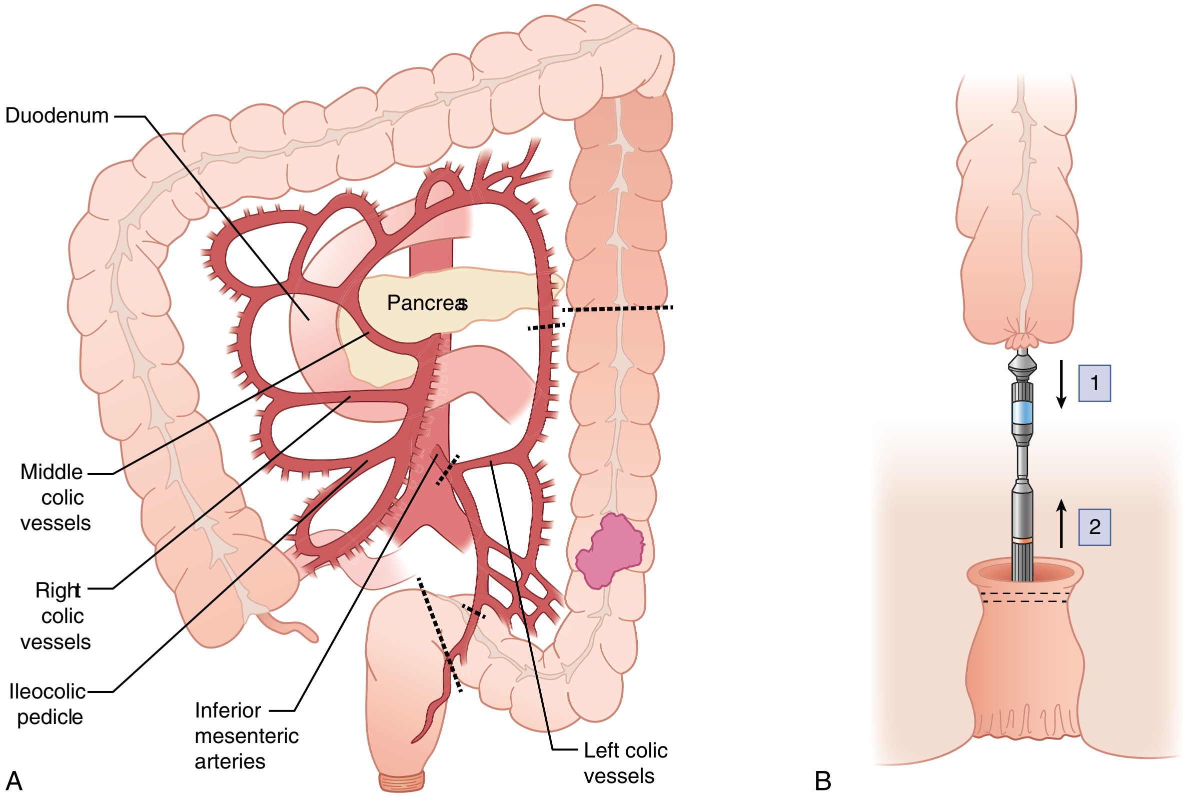

FIGURE 96.9 Left hemicolectomy. (A) The inferior mesenteric artery is ligated, and the marginal artery is ligated just distal to the level of transection of the colon. The hemorrhoidal vessels are ligated within the proximal mesorectum. (B) A double stapled technique is used to create an end-to-end anastomosis.

Approach to Colon Cancer With Synchronous Metastasis

For patients with synchronous metastatic disease, management depends on the extent of distant disease and on whether the primary tumor is symptomatic. If the primary is symptomatic, it is usually addressed first for palliation of symptoms before moving on to treatment of distant disease. With an asymptomatic primary, systemic treatment is the first line of therapy. Neoadjuvant chemotherapy before surgery improves progression-free survival in patients with liver metastasis.[76] Patients with colon cancer and resectable liver disease can be considered for a combined approach for low-complexity operations or a staged approach for more complex scenarios.[77] In patients with resectable lung metastasis, surgical resection allows improved survival.[78] In select cases with colon cancer and peritoneal metastasis, in-depth evaluation in a multidisciplinary conference should be done, and a recommendation of cytoreductive surgery with hyperthermic intraperitoneal chemotherapy can be considered.[79]

Obstructing Colon Cancer

Obstructing colon cancer changes the management of patients because of the time-sensitive nature of treating symptoms and potentially impending perforation. Significant bowel obstruction complicates 8% to 29% of colon cancers and accounts for most emergency presentations.[80] Patients with obstructing tumors of the colon may present indolently with pencil-thin stools, increasing constipation, and an increasingly distended abdomen or acutely with obstipation, complete obstruction, abdominal pain, and vomiting that may be feculent. Diagnosis is commonly confirmed with imaging, such as plain films or abdominal computed tomography. Treatment objectives entail relief of the obstruction, resection of ischemic or nonviable bowel, and resection of the tumor when able. Management depends on the location of tumor and clinical situation. Treatment of right-sided obstructions generally includes an oncologic segmental resection. In most cases, a primary ileocolic anastomosis can be performed safely, but for patients with a high risk of anastomotic failure, a temporary stoma can be created. The approach to left-sided obstructions is tailored according to the location of obstruction, viability of the proximal bowel, and general stability of the patient. In sigmoid and left colon obstructions, patients are commonly referred for urgent surgery. A segmental resection of the primary tumor is typically performed. If the proximal large bowel has perforated or is showing signs of ischemia, a subtotal colectomy is indicated. Historically, primary anastomosis has been avoided, with the distal stump closed and a proximal stoma exteriorized. However, more recent evidence supports the option of a primary anastomosis in appropriate patients who are hemodynamically stable and in whom a tension-free anastomosis with a good blood supply can be achieved. Endoscopic stenting as a bridge for surgery is an option to relieve obstructions and permit elective surgery under more favorable conditions. Stenting has been shown to result in higher rates of primary anastomosis, decreased wound infections, and a higher rate of completion of surgery laparoscopically. Stenting is contraindicated in suspected ischemic or perforated bowel.

Pathologic Staging and Prognostic Factors

The American Joint Committee on Cancer (AJCC) outlines a staging system based on the tumor-node-metastases (TNM) staging system.[81] Table 96.3 details and defines the stages. The staging system has been implemented to predict survival, the need for adjuvant therapy, and prognosis. The AJCC reports other prognostic factors:

- ***Serum CEA levels:*** Patients with CEA levels greater than 5 ng/mL both before and after surgical resection have lower DFS.[82]
- ***Lymphovascular invasion (LVI):*** Patients with LVI have an increased risk of death compared with those without LVI.[83] In addition, patients with resected stage II colon cancer with LVI had worse DFS and overall survival (OS).[84]
- ***Perineural invasion (PNI):*** PNI is an independent poor prognostic factor for 5-year DFS and OS.[84]
- ***Tumor budding:*** Tumor budding is the presence of single or small clusters of tumor cells in the tumor stroma. Intermediate and high tumor budding are more strongly associated with worse OS and DFS than low tumor budding in stage III colon cancer.[85]
- ***Mucinous histology and the presence of signet ring cells:*** Colon adenocarcinomas with mucinous features have worse progression-free survival and OS compared with nonmucinous cancers.[86,87] Signet cell colon cancer has an overall poor prognosis, with 5-year survival reported between 9% and 36% and an average survival time of 20 to 45 months.[88,89]
- **Somatic profile (*KRAS, BRAF,* and MSI status):** *BRAF* and *KRAS* mutant CRCs have a worse prognosis.[90,91] MSI predicts a better survival rate, even 15% more, than patients with microsatellite stable (MSS) CRC.[92–94]

Adjuvant Therapy

According to the NCCN guidelines,[44] adjuvant chemotherapy is recommended for stage III and IV patients and those with stage II who are at high risk for systemic recurrence. High-risk factors for systemic recurrence in stage II patients include the following: poorly differentiated histology; LVI; PNI; bowel obstruction from the tumor; less than 12 lymph nodes sampled after resection; localized perforation; close, indeterminate, or positive margin; and high tumor budding. Treatment regimens that use CAPEOX (capecitabine and oxaliplatin) or FOLFOX (leucovorin, fluorouracil, oxaliplatin) are superior to using the combination of 5-fluorouracil (5-FU) and leucovorin in patients with stage III colon cancer.[95,96] The addition of oxaliplatin to 5-FU and leucovorin has not shown any survival benefit in patients with high-risk stage II disease or patients older than 70 years old.[97,98] In low-risk stage III patients, defined as T1-3 N1, 3 months of CAPEOX is noninferior to 6 months of CAPEOX in terms of DFS and is associated with less toxicity. However, in high-risk stage III colon cancer, defined as T4 N1-2 or T any N2, 3 months of FOLFOX was inferior to 6 months of FOLFOX.[99] The International Duration Evaluation of Adjuvant Therapy (IDEA) collaboration did not show noninferiority of 3 months versus 6 months of treatment in stage II patients and showed a slight difference in DFS in stage III patients.[100] These recommendations have been made for patients with MMR proficient tumors or MSS cancer (MSS/MMR). For patients with dMMR, observation without adjuvant therapy is recommended for patients with stage I and stage II disease.[44] For high-risk stage III patients, the recommendation is for 3 to 6 months of CAPEOX or 6 months of FOLFOX, and further options include capecitabine or 5-FU for 6 months.

Although the concept of neoadjuvant treatment has not been introduced as a standard of care, dMMR tumors have a high response rate to checkpoint inhibitors, such as ipilimumab and nivolumab, as shown in the NICHE study.[101] The authors reported a major pathologic response rate of 95% and a complete

TABLE 96.3 **Colorectal Cancer AJCC Staging (TNM)**

AJCC STAGE	STAGE GROUPING	STAGE DESCRIPTION
0	Tis N0 M0	The cancer is in its earliest stage. This stage is also known as *carcinoma in situ* or *intramucosal carcinoma* (Tis). It has not grown beyond the inner layer (mucosa) of the colon or rectum.
I	T1 or T2 N0 M0	The cancer has grown through the muscularis mucosa into the submucosa (T1), and it may also have grown into the muscularis propria (T2). It has not spread to nearby lymph nodes (N0) or to distant sites (M0).
IIA	T3 N0 M0	The cancer has grown into the outermost layers of the colon or rectum but has not gone through them (T3). It has not reached nearby organs. It has not spread to nearby lymph nodes (N0) or to distant sites (M0).
IIB	T4a N0 M0	The cancer has grown through the wall of the colon or rectum but has not grown into other nearby tissues or organs (T4a). It has not yet spread to nearby lymph nodes (N0) or to distant sites (M0).
IIC	T4b N0 M0	The cancer has grown through the wall of the colon or rectum and is attached to or has grown into other nearby tissues or organs (T4b). It has not yet spread to nearby lymph nodes (N0) or to distant sites (M0).
IIIA	T1 or T2 N1/N1c M0	The cancer has grown through the mucosa into the submucosa (T1), and it may also have grown into the muscularis propria (T2). It has spread to 1 to 3 nearby lymph nodes (N1) or into areas of fat near the lymph nodes but not the nodes themselves (N1c). It has not spread to distant sites (M0).
	T1 N2a M0	The cancer has grown through the mucosa into the submucosa (T1). It has spread to 4 to 6 nearby lymph nodes (N2a). It has not spread to distant sites (M0).
IIIB	T3 or T4a N1/N1c M0	The cancer has grown into the outermost layers of the colon or rectum (T3) or through the visceral peritoneum (T4a) but has not reached nearby organs. It has spread to 1 to 3 nearby lymph nodes (N1a or N1b) or into areas of fat near the lymph nodes but not the nodes themselves (N1c). It has not spread to distant sites (M0).
	T2 or T3 N2a M0	The cancer has grown into the muscularis propria (T2) or into the outermost layers of the colon or rectum (T3). It has spread to 4 to 6 nearby lymph nodes (N2a). It has not spread to distant sites (M0).
	T1 or T2 N2b M0	The cancer has grown through the mucosa into the submucosa (T1), and it might also have grown into the muscularis propria (T2). It has spread to 7 or more nearby lymph nodes (N2b). It has not spread to distant sites (M0).
IIIC	T4a N2a M0	The cancer has grown through the wall of the colon or rectum (including the visceral peritoneum) but has not reached nearby organs (T4a). It has spread to 4 to 6 nearby lymph nodes (N2a). It has not spread to distant sites (M0).
	T3 or T4a N2b M0	The cancer has grown into the outermost layers of the colon or rectum (T3) or through the visceral peritoneum (T4a) but has not reached nearby organs. It has spread to 7 or more nearby lymph nodes (N2b). It has not spread to distant sites (M0).
	T4b N1 or N2 M0	The cancer has grown through the wall of the colon or rectum and is attached to or has grown into other nearby tissues or organs (T4b). It has spread to at least one nearby lymph node or into areas of fat near the lymph nodes (N1 or N2). It has not spread to distant sites (M0).
IVA	Any T Any N M1a	The cancer may or may not have grown through the wall of the colon or rectum (Any T). It might or might not have spread to nearby lymph nodes (Any N). It has spread to 1 distant organ (e.g., the liver or lung) or distant set of lymph nodes but not to distant parts of the peritoneum (the lining of the abdominal cavity) (M1a).
IVB	Any T Any N M1b	The cancer might or might not have grown through the wall of the colon or rectum (Any T). It might or might not have spread to nearby lymph nodes (Any N). It has spread to more than 1 distant organ (e.g., the liver or lung) or distant set of lymph nodes but not to distant parts of the peritoneum (the lining of the abdominal cavity) (M1b).
IVC	Any T Any N M1c	The cancer might or might not have grown through the wall of the colon or rectum (Any T). It might or might not have spread to nearby lymph nodes (Any N). It has spread to distant parts of the peritoneum (the lining of the abdominal cavity) and may or may not have spread to distant organs or lymph nodes (M1c).

AJCC, American Joint Cancer Committee; *TNM*, tumor-node-metastasis.

pathologic response of 67% in patients with high-risk stage III dMMR colon cancer. Larger studies with long-term follow-up are needed to define the role of immunotherapy in the neoadjuvant treatment of colon cancer.

Postoperative Surveillance

Colon cancer survival is reported to be 91% for localized cases, 72% for regional disease, and 13% for cases with distant disease, with an overall Surveillance, Epidemiology, and End Results Program (SEER) 5-year survival rate of 63%.[102] Although those numbers combine all patients with similar stages without differentiating between high-risk features and MMR status, the risk of recurrence is still concerning. Thus, surveillance protocols should be followed to ensure patient safety and early diagnosis of any disease recurrence. According to the NCCN guidelines,[44] all patients with colon cancer need a complete colonoscopy 1 year after surgery. If there is a presence of any advanced adenoma, repeat colonoscopy in 1 year. If there are no advanced adenomas, then repeat colonoscopy in 3 years. For stage II or III patients, a history and physical examination are recommended every 3 to 6 months for 2 years, then every 6 months for a total of 5 years. CEA tumor markers will also follow the same frequency of physical examination visits. CT chest, abdomen, and pelvis are recommended every 6 to 12 months for 5 years. No imaging or tumor marker follow-up is recommended in patients with stage I disease. For patients with stage IV disease having undergone curative-intent resection, the recommendation is for a similar frequency of physical examination and CEA as for patients with stage II or III disease, with imaging studies to be repeated every 3 to 6 months for the first 2 years and every 6 to 12 months for a total of 5 years.

RECTAL CANCER

Incidence and Risk Factors

There were an estimated 46,050 new cases of rectal cancer diagnosed in the United States in 2023.[57] The proportion of CRCs occurring in the rectum has steadily increased over the past two decades, from 27% in 1995 to 31% in 2019. The trend of increasing rectal cancer is especially notable in people under the age of 50, where an increase of approximately 2% per year has been noted over the past decade.[57] Risk factors for rectal cancer are similar to those for colon cancer, as discussed earlier.

Clinical Evaluation and Staging

Initial evaluation of a patient with rectal cancer includes a cancer-specific history and physical examination. Eliciting symptoms such as nausea, vomiting, bloating, or constipation can provide important information regarding an impending large bowel obstruction and the potential need for more urgent intervention. Pain, especially neuropathic pain, can be indicative of a locally invasive tumor involving sacral nerve roots. It is also critically important to discuss the patient's baseline urinary, sexual, and bowel function. Imperfect stool continence before surgery will often predict poor bowel function and associated decreased quality of life after low anterior resection with sphincter preservation. Patients reporting tenesmus and rectal pain are often found to have low tumors with sphincter invasion. The patient's medical history, fitness, and frailty can guide preoperative optimization and risk stratification and predict the ability of the patient to tolerate neoadjuvant therapies and surgery. As discussed earlier for colon cancer, it is important to obtain a detailed family history to determine the likelihood of an underlying hereditary syndrome predisposing to CRC that could affect treatment and surveillance and therefore call for genetic counseling and testing.

In addition to general physical examination, the digital rectal examination (DRE) supplemented by flexible and/or rigid proctoscopy performed by the evaluating surgeon is of critical importance to guide further workup and treatment. The distance of the tumor from the anal verge and dentate line should be carefully assessed and documented. For tumors that are within the surgical anal canal, potential sphincter or adjacent structure invasion should be determined by assessing mobility of the lesion in relationship to the prostate, vagina, and sphincter complex. For early lesions or malignant polyps, endoscopic evaluation with assessment of polyp morphology and pit pattern provides important information that can guide appropriateness of local excision. If the tumor has not yet been histologically confirmed to be an invasive adenocarcinoma, further biopsies should be obtained that can confirm the diagnosis and also allow for immunohistochemical (IHC) analysis of MMR protein expression, if not already performed.

Routine laboratory examinations should include a baseline CEA level. In the absence of an obstructing rectal lesion, patients should undergo a complete colonoscopic evaluation to assess for synchronous cancers or premalignant neoplastic lesions, which have a reported incidence of approximately 3% and 30%, respectively.[103,104] If an obstructing tumor does not allow for complete colonoscopic evaluation, CT colonography can be used to assess the proximal colon. Alternatively, in patients receiving neoadjuvant therapy, a repeat full colonoscopy can be attempted after completion of neoadjuvant therapy, assuming downsizing of the obstructing tumor. If a complete colonoscopy still cannot be performed before surgery, it should be planned to be done in the early postoperative period.

Before considering treatment, rectal cancers should be clinically staged according to the AJCC TNM staging system (see Table 96.3). Similar to colon cancer, contrast-enhanced CT of the chest, abdomen, and pelvis should be obtained to assess for any metastatic disease. Although endorectal ultrasound has historically had an important role in locoregional staging of rectal cancer, pelvic MRI is currently the preferred imaging modality to determine T and N stage and also provide critical information regarding the location of the tumor in relationship to the anterior peritoneal reflection, the circumferential resection margin (CRM), and potential invasion of adjacent structures.[105,106] Fig. 96.10 provides an example of tumor staging of rectal cancer by pelvic MRI.

After completion of diagnostic evaluation and staging, all findings should be reviewed in the setting of a multidisciplinary tumor board composed of experts in colorectal surgery, medical and radiation oncology, surgical oncology, pathology, and radiology. A multidisciplinary tumor board discussion is one of the central quality metrics for rectal cancer care as recommended by the National Accreditation Program for Rectal Cancer (NAPRC) and other national guidelines.[107] Multidisciplinary tumor board review and discussion often change the initial management plan, even for experienced practitioners.[108] One of the key questions to

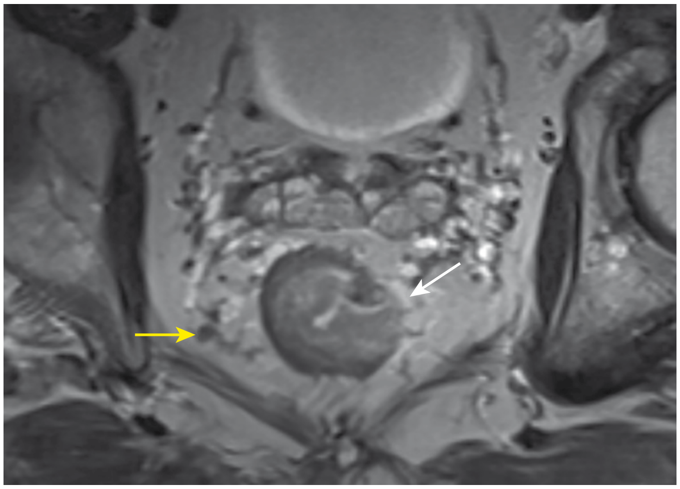

FIGURE 96.10 MRI image of pelvis that shows a T3 tumor penetrating through the rectal wall and into the mesorectal fat *(white arrow)*. There is enlarged and abnormal adenopathy in the mesorectum *(yellow arrow)*. This rectal cancer would be clinically staged as a T3N1 tumor.

be addressed during multidisciplinary review is whether the patient should be treated with surgery first or would benefit from neoadjuvant therapy.

Treatment

The treatment of rectal cancer has dramatically changed over the past 20 to 30 years and continues to rapidly evolve. Historically, rectal cancer was generally treated surgically with abdominoperineal resection (APR) and was plagued by high rates of postoperative morbidity and local recurrence. However, the modern treatment of rectal cancer, including neoadjuvant therapies, organ preservation, and minimally invasive restorative surgery strictly adhering to oncologic surgical principles, including total mesorectal excision (TME), has demonstrated significant improvement in outcomes with low local recurrence rates. To achieve optimal outcomes, the treatment of rectal cancer calls for a multidisciplinary approach provided by a team of experts, including surgeons, oncologists, radiation oncologists, radiologists, and pathologists, starting from the time of initial patient presentation and rectal cancer diagnosis and continuing through treatment, surveillance, and survivorship.

Neoadjuvant Therapy

At the beginning of the 21st century, several seminal trials evaluated the role of neoadjuvant radiotherapy in reducing rectal cancer local recurrence rates. It is important to note that neoadjuvant therapy is usually reserved for locally advanced tumors (T3-4 and/or N+) in the extraperitoneal rectum because of the historically high rates of local recurrence found with these tumors. The German Rectal Cancer Study[109] compared pre- and postoperative long-course chemoradiotherapy (CRT) in 823 patients with clinically staged locally advanced rectal cancer (LARC). The 5-year local recurrence rate was significantly lower in the neoadjuvant treatment group, 6% versus 13% ($p = 0.006$), whereas OS and the frequency of distant metastases were not significantly different. Furthermore, preoperative CRT was associated with a lower risk of severe toxicities (27%) compared with postoperative CRT (40%). Based on this and other similar prospective trials,[110,111] neoadjuvant CRT became the standard of care for LARC in the United States.

More recently, in an effort to not only optimize local control but also reduce distant recurrences and increase OS, several trials investigated the role of administering systemic chemotherapy (beyond the radiosensitizing dose of 5-FU given during CRT) in the neoadjuvant setting. *Total neoadjuvant therapy* (TNT) is the term used to describe a treatment algorithm where all chemotherapy and radiotherapy are given in the neoadjuvant setting. Promising results from recent prospective randomized controlled trials (RCTs) show that TNT improves DFS, pathologic complete response (pCR) rates, and chemotherapy completion rates.[112,113] The PRODIGE-23 trial, which randomized patients to traditional long-course neoadjuvant CRT followed by surgery and adjuvant therapy versus neoadjuvant TNT with FOLFIRINOX (leucovorin calcium, fluorouracil, irinotecan hydrochloride, and oxaliplatin) and CRT followed by surgery, showed that patients in the TNT arm had superior 3-year DFS (hazard ratio [HR] 0.69, 95% CI 0.49–0.097; $p = 0.034$), metastasis-free survival (HR 0.69, 95% CI 0.54–0.90; $p = 0.0048$), and increased rates of pCR (27.8% vs. 12.1%; $p < 0.001$). Of patients treated with TNT, 81% completed chemotherapy, compared with 75% in the standard arm.[112] Another randomized trial evaluated the use of short-course neoadjuvant radiation along with neoadjuvant chemotherapy as an alternative TNT regimen. In the RAPIDO trial, patients with LARC were randomized to the experimental arm and received short-course radiotherapy (5 × 5 Gy) followed by six cycles of CAPEOX or nine cycles of FOLFOX4 before TME surgical resection, whereas the standard-of-care group had traditional long-course radiation (28 × 60.4 Gy) followed by TME surgery with adjuvant therapy.[113] Three-year treatment failures, defined as the first occurrence of locoregional failure, distant metastasis, new primary colorectal tumor, or treatment-related death, were lower in the experimental group (23.7%) than the standard-of-care group (30.4%) mostly as a result of a decrease in distant metastasis. A higher pCR (28% vs. 14%) was observed in the experimental group as well. Both of these RCTs demonstrated that TNT followed by TME improved DFS compared with standard CRT before TME and adjuvant therapy. Current guidelines from the NCCN therefore consider TNT as a standard-of-care neoadjuvant treatment for patients with LARC.[114]

Organ Preservation

Before the advent of TNT, the finding of a pCR in approximately 20% to 25% of patients who had surgery after neoadjuvant CRT had already triggered an interest in nonoperative management (NOM) of rectal cancer. Professor Habr-Gama's group first published long-term outcome data on NOM in a group of patients with a complete clinical response (cCR) to neoadjuvant CRT in 2004.[115] In this groundbreaking observational study, a group of patients ($n = 71$) with cCR was managed nonoperatively with close observation, including frequent DRE, proctoscopy, and imaging. In this "watch-and-wait" protocol, there was a 5-year OS of 100% and DFS of 92%. Although initially controversial, this study challenged the dogma that all patients with rectal cancer needed surgery by demonstrating that in complete responders, surgical resection may not be required to achieve excellent long-term outcomes. With growing evidence for NOM from multicenter cohorts[116] and strong patient interest in organ preservation, recent guidelines call for a selective approach to NOM for patients with a cCR as long as it is provided by an experienced multidisciplinary team in the context of defined protocols.[107,114] The prerequisite of a cCR for NOM requires comprehensive restaging after the completion of neoadjuvant therapy with CT scan of the chest and abdomen, MRI of the pelvis, and DRE with flexible proctoscopy performed by a surgeon with experience in NOM. Findings consistent with a cCR include no mass or nodularity on DRE, a smooth white or pale scar with or without telangiectasia and no ulceration, mucosal irregularity or stricture on high-definition endoscopy, and no mass or lymph nodes on diffusion-weighted MRI.[117,118] An example of an endoscopic cCR to treatment is shown in Fig. 96.11. MRI findings of a cCR may include a fibrotic scar with low signal intensity on T2-weighted imaging and no restriction of diffusion. Although optimal surveillance modalities and intervals for NOM still require further study, current protocols call for digital examination with flexible endoscopy and CEA levels every 3 to 6 months, MRI of the pelvis every 6 months, and CT of the chest and abdomen every 6 to 12 months for the first 2 years after the completion of treatment. After 2 years, with significantly decreasing rates of tumor regrowth,[119] surveillance intervals can be extended, but ongoing close monitoring is required for at least 5 years.

Considering the higher rates of pCR found with TNT protocols, the multicenter randomized Organ Preservation for Rectal Adenocarcinoma (OPRA) trial set out to examine the optimal sequence of therapies in patients with LARC. Patients were

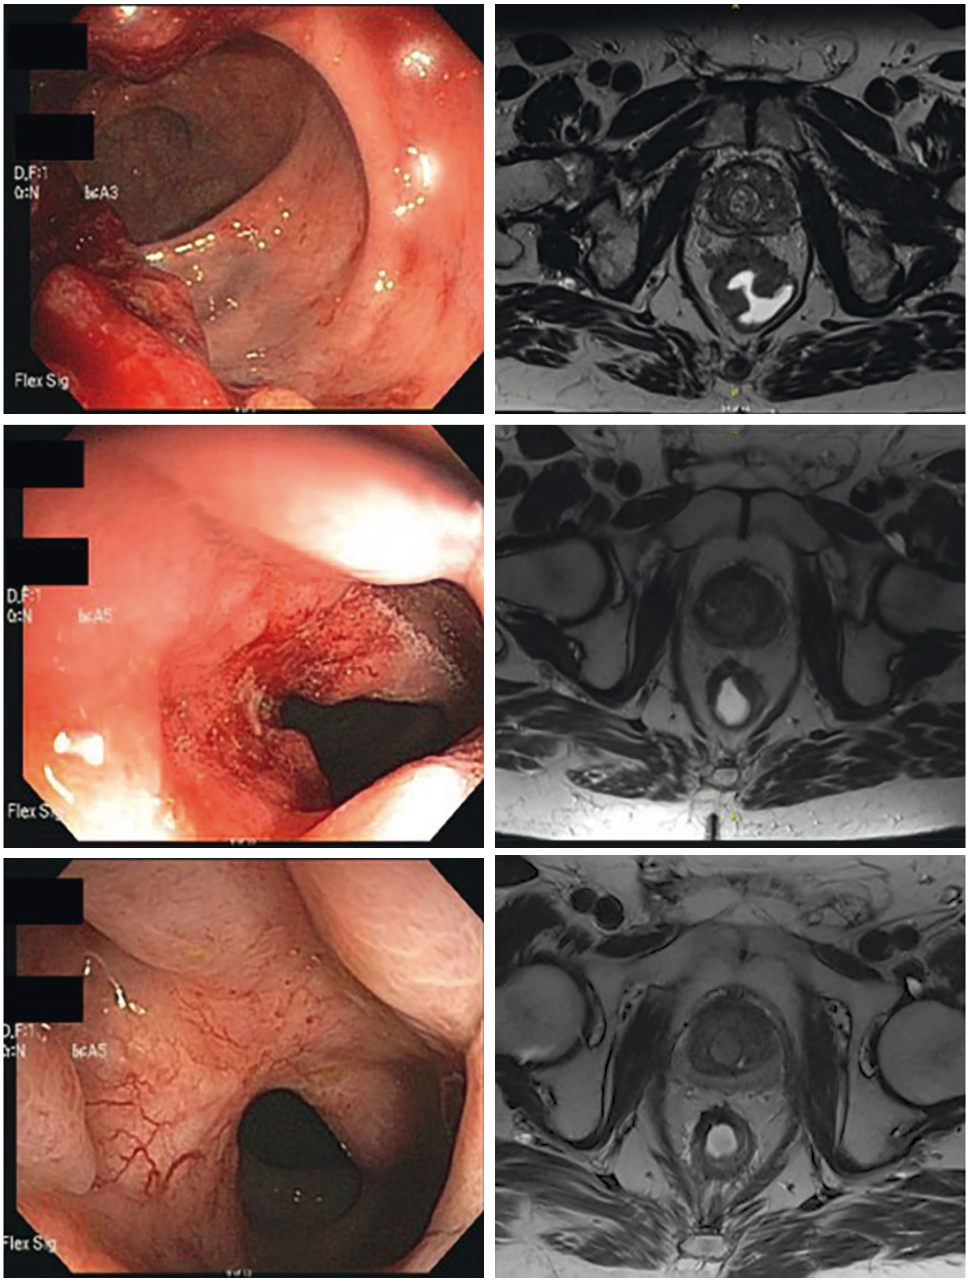

FIGURE 96.11 Clinical evaluation of rectal cancer with flexible endoscopy and MRI before and after neoadjuvant treatment. At the time of diagnosis, an oozing tumor is seen at the top of the anal canal, with MRI demonstrating a T3 tumor abutting the prostate. Restaging 6 to 8 weeks after the completion of neoadjuvant chemoradiotherapy demonstrates a partial tumor response on flexible sigmoidoscopy and MRI. Restaging evaluation after completion of total neoadjuvant therapy, including consolidation chemotherapy, shows a flat white scar with telangiectasia on endoscopy and a T2 dark scar on MRI, indicating a complete clinical response.

randomized to start with induction chemotherapy followed by chemoradiation (INCT-CRT) or to start with CRT followed by consolidation chemotherapy (CRT-CNCT), with patients who achieved a cCR after TNT being offered NOM.[120] The three-year DFS was 76% in both arms, but CRT-CNCT resulted in a higher rate of cCR and 3-year organ preservation rates of 53% compared with 41%for INCT-CRT. Patients who experienced tumor regrowth while on the watch-and-wait protocol proceeded directly to surgery (40% in the INCT-CRT arm and 28% in the CRT-CNCT arm), with no demonstrable survival detriment resulting from delayed surgery. This trial demonstrated that TNT with selective use of NOM achieves similar long-term outcomes as historical controls treated with CRT followed by surgery and adjuvant chemotherapy and also that use of a consolidation chemotherapy protocol for TNT maximizes the percentage of patients eligible for organ preservation.[121]

Surgical Anatomy and Principles of Surgical Technique

Although advances in neoadjuvant therapies and NOM have revolutionized the modern treatment of rectal cancer, high-quality surgery with strict adherence to oncologic surgical principles remains the cornerstone to cure and optimizing quality of life for most patients. A thorough understanding of rectal and pelvic anatomy is critical to achieve excellent surgical outcomes. The distal limit of the rectum is surgically defined by the anorectal ring, an anatomic landmark palpable on physical examination or visible radiographically as the upper border of the anal sphincter and puborectalis muscles. The proximal extent of the rectum is somewhat more challenging to define because of variations in the distance between the peritoneal reflection and the distance from the anal verge. A recent consensus conference defined the junction of the sigmoid mesocolon and mesorectum as seen intraoperatively or on cross-sectional imaging as the upper limit of the rectum.[122] In practice, the anterior peritoneal reflection is a landmark that is consistently identifiable on staging MRI and is used as a border to select patients at increased risk for local recurrence for neoadjuvant therapy. The rectum proximal to the anterior peritoneal reflection is considered the intraperitoneal rectum.

The rectum receives its blood supply from the IMA via the superior rectal artery and the internal iliac artery via the middle and inferior rectal arteries (Fig. 96.12). The venous drainage of the rectum is via the inferior mesenteric vein, which is often ligated at the inferior border of the pancreas in the setting of low resections to allow for a tension-free anastomosis. Lymph flow from the upper two-thirds of the rectum drains toward the inferior mesenteric nodes. Lymphatic drainage from the lower third of the rectum occurs cephalad, toward the inferior mesenteric nodes, but also laterally along the middle hemorrhoidal vessels to the internal iliac nodes. Below the dentate line, lymph drains toward the inguinal lymph nodes. This explains the patterns of metastatic lymph node involvement based on the location of the tumor. High ligation of the IMA, proximal to the takeoff of the left colic artery, is performed by many centers to allow for clearance of all locoregional lymph nodes comprising the cephalad lymphatic drainage of the rectum. However, current evidence has not conclusively shown improved oncologic outcomes when compared with ligation at the origin of the superior rectal artery, just distal to the takeoff of the left colic artery, which can reduce the risk of injury to adjacent autonomic nerves. Besides the cephalad lymphatic spread, it is important to bear in mind that distal rectal cancers have the potential to give rise to nodal disease in the pelvic sidewall. These lateral pelvic nodes along the internal iliac and obturator vessels, if suspicious on preoperative MRI, warrant consideration for a lateral pelvic node dissection.[123]

Recognition of fascial planes in the pelvis that separate structures derived from different embryologic origins has dramatically changed the surgical approach to rectal cancer, resulting in improved oncologic and functional outcomes. The endopelvic fascia lines the pelvis and internal organs as a visceral fascia. The mesorectum is thus surrounded circumferentially by a thin "fascia propria" and contains the terminal branches of the IMA and the rectal lymphatics (Fig. 96.13). A TME, as emphasized and promoted by Bill Heald as the "holy plane" of rectal cancer surgery,[124] is performed just outside of the fascia propria of the rectum and anterior to the presacral fascia, thereby removing the rectum en bloc with its mesorectum, blood vessels, lymphatics, and lymph nodes (Fig. 96.14). The impact of performing a TME in the correct plane on long-term oncologic outcomes cannot be overstated. Traditional blunt dissection resulted in a 25% rate of positive CRM with high rates of recurrence and mortality. In an observational national cohort study of 3319 patients in Norway, implementation of TME resulted in a decrease in local recurrence from 12% to 6% and an increase in survival rates to 73% compared with 60% with conventional surgery.[125] In addition, surgical dissection outside the TME plane, such as deep to the presacral fascia, can cause severe bleeding from the underlying presacral venous plexus. Such bleeding can be very difficult to control because the torn vessels tend to withdraw into the sacral foramina. In cases where the CRM remains involved even after neoadjuvant therapies, a dissection plane beyond the TME plane must be followed to ensure negative margins, including the en bloc resection of involved adjacent organs, such as prostate or vagina.

In the absence of a preoperatively identified threatened or involved CRM, sharp dissection in the correct TME plane ensures an appropriate oncologic resection and also allows for autonomic nerve protection and consequent preservation of urinary and sexual function. The sympathetic supply of the upper rectum arises from L1, L2, and L3. The preaortic plexus and postganglionic fibers follow branches of the IMA and superior rectal artery to form the hypogastric plexus, which in turn forms two main trunks on either side posterior to the rectum. The parasympathetic fibers to the rectum, or nervi erigentes, originate from the sacral foramina (S2, S3, and S4). They join the sympathetic hypogastric nerves at the pelvic plexus, giving rise to broadly distributed combined sympathetic and parasympathetic fibers (Fig. 96.15). During oncologic proctectomy, injury to these nerves can occur at several

points during the dissection. The hypogastric plexus is at risk when performing a high ligation of the IMA and when dissecting behind the superior rectal artery over the sacral promontory. Injury to the hypogastric plexus at these points may result in sympathetic dysfunction characterized by retrograde ejaculation in males. A second point of caution is during lateral mesorectal dissection, where division of the lateral stalks too close to the pelvic sidewall may injure the pelvic plexus and nervi erigentes and cause erectile dysfunction, impotence, and atonic bladder. Lastly, injury to the periprostatic plexus when dissecting anteriorly can also cause sexual and bladder dysfunction.

For upper rectal tumors and rectosigmoid tumors, the distal extent of the dissection and inclusion of the mesorectum should be 5 cm distal to the tumor. Therefore, the dissection does not need to go to the top of the sphincter complex, and a partial or tumor-specific mesorectal excision may be done. This technique still adheres to the principles of not violating the fascia propria of the rectum around the tumor, but the mesorectum is thinned to the level of the bowel wall at least 5 cm distal to the most distal aspect of the tumor. An example of this is shown in Fig. 96.16.

If the tumor involves the sphincter, complex complete excision of both the rectum and the anus, en bloc with the sphincter apparatus, must be performed, with creation of a permanent colostomy. Because this is done via an abdominal and perineal approach, the procedure is called an *abdominoperineal resection* (APR) (Fig. 96.17). This might also be a choice for elderly patients with distal rectal cancer with poor sphincter function because an end colostomy offers a better quality of life compared with an ultra-low coloanal anastomosis (CAA) that could further compromise continence. The same principles as performed in a low anterior resection are followed for the abdominal approach, adhering to the TME planes to the level of the pelvic floor muscles posterolaterally and the prostate or rectovaginal septum anteriorly. Care must be taken to avoid dissection close to the rectum and avoid narrowing or coning of the specimen, which can lead to involved circumferential margins. Attention is then turned to the perineal dissection. A purse-string suture is placed around the anus, and an elliptical incision is made around the anus that is then excised en bloc with the sphincter. Dissection continues cephalad until the abdominal plane of dissection is reached. The specimen is removed through the perineal incision, and the perineum is closed in layers. The empty space in the pelvis can often be filled with an omental pedicle flap and thereby keep the small bowel out of the proctectomy bed. Rotational tissue flaps (e.g., a vertical rectus abdominus myocutaneous or gracilis muscle flap) can be used selectively to decrease perineal wound complication rates, which are more common in patients treated with radiotherapy.

Sphincter Preservation and Bowel Function

The decision about whether a patient is a candidate for sphincter preservation with a LAR or requires APR with a permanent ostomy should generally be made in conjunction with the patient before surgery. As discussed earlier, this decision should be based on history, DRE, imaging studies, and the ability to obtain clear surgical margins. Patient factors, including age, comorbidities, body habitus, continence status, and patient desires, should also be considered. Because involved distal and CRMs are the most important risk factors for local recurrence, the relationship of the tumor to the anal verge and the internal and external sphincters

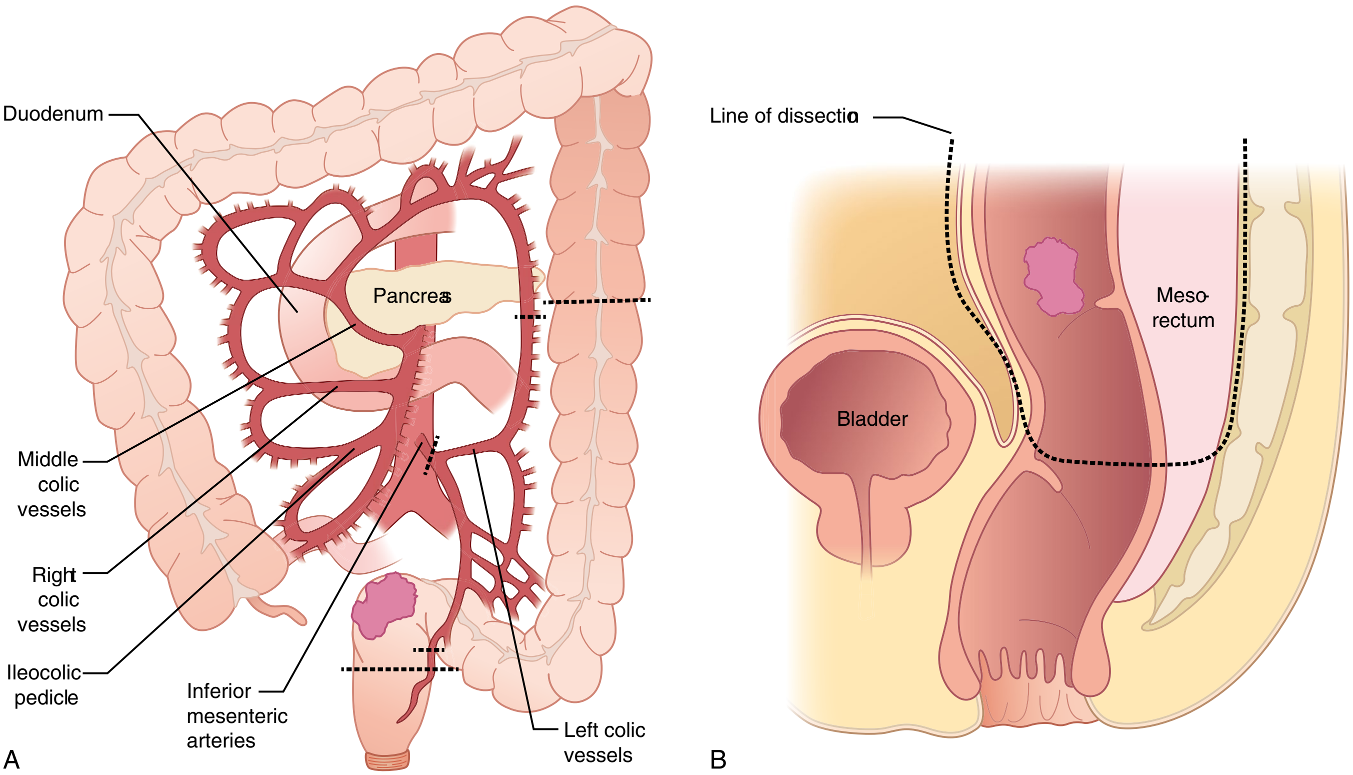

FIGURE 96.16 Low anterior resection for cancer of the upper rectum. (A) The inferior mesenteric artery is ligated. The marginal artery is ligated just distal to the level of colon transection; the hemorrhoidal vessels are ligated in the mesorectum. (B) For upper rectal cancer tumors, the distal margin in the mesorectum should be at least 5 cm.

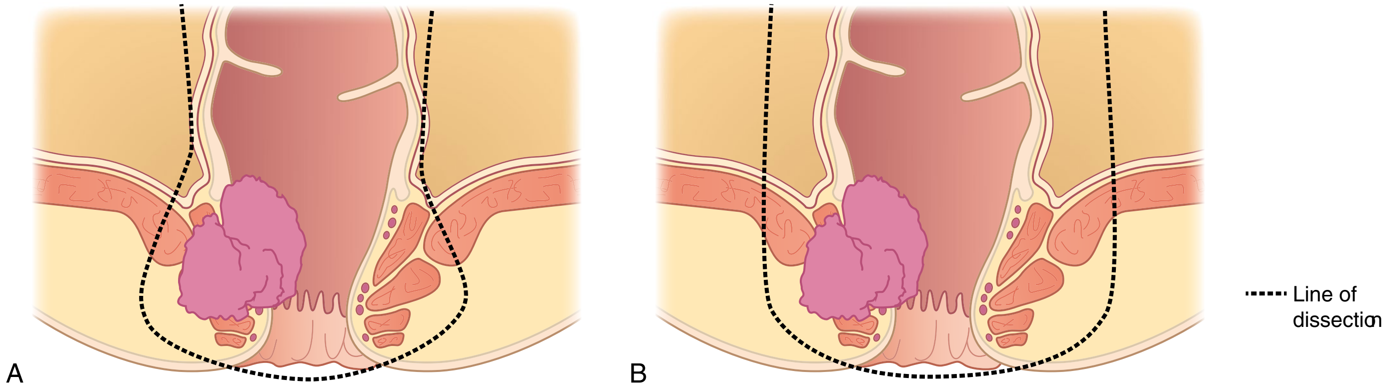

FIGURE 96.17 Abdominoperineal resection. Attention must be taken to avoid narrowing or coning of the specimen in the area around the levators (A). This can lead to higher rates of circumferential margin positivity and higher rates of local recurrence. The more oncologic techinque involves creating a cylindrical abdominoperineal resection with en bloc removal of the levator ani (B).

must be carefully examined and documented on preoperative MRI. For tumors in the distal rectum, a 2-cm distal margin should generally be the goal, although a clear margin that is less than 1 cm may be acceptable for low rectal tumors, particularly after CRT. However, there is a higher risk of local recurrence for very close distal margins, especially in tumors that did not show a good response to CRT. In cases of sphincter involvement at the time of diagnosis, after neoadjuvant therapy, it can often be difficult to discern between fibrosis and residual tumor that may still be involving the sphincters. Therefore, when residual viable tumor is suspected, it is generally oncologically safer to assume that the sphincter is still involved rather than relying on intraoperative findings to guide this important decision. Patients with levator or external sphincter involvement are not candidates for sphincter preservation. However, if only the internal sphincter is involved, motivated patients can safely be selected for LAR with intersphincteric resection (ISR) and hand-sewn CAA.[126] Such patients should be thoroughly counseled about expected functional outcomes, such as increased rates of fecal incontinence after ISR and CAA. In general, patients with poor preoperative anal sphincter function or bowel habits are not appropriate candidates for LAR with a low stapled anastomosis and are likely to have improved quality of life with a permanent colostomy.

Low anterior resection syndrome (LARS), a constellation of symptoms that includes increased bowel frequency, urgency, and clustering, is experienced to varying degrees by the majority of patients after LAR and the inherent loss of the rectum's reservoir function. Risk factors contributing to severe LARS include female sex, neoadjuvant therapy, TME, and low tumors.[127] Several RCTs have shown that for patients undergoing an ultra-low anterior resection, the construction of a colonic reservoir using a colonic J pouch or a side-to-end anastomosis can significantly improve postoperative bowel function for the first 1 to 2 years without an increase in anastomotic complications.[128]

Use of a Diverting Ileostomy

Prospective studies have shown that in patients undergoing LAR for rectal cancer, a diverting loop ileostomy (DLI) significantly reduces the rate of clinical anastomotic leaks and reoperations. This protective effect of the DLI, however, comes at the expense of higher stoma-related morbidity, such as dehydration.[129] Risk factors for anastomotic leak include a low rectal anastomosis, male sex, and neoadjuvant radiotherapy. In patients at increased risk for anastomotic leak and its dreaded consequences, construction of a DLI should be strongly considered. It is critical that this is discussed with the patient before surgery and that the patient is seen by a trained wound ostomy continence nurse (WOCN) for preoperative counseling and marking of an optimal anatomic location for a potential ostomy.

Role of Local Excision

Technical advances, including transanal endoscopic microsurgery (TEM) and transanal minimally invasive surgery (TAMIS), have enabled the en bloc, full-thickness local excision of relatively large rectal tumors with negative mucosal and deep margins.[130] Although local excision is another modality to facilitate rectal preservation and thereby reduce short- and long-term morbidity, it does not remove or pathologically stage mesorectal lymph nodes. Therefore, local excision should be reserved for highly selected patients with clinically staged T1 tumors without any high-risk features for occult lymph node metastases. These risk factors include lesions with deep T1 invasion (>1 mm into the submucosa or Kikuchi SM3), poorly differentiated tumors, lymphovascular and PNI, tumor budding, and positive margins.[131] To allow for accurate histologic assessment, it is critical that local excision be performed en bloc with a grossly normal circumferential margin and with the specimen fixed and oriented. If high-risk features are found on final pathology, the patients should be counseled about the risk for local recurrence and lymph node metastasis. In this situation, an oncologic formal TME should be recommended in the medically fit patient. A recent prospective phase II trial showed that for cT1-T3abN0 tumors, neoadjuvant chemotherapy followed by transanal local excision has the potential to expand criteria for organ preservation without compromising oncologic outcomes.[132]

Minimally Invasive Total Mesorectal Excision

Minimally invasive surgery (MIS) approaches to rectal cancer, including laparoscopic TME, robotic TME, and transanal TME (taTME), significantly improve short-term outcomes and accelerate recovery from surgery.[133] However, despite the wide acceptance of MIS approaches to rectal cancer, RCTs have failed to demonstrate that, from an oncologic perspective, laparoscopic TME is noninferior to open surgery.[134,135] The ambiguity related to oncologic outcomes after MIS TME is related to the technical challenge of obtaining a pathologic specimen with negative circumferential and distal resection margins and intact mesorectum within the confines of the bony pelvis. Current guidelines therefore recommend that MIS approaches to TME can be considered but should be performed by experienced surgeons with technical expertise.[107]

Adjuvant Therapy

Patients who received TNT with pathologic stage II or III disease should not receive adjuvant chemotherapy. Patients with clinical or pathologic stage II or III tumors who did not receive a full course of neoadjuvant chemotherapy are usually recommended to receive chemotherapy in the adjuvant setting. Although the evidence for the benefit of adjuvant therapy after neoadjuvant CRT is not strong, the NCCN recommends oxaliplatin-containing 5-FU regimens, such as FOLFOX for eight cycles, as the preferred adjuvant regimen, except for clinical T3N0 patients, in whom oxaliplatin can potentially be omitted. Studies have shown that early initiation of chemotherapy after resection was associated with improved outcomes.[136] Current guidelines recommend giving adjuvant radiotherapy selectively to patients with pathologic stage II or III cancers who did not receive any neoadjuvant radiotherapy and who are at increased risk for local recurrence. However, this needs to be carefully balanced with the potential risk of pelvic radiation negatively affecting postsurgical bowel function and wound healing.

Management of Rectal Cancer With Synchronous Metastases

Approximately 20% of patients with rectal cancer are diagnosed with synchronous metastatic disease. Although lung metastases are significantly more common in rectal cancer compared with colon cancer, the liver is still the most common site of disseminated disease found in rectal cancer, with about half of stage IV patients presenting with liver-only metastases. Retrospective studies have demonstrated superior outcomes for patients selected for surgical treatment of stage IV CRC. Patients with solitary liver metastases can have a 5-year OS rate as high as 71% if treated with a combination of chemotherapy and surgery. Therefore, for a rectal cancer patient presenting with synchronous metastases, it is critical to assess if all disease is resectable in a multidisciplinary setting that includes hepatic and/or thoracic surgeons. Metastatic disease is only considered resectable if margin-negative removal of all known tumor is realistically possible while maintaining adequate liver (or lung) reserve. In the absence of symptoms, there is no proven benefit to incomplete resection or debulking (R1/R2 resection), and these patients should typically be treated with systemic chemotherapy to extend survival. However, in symptomatic patients, palliative intervention should be strongly considered, even in the setting of unresectable metastases. Potential palliative interventions include radiotherapy, endoscopic self-expanding metal stent placement, fecal diversion, or resection of the primary tumor, depending on the presenting symptoms (e.g., bleeding, obstruction, pain), metastatic burden and prognosis, the morbidity and efficacy of the proposed palliative intervention, and impact of interrupting systemic chemotherapy. Shared decision-making regarding the optimal palliative intervention should be made in conjunction with the multidisciplinary team, including oncology, radiation oncology, surgery, and palliative medicine.

Rectal cancer patients with resectable or potentially resectable liver metastases should be treated with an individualized approach. Generally, initiating treatment with 3 to 4 months of systemic therapy can help assess disease biology, facilitate resectability, and potentially reduce the risk for early postoperative disease progression.[76] However, it is important to keep in mind that oxaliplatin and irinotecan regimens are associated with liver injury, which can then impair the liver functional reserve after resection. If follow-up imaging demonstrates good (or at least partial) treatment response and resectable disease, several surgical algorithms can be considered, including a “combined” approach where the primary and metastatic liver disease are resected jointly or a “rectum-first” or “liver-first” approach. The optimal approach depends on the comparative and cumulative disease burden in the rectum and liver, complexity of surgery required, symptoms related to the primary tumor, and medical fitness of the patient. Scenarios that favor a combined approach include healthy patients with upper rectal tumors and liver metastases that don’t require major hepatic resections.[137] For low rectal tumors with threatened CRM, short-course radiotherapy should be strongly considered to reduce the risk of local recurrence while minimizing the interruption of systemic chemotherapy.[138]

Immunotherapy

Immunotherapy with checkpoint inhibitors has significantly changed the outcomes for dMMR or MSI-H CRC in the metastatic setting and is currently well established as a first-line therapy for stage IV patients.[139] Unfortunately, dMMR is only present in approximately 3% to 7% of rectal cancer patients because most dMMR tumors occur in the right colon. In this subgroup of patients, recent small studies have demonstrated that immunotherapy used in the neoadjuvant setting has a dramatic response. One important prospective study with 12 patients found a 100% cCR rate to neoadjuvant immunotherapy, without the need for subsequent CRT or surgery.[53] Long-term follow-up is required to establish the durability of these response rates and evaluate the risk for metachronous cancers in this patient population enriched in Lynch syndrome patients. Further maturation of data from prospective trials on neoadjuvant immunotherapy will likely change current neoadjuvant treatment paradigms for patients with dMMR LARC.[140]

Pathologic Staging and Prognosis

Pathologic assessment and staging of the resected specimen are critical in postoperative prognosis and risk stratification. Guidelines established by the College of American Pathologists (CAP) delineate the Protocol for the Examination of Specimens From Patients With Primary Carcinoma of the Colon and Rectum.[141] A synoptic pathology report developed by the CAP ensures standardized and comprehensive documentation of critical findings besides histologic grade, margins, and TNM stage that are specific to rectal cancer specimens, including macroscopic intactness of the mesorectum, relationship of the tumor to the peritoneal reflection, and the response to preoperative therapy, also known as the AJCC tumor regression grade (TRG), ranging from 0 (complete pathologic response with no viable cancer cells) to 3 (no treatment effect with extensive residual cancer). A summary of AJCC pathologic staging is shown in Table 96.3. If not already performed on the initial biopsy specimen, IHC analysis should be performed on the resected specimen to assess for MMR deficiency. In cases of metastatic disease, tumor genomic sequencing can guide the selection of targeted therapies.

Although clinical stage at presentation is an important prognosticator and guides the selection of multimodal therapies, for LARC patients receiving neoadjuvant therapy, the posttreatment pathologic stage (given a yp designation) and TRG is a more accurate predictor of survival and recurrence.[142,143] Patients with a TRG 0 (pCR) have the best prognosis, with 5-year OS rates of approximately 90%. TRG is directly correlated with OS.[144] In patients with margin-negative resections and residual tumor on final pathology, ypT and N stage, TRG, tumor distance from the anal verge, LVI, and PNI are all factors that predict survival.

Postoperative Surveillance

The goal of surveillance after the curative-intent treatment of rectal cancer is the early identification of recurrences that could potentially be cured by further surgical intervention and to detect and prevent the development of metachronous cancers. In general, surveillance regimens for stage II to III rectal cancer mirror those for colon cancer discussed earlier, including regular clinical encounters; CEA levels; cross-sectional imaging of the chest, abdomen, and pelvis; and colonoscopies at predetermined intervals for at least 5 years. For patients at increased risk for local recurrence (e.g., after local excision, patients treated without neoadjuvant CRT, or resections with positive margins), proctosigmoidoscopy every 6 months for at least 2 years is an important adjunct to other surveillance examinations.[145,146] In patients at high risk for local recurrence, proctosigmoidoscopy should be supplemented by pelvic MRI or EUS.

ANAL CANCER

Anatomy and Pathology

The anal canal is the most distal part of the GI tract. The average length is about 4 to 5 cm, and it extends proximally from the top of the anorectal ring to the anal verge. The anal canal contains both rectal columnar epithelium proximally and squamous epithelium distally. The area where these cells tend to overlap and transition in histology is called the *ATZ,* which starts about 1 cm proximal to the dentate line and extends for approximately 0.5 to 1.5 m in length. The anal margin extends from the anal verge to the area of hair-bearing and appendage skin (Fig. 96.18). Dysplastic and malignant cells can arise in the anal canal and anal margin. The most common cancer arising in this area is anal squamous cell carcinoma (SCC). Additional nonsquamous malignancies that occur in the anal canal are extremely less common and include adenocarcinoma, neuroendocrine tumors, melanomas, and rarely, lymphomas and sarcomas. It should be noted that histology is generally more important than location within the anal canal and usually dictates overall patient management.

Epidemiology

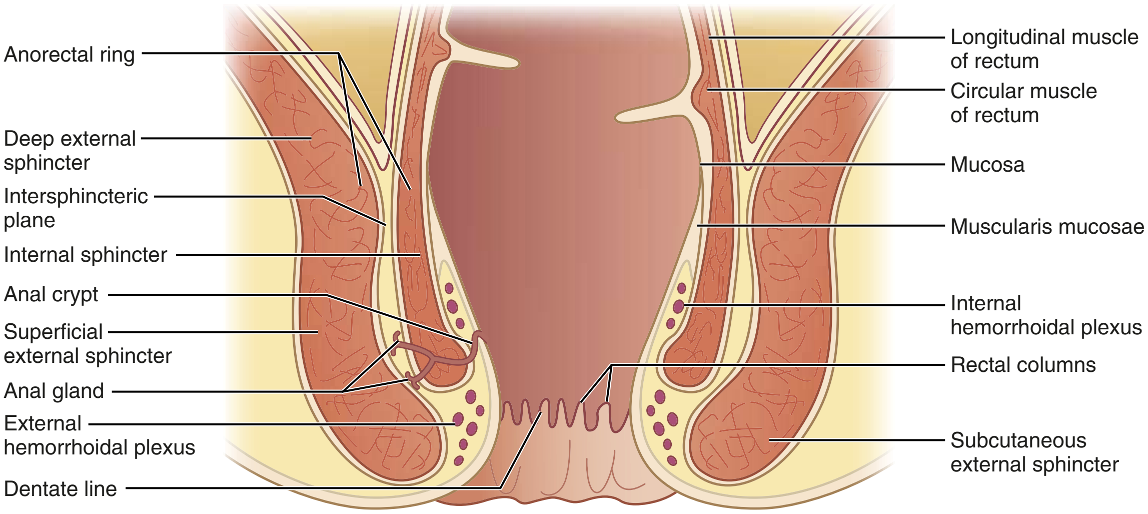
Anal carcinoma is rare and accounts for approximately 1% to 2% of all cancers of the large bowel. Nearly 10,000 people are affected annually in the United States, and anal carcinoma accounts for 1870 deaths annually.[147] It occurs more frequently in females compared with males, at a ratio of 2:1. The highest incidence is in White females and Black males. There has been increasing incidence and mortality over the past few decades, an increase of approximately 2.7% and 3.1%, respectively, per year.[148] The average age of diagnosis is approximately 61 years, and it is rare before age 35 years.

Risk Factors

The main risk factor for developing anal cancer is human papillomavirus (HPV) infection, with HPV being detected in nearly 90% of anal SCCs. The vast majority of anal SCCs demonstrate the presence of multiple HPV genotypes, and the high-risk genotypes are HPV-16 and HPV-18. HPV is usually sexually transmitted, and the risk of HPV-related SCC is greatly elevated in those who participate in anoreceptive intercourse, both males and females. Human immunodeficiency virus (HIV) infection is also a risk factor for anal cancer, and SCC rates are increased 30 times in people with HIV compared with the general population.[149] Other risk factors include age, cervical cancer, tobacco smoking, and immunosuppression.

Clinical Presentation

The most common presentation of anal cancer is bleeding, but patients often also report feelings of a mass or fullness, itching, pain, or anal discharge. Presenting symptoms may be mistaken for



Anorectal ring
Deep external sphincter
Intersphincteric plane
Internal sphincter
Anal crypt
Superficial external sphincter
Anal gland
External hemorrhoidal plexus
Dentate line
Longitudinal muscle of rectum
Circular muscle of rectum
Mucosa
Muscularis mucosae
Internal hemorrhoidal plexus
Rectal columns
Subcutaneous external sphincter

TABLE 96.4 Anal SCC AJCC Staging Table

AJCC STAGE	PRIMARY TUMOR SIZE (cm)	T STAGE	LYMPH NODES	METASTASES
1	<2	1	—	–
2	2–5	2	—	–
	>5	3	—	–
3A	—	Any	Perirectal (N1)	–
3A	Invasion of adjacent organ	4	—	–
3B	Invasion of adjacent organ	4	Perirectal (N1)	–
3B	—	Any	Unilateral internal iliac and/or inguinal regions (N2)	–
3B	—	Any	Perirectal and inguinal or bilateral internal iliac and/or inguinal regions (N3)	–
4	—	Any	Any	+

AJCC, American Joint Cancer Committee; *SCC*, squamous cell carcinoma.

benign etiologies, such as hemorrhoids, and it is important that symptoms are further evaluated. More advanced lesions may cause bowel obstruction, incontinence, rectovaginal fistula, or inguinal adenopathy. Any suspicious mass or lesion should be biopsied for diagnosis.

Clinical Evaluation and Staging

Evaluation and staging are performed with a combination of clinical examination, endoscopy, and imaging (Table 96.4). A clinical history, including symptoms and risk factors, should be documented. Physical examination should evaluate for primary tumor size, location, and relationship to the anal sphincters; involvement of surrounding structures, such as prostate or vagina; and inguinal lymphadenopathy. Anoscopy or flexible proctosigmoidoscopy in the office can delineate the relationship to the dentate line and allows for biopsy as needed. A full colonoscopy should be performed to evaluate for synchronous CRC, which occurs in up to 15% of cases.[150,151] For females, a gynecologic examination should be conducted, including screening for cervical cancer. HIV testing should be done for both males and females. Cross-sectional imaging is recommended for chest, abdomen, and pelvis to evaluate both local and distant disease.[152] Pelvic MRI may be considered for additional evaluation of the primary tumor. PET scan has been suggested by some groups to help detect distant disease and nodal disease, but this does not replace cross-sectional imaging. Clinically suspicious inguinal nodes should undergo biopsy, particularly if they are not fludeoxyglucose F18 (FDG) avid.[153]

Treatment

Anal Margin Squamous Cell Carcinoma

The anal margin is generally defined as the area extending from the anal verge radially for 5 cm onto the perianal skin. SCC in the anal margin may be managed like SCC skin tumors in other parts of the body, depending on size and location. Wide local excision with 1-cm margins may be appropriate if adequate margins can be obtained without encroaching on the anal canal or musculature and there are no high-risk histologic features. For larger tumors or those with high-risk features or suspicion of lymph node involvement, CRT is the first line of treatment.

Anal Canal Squamous Cell Carcinoma

Local excision. Local excision of anal canal SCC is limited to early lesions without high-risk features. These early lesions are often superficial SCCs that are found incidentally after excision of presumed benign lesions, such as hemorrhoids, condylomas, or skin tags. If margins are negative and there are no high-risk features or evidence of nodal disease, only surveillance may be needed. Early discrete T1 well or moderately differentiated lesions that do not involve the sphincter complex can be resected with 1-cm margins, and if there is no regional involvement, they may be adequately treated with wide local excision alone.

Radiation and chemotherapy. Radiation with chemotherapy is the primary treatment for anal SCC and can be the definitive treatment in the majority of cases. Initially described by Nigro, CRT that includes concurrent pelvic external-beam radiation and 5-FU with mitomycin C[154] is the standard regimen. In a randomized trial, anal SCC patients treated with radiation therapy (45 Gy, with a boost dose of 15 to 20 Gy after a 6-week break) with concurrent infusional 5-FU and mitomycin C resulted in an 80% complete response rate and a 72% colostomy-free rate.[155] Current standard approaches include 5-FU, mitomycin C, and radiation therapy. Cisplatin may be substituted for mitomycin C without detriment to overall oncologic outcomes. Clinically or histologically positive lymph nodes should be included in the radiation fields.

Initial evaluation for response to treatment and persistent disease should be at approximately 12 weeks after completion of therapy and include anoscopy/proctoscopy and DRE. If there is no residual disease on clinical examination, patients can enter into surveillance protocols as described later. If they have had a good but incomplete response, it is reasonable to reassess in an additional 6 weeks. If there is no evidence of progression, surveillance without surgery may continue for up to 6 months. In one study, at initial assessment (11 weeks), 64% were found to have had a clinical complete response, and the complete response rate increased to 85% at 26 weeks. Of patients who experienced a good but not complete response at 11 weeks, 72% went on to achieve a complete response by 26 weeks. Patients who failed to achieve a complete response at 26 weeks had a significantly inferior 5-year OS (87% vs. 48%).[156] If a lesion persists at that time or if there is progression in the interval, the tumor should be biopsied for confirmation of SCC and then treated with salvage APR, as described later.

Posttreatment Evaluation and Surveillance

For those patients with a complete remission after CRT, NCCN guidelines recommend DRE and examination of the inguinal nodes by palpation every 3 to 6 months for 5 years; anoscopy every 6 to 12 months for 3 years; and a CT scan of the chest, abdomen, and pelvis (or pelvic MRI) annually for 3 years for patients who had stage II or stage III.[153] If local recurrence occurs without metastatic disease, an APR should be performed.

Salvage Surgery

Patients who have chronically persistent disease after CRT or those who develop local recurrence are recommended surgical treatment with APR. Preoperative evaluation should include cross-sectional imaging with either pelvic CT or MRI to define the local extent of disease and determine the need for en bloc resection of other organs, such as prostate, bladder, or vagina. General surgical oncology principles for APR using TME like those described for rectal cancer should be used (see Fig. 96.17). For patients who failed CRT, those who underwent surgery with curative intent had a 5-year OS of 66% compared with only 13.5% for those who had palliative treatment.[157] For pathologically proven or clinically suspected positive inguinal lymph nodes, a formal groin dissection should be performed. Negative margins remain the most important prognostic factor after surgical resection. Patients with an R0 resection may experience up to 75% 5-year OS.[158] Because radiation therapy and often-extensive surgery leave a large soft tissue defect, wound healing and morbidity are significant issues. A rotational tissue flap decreases complication rates. Commonly employed flaps include a vertical rectus abdominis myocutaneous flap, a gracilis muscle flap, or an omental pedicle flap.

Anal Adenocarcinoma and Anal Melanoma

Anal canal adenocarcinoma is rare and accounts for less than 5% of anal canal tumors. Because the histology is that of rectal adenocarcinoma, treatment is the same as rectal cancer, with neoadjuvant CRT followed by APR for those with persistent disease. Patients with anal adenocarcinoma have worse OS rates than those with rectal adenocarcinoma or anal SCC.[159] Best outcomes are achieved with CRT followed by APR. Anal melanoma is also an extremely rare disease and accounts for 0.5% of all anal canal tumors. Anal canal melanomas are usually pigmented lesions, but they can be amelanotic in as many as 29% of cases. Prognosis is generally poor, with 5-year survival rates of about 14% to 31%.[160,161] Surgery has traditionally been the standard treatment, with no significant difference in survival between wide local excision and APR; thus, local excision is the preferred approach when able to technically achieve negative margins. The advent of immunotherapy for anorectal melanoma has modified treatment paradigms, and its role continues to evolve. Early studies suggest improved short-term OS.

Nelson H, Sargent DJ, Wieand HS, et al. A comparison of laparoscopically assisted and open colectomy for colon cancer. *N Engl J Med*. 2004;350(20):2050-2059. doi:10.1056/NEJMoa032651

This was the first randomized controlled trial comparing open to laparoscopic partial colectomy for colon cancer. This was a multicenter trial designed to demonstrate noninferiority of the laparoscopic approach in terms of time to recurrence. The overall 3-year survival rate and time to recurrence was similar in the two groups, while the laparoscopic group had a shorter hospital length of stay and less narcotic use.

André T, Boni C, Mounedji-Boudiaf L, et al. Oxaliplatin, fluorouracil, and leucovorin as adjuvant treatment for colon cancer. *N Engl J Med*. 2004;350(23):2343-2351. doi:10.1056/NEJMoa032709

This is the key adjuvant trial that established the addition of oxaliplatin to 5-FU and leucovorin as a standard for adjuvant chemotherapy for surgically treated stage II and III colon cancer. The FOLFOX group had a statistically better 3-year recurrence and disease-free survival.

Habr-Gama A, Perez RO, Nadalin W, et al. Operative versus non-operative treatment for stage 0 distal rectal cancer following chemoradiation therapy: long-term results. *Ann Surg*. 2004;240(4):711-718. doi:10.1097/01.sla.0000141194.27992.32

This article was one of the earliest to establish and demonstrate safety and effectiveness of non-operative management for rectal cancer after neoadjuvant therapy in patients with a complete clinical response. This concept and approach were slow to be adopted but eventually has been reproduced in randomized controlled trials and is an acceptable approach to rectal cancer according to National Comprehensive Cancer Network guidelines.

Verheij FS, Omer DM, Williams H, et al. Long-term results of organ preservation in patients with rectal adenocarcinoma treated with total neoadjuvant therapy: the randomized phase II OPRA trial. *J Clin Oncol*. 2024;42(5):500-506. doi:10.1200/jco.23.01208

This was a randomized multicenter trial that examined oncologic outcomes after total neoadjuvant therapy for clinically stage II and III rectal cancers. It compared long course chemoradiation followed by consolidation chemotherapy vs. Induction chemotherapy followed by chemoradiation. This manuscript provided long term results of organ preservation. In the trial, patients who achieved a complete clinical response after finishing neoadjuvant therapy were offered non-operative management with active surveillance. The 5-year disease-free survival rates were similar, but the total mesorectal excision-free survival was greater in the group treated with chemoradiation first (54% vs 39%).

Le DT, Uram JN, Wang H, et al. PD-1 Blockade in tumors with mismatch-repair deficiency. *N Engl J Med*. 2015;372(26):2509-2520. doi:10.1056/NEJMoa1500596

This was the first major trial to demonstrate the clinical effectiveness of an anti-programmed death 1 immune checkpoint inhibitor, pembrolizumab in progressive metastatic colorectal cancer with mismatch repair deficiency. Patients treated with pembrolizumab demonstrated improved immune-related objective response rates and better progression-free survival. This study provided the foundation for additional studies of immune checkpoint inhibitors in colorectal cancer.

  Pilonidal Sinus
  Hidradenitis Suppurativa
  Perianal Crohn Disease
Functional Bowel and Pelvic Floor Disorders
  Fecal Incontinence
  Constipation
  Rectal Prolapse

ANATOMY

The anal canal is approximately 4 cm in length, extending from the anal verge to the top of anorectal ring (Fig. 97.1). The proximal anal canal is lined by columnar epithelium, and the distal anal canal is lined by modified squamous epithelium. The junction between the columnar and squamous epithelium, located at the midpoint of the anal canal, appears as an undulating demarcation referred to as the *dentate line* and represents the division between the embryonic endoderm (proximal) and ectoderm (distal). Notably, the modified squamous epithelium in the distal anal canal, called *anoderm,* differs from the squamous epithelium of the skin because it is devoid of hair follicles and glands. The innervation of the anoderm distal to the dentate line is via somatic nerves, whereas the innervation of the mucosa proximal to the dentate line is via the sympathetic and parasympathetic systems. At the anal verge, the anoderm transitions to normal skin containing hair follicles and sweat and sebaceous glands.

The mucosa above the dentate line appears pleated with longitudinal folds, known as the *columns of Morgagni.* There is a small pocket or crypt at the base of most columns, in the region of the dentate line, that communicates with the anal glands. The glands themselves reside in the intersphincteric plane. These anal glands secrete lubricating fluid to assist with defecation. The glands number from 6 to 12 and are mostly concentrated in the posterior aspect of the anus. The anal gland duct traverses the submucosal plane, and its branches terminate within the internal anal sphincter or extend into the intersphincteric plane.

The submucosa in the distal anal canal is formed by a discontinuous layer of thickened tissue, creating hemorrhoidal "cushions," typically found in the left lateral, right anterior, and right posterior positions. These cushions generally receive their blood supply from six hemorrhoidal arteries distributed along the circumference of the distal rectum and anus.[1] The venous drainage is provided by the superior, middle, and inferior hemorrhoidal vessels, allowing for communication between the portal and systemic circulations. These vessels form direct arteriovenous communications within the cushions, and for this reason, hemorrhoidal bleeding is arterial rather than venous in nature. Venous and lymphatic drainage above the dentate line flows into the internal iliac vessels; below the dentate line, blood supply and drainage are provided by the inferior hemorrhoidal system.

The sphincter complex of the anus can be thought of as two concentric cylinders of muscle. The inner cylinder, the internal anal sphincter, is a thickened continuation of the circular layer of the muscularis propria of the distal rectum. This autonomically innervated smooth muscle occupies the distal 2 to 4 cm of the anal canal. The outer cylinder, the external anal sphincter, is a downward extension of skeletal muscle extending from the levator ani to the anoderm. The puborectalis muscle, often referred to as the *rectal sling,* is one of the main muscles contributing to the external anal sphincter. It originates at the pubis, passes around the rectum posteriorly, and returns to the pubis.

The internal anal sphincter is supplied by sympathetic (L5) and parasympathetic (S2, S3, and S4) nerves. The external anal sphincter is innervated on each side by the inferior rectal branch of the pudendal nerve (S2 and S3) and by the perineal branch of S4. There is considerable redundancy in innervation of the anal sphincter; therefore, unilateral interruption of the pudendal nerve will not result in external anal sphincter dysfunction, but the loss of bilateral S3 nerve roots (e.g., by surgical transection) will result in fecal incontinence. If the S1 through S3 nerve roots remain intact only on one side, the patient is still expected to maintain control of the anal sphincters and control continence.

FIGURE 97.1 Anal canal. (From Bai JC, Bosworth BP, Cruz-Correa M, et al. Colon. In: Reynolds JC, Ward PJ, Rose S, et al., eds. *The Netter Collection of Medical Illustrations: Digestive System: Part II—Lower Digestive Tract*. St. Louis: Elsevier; 2017:Plate 3-12.)

The rectal branch of the pudendal nerve transmits anal sensation, and it is thought to play a role in maintenance of anal continence. The anal canal contains a rich supply of free and organized sensory nerve endings. Organized nerve endings include Meissner corpuscles (touch), Krause bulbs (temperature sensation), Golgi-Mazzoni bodies (pressure), and genital corpuscles (friction). Because of the robust concentration of nerves, the anus is extremely sensitive.

PHYSIOLOGY

Normal continence requires rectal wall compliance to accommodate fecal material, appropriate neurogenic control of the pelvic floor muscles, and properly functioning internal and external sphincter muscles. At rest, the puborectalis muscle creates a sling around the distal rectum, forming a relatively acute anorectal angle that distributes intraabdominal forces onto the pelvic floor rather than along the axis of the rectum and anus. The internal and external anal sphincters, together with the hemorrhoidal cushions, provide a complete airtight and watertight seal, with the pressure in the anal canal at rest measuring 25 to 120 mm Hg compared with 5 to 20 mm Hg in the rectum.[2] This pressure gradient is a dynamic process in which rapid increases in intraabdominal pressure or intrarectal pressure lead to a reflexive and voluntary contraction of the external anal sphincter and puborectalis to prevent fecal leakage during rapid filling of the distal rectum with gas or with sneezing or coughing.

The process of defecation is a complex, coordinated event involving increased intraabdominal pressure, rectal contraction, and synchronized relaxation of the anal sphincters and pelvic floor musculature. This coordination is innervated by both the somatic and autonomic nervous systems and involves both conscious and unconscious responses to sensory input from nerves originating in the rectum and the anal canal. Distention of the rectum results in reflexive relaxation of the internal anal sphincter. This is known as the *rectoanal inhibitory reflex* (RAIR). This allows sensory epithelium of the anus to sample the fecal material in order for the individual to consciously distinguish between solid stool, liquid stool, and gas. If defecation is deemed appropriate, the external anal sphincter is voluntarily relaxed, together with the puborectalis muscle, which allows for straightening of the anorectal angle, descent of the pelvic floor, and opening of the anal canal, resulting in evacuation of the contents of the rectum.

HISTORY

Patients with diseases of the anus may present with various nonspecific complaints, including rectal pain, bleeding, tissue prolapse, seepage, or anal itching. The skilled provider asks focused questions that elucidate the nature of the problem. Patient history is the cornerstone of diagnosis, and asking discerning questions will almost always lead to a presumptive or even definitive diagnosis. When the provider has an impression of the likely diagnosis, it leads to a more focused examination of the anus.

In addition to questions about the character of the symptoms, time of onset, and exacerbating and relieving factors, the history includes detailed questioning about defecation. It is important to ask specific questions regarding the number of daily bowel movements, straining with defecation, time spent on the toilet, caliber of stool and consistency of bowel movements (soft, formed, or liquid), incontinence episodes, seepage, and soiling. Regarding pain, differentiating the type of pain can help accurately diagnose many conditions before examining the patient because the common diagnoses typically present in distinct ways. Sharp, razor-like pain that occurs with bowel movements, sometimes followed by prolonged hours of painful spasm, will almost always indicate an anal fissure. Acute onset of anal pain with a palpable firm perianal lump may suggest a thrombosed hemorrhoid. Acute worsening pain associated with fever and malaise may suggest that a perianal or ischiorectal abscess is a likely culprit. Pain occurring even without defecation, especially with bleeding, could indicate malignancy. Patients may complain of anal itching rather than pain. Itching is often worse at night and may wake patients from sleep because the associated nerve fibers are more sensitive based on the circadian rhythm. Regarding bleeding, a provider must inquire about the presence or absence of blood per anus, the character of the bleeding (bright vs. dark, amount of blood, presence or absence of blood clots), association with bowel movements, blood mixed within the fecal material or present as streaks of blood on the surface of the stool, and whether blood is noted with wiping. Patients may report prolapsing tissue that reduces spontaneously, may require manual reduction, or may not be reducible. The patient should be asked about the presence or absence of anal seepage or drainage, fecal soilage, or perianal moisture. Tactful questioning regarding sexual history, particularly anoreceptive intercourse, should be obtained from both males and females. Questions may include the number of partners, use of protection, and sex without a partner as well as a detailed history of prior abnormal Pap smears, sexually transmitted infections (STIs), and human immunodeficiency virus (HIV). Focused surgical history should include previous anorectal surgeries, interventions for drainage of perirectal abscesses, fistulas, hemorrhoid surgery, or sphincterotomy. A history of radiation exposure for treatment of malignancy should be elicited. Females should be asked about number of pregnancies, vaginal deliveries, any tears or interventions during delivery, and a history of episiotomy. Urinary symptoms and dyspareunia may suggest pelvic floor dysfunction.

PHYSICAL EXAMINATION

Anorectal examination may be very sensitive or uncomfortable for the patient. Communication with the patient is critical. The provider should describe the proposed examination and ensure the patient is comfortable with proceeding. It is important to have a chaperone present in the room throughout the examination, to protect both the patient and the provider irrespective of the sex of the patient and the provider.[3]

Examination is generally conducted in either the left lateral position or in the prone jackknife position, depending on the availability of a proctology table and provider preference. The examination begins by inspecting the perianal skin and anal margin. Gentle spreading of the buttocks will reveal the anal verge and anoderm. The patient can be asked to squeeze and relax their sphincter muscle, which can reveal asymmetric contraction or abnormal recruitment of the gluteus muscles to aid with anal squeeze. When asked to bear down, the patient is expected to reflexively relax their anal sphincter, which may reveal rectal prolapse and/or abnormal pelvic floor descent. If prolapse is not present or produced on the exam table, it may be elicited by having the patient sit on the commode/toilet. Before inserting the examining finger into the anal canal, systematic palpation of the perianal skin and anal verge assesses for tenderness and allows the patient an opportunity to prepare for digital rectal examination.

Digital rectal examination should always use lubrication gel. The exam begins with evaluation of the length of the surgical anal canal to the top of puborectalis sling posteriorly, followed by a sweep around the sacrum with palpation of the tip of the coccyx and evaluation of the levator muscles on the posterolateral aspect of the rectal vault. In males, the prostate is palpated anteriorly; in females, the presence of a rectocele may be determined by gently flexing the examining finger anteriorly. Particular attention should be paid to digital examination of the anus, which can be overlooked if the provider palpates only the rectal vault. Using the first phalanx of the examining finger, a sweep of the anal canal should be performed. If a mass is detected within the rectum or anal canal, its location and relationship to the anterior-posterior or lateral aspect of the rectum should be noted, its size should be estimated, and the provider should observe if it is fixed or mobile and soft or firm. Care should be taken to specifically assess the relationship of the mass to the top of the anorectal ring to clinically ascertain involvement of the internal sphincter.

Before concluding the digital rectal examination, the patient is asked to squeeze in order to assess function of the pelvic floor musculature and to perform a Valsalva maneuver, during which the muscles of the internal and external sphincters should relax, indicating appropriate coordination of the anal sphincter complex.

Anoscopy is an important modality for the complete evaluation of any anorectal complaint and provides direct visualization of the anoderm, dentate line, internal and external hemorrhoids, and distal rectal mucosa. Although there are many varieties of anoscopes, they generally consist of a lighted, hollow scope fitted with an obturator. After generous lubrication, the anoscope is gently inserted into the anal canal, and then the obturator is removed. The anoscope should be gently rotated to spread the anal mucosa to provide a complete and thorough circumferential evaluation.

For patients with a reported history and visual external examination suggestive of an anal fissure, digital rectal examination and anoscopy may need to be deferred because of patient discomfort. Close monitoring of symptoms and examination after improvement of symptoms is reasonable. Patients presenting with pain, bleeding, or other concerning symptoms and in whom the diagnosis is less certain or whose symptoms do not improve should be evaluated by anorectal examination in the operating room under anesthesia. Until evaluation of the anal canal is completed, a complete assessment cannot be rendered.

IMAGING

Imaging can play an important role in the assessment of some benign anorectal disorders, including abscesses, fistula-in-ano, and pelvic floor dysfunction. Endoanal ultrasound may be used to evaluate the layers of

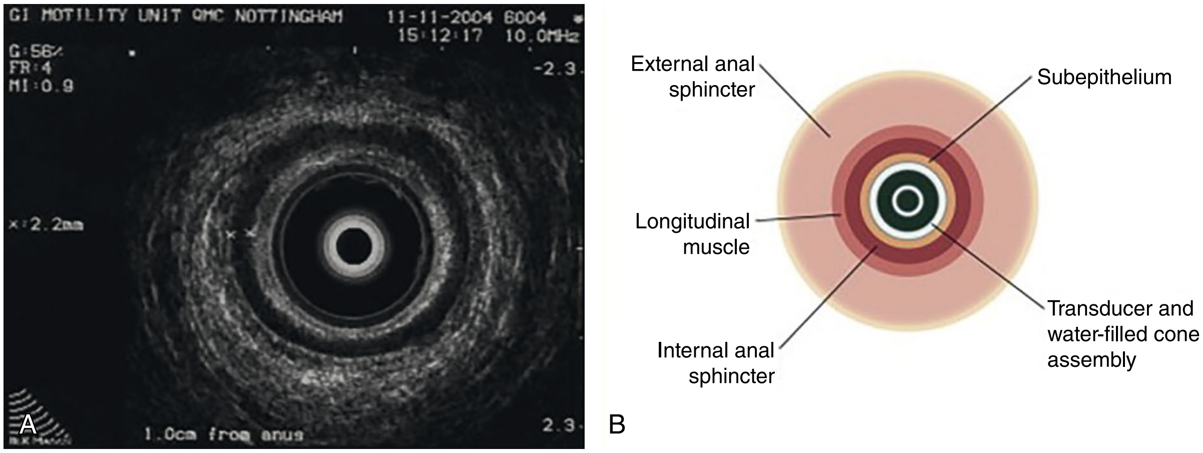

FIGURE 97.2 (A–B) Normal endoanal ultrasound. Axial image of the anal canal. The outer edge of the plastic transducer cone is seen. The subepithelium is hyperechoic and is surrounded by the dark hypoechoic internal anal sphincter, which has a thickness of 2.2 mm (indicated by *x-x* on the scan). The longitudinal muscle is moderately hyperechoic and is bordered by the mixed echogenicity of the external anal sphincter. (From Wright JW. Endoanal ultrasound. *Surgery*. 2008;26[6]:247-249. Copyright 2008 Elsevier Ltd.)

the anal canal, internal anal sphincter, external sphincters, and puborectalis muscle. Ultrasound can be used to accurately estimate the degree of anal sphincter disruption and outline the anatomy of a complex anal fistula. Although endoanal ultrasound is less costly than alternative imaging modalities and does not expose patients to radiation, it is often less available and is operator dependent (Fig. 97.2). Computed tomography (CT) of the pelvis can be a useful imaging modality to assess for the presence of anorectal abscess in the emergency department when physical exam findings are equivocal. Magnetic resonance imaging (MRI) can provide much higher resolution when evaluating the anorectal anatomy and is more sensitive than CT for the detection and delineation of a complex fistula-in-ano, especially when dedicated protocols, termed *MRI fistulography*, are performed (Fig. 97.3).

For patients suspected of defecatory dysfunction or fecal incontinence, functional studies, including anal manometry and defecography, provide a dynamic assessment. Anorectal manometry measures the pressures generated by the anal sphincter muscles, sensation in the rectum, and the neural reflexes that are needed for normal defecation and continence. Defecography studies, performed under fluoroscopy or MRI, demonstrate the dynamic changes in and around the rectum, anal canal, vagina, and pelvic floor during the process of defecation. These studies demonstrate functional and anatomic causes for obstructive defecation, which results in excessive straining and incomplete rectal emptying and may include rectocele (or the anterior bulging of the rectal wall), enterocele, cystocele, rectal intussusception/prolapse or other pelvic organ prolapse, abnormal perineal descent, and paradoxical contraction of the puborectalis.

Evaluation of colonic transit/motility is an important part of evaluation of the constipated patient. The most common transit study involves the ingestion of radiopaque Sitz markers followed by serial abdominal radiographs to assess transit of the markers

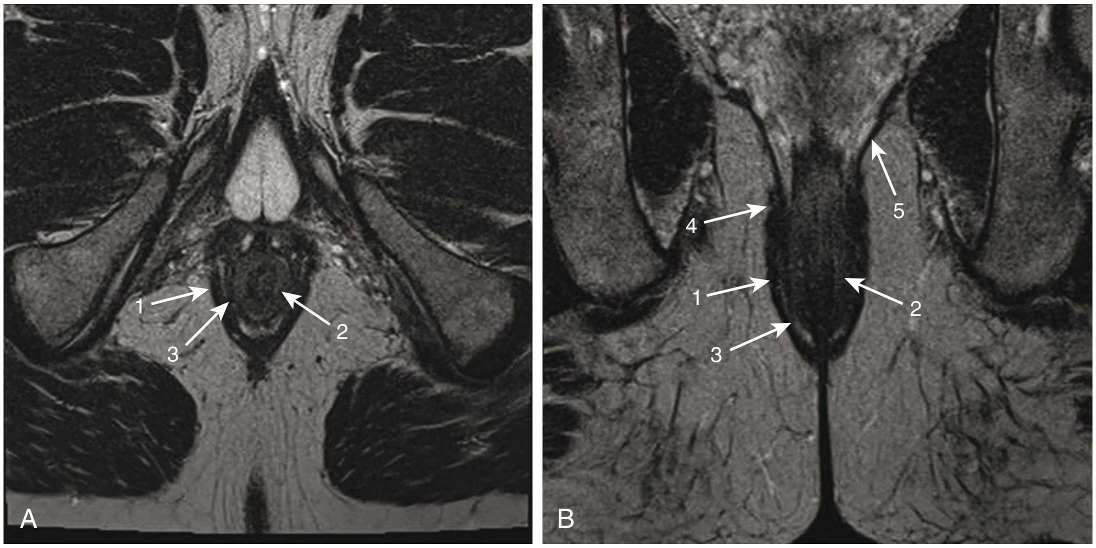

FIGURE 97.3 Normal MRI anal canal. (A) Axial T2 MRI of the anal canal: (1) external anal sphincter, (2) internal anal sphincter, (3) intersphincteric space. (B) Coronal T2 MRI of the anal canal: (1) external anal sphincter, (2) internal anal sphincter, (3) intersphincteric space, (4) puborectalis muscle, (5) levator ani complex.

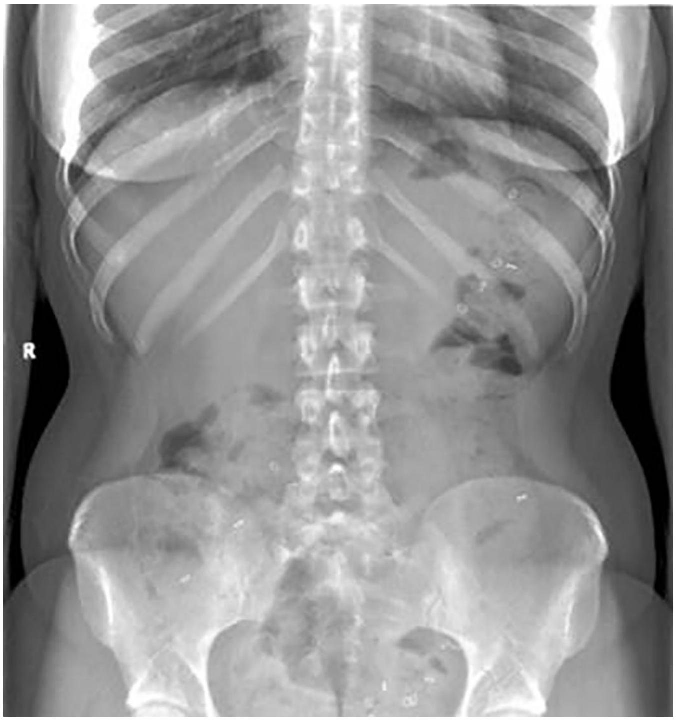

FIGURE 97.4 Example of Sitz marker study consistent with slow-transit constipation. (From Savitt L, Thurler A. biofeedback for constipation and fecal incontinence. *Semin Colon Rectal Surg*. 2011;22[1]:56-62. Copyright 2011 Elsevier Inc.)

through the gastrointestinal (GI) tract (Sitz marker study). With normal motility, at least 80% of the markers should pass within 5 days. If more than 20% of the markers are retained in the colon, the transit study is considered abnormal (Fig. 97.4). The position of the markers within the colon may distinguish between a defecatory disorder in which the markers pass through the colon normally, but accumulate in the rectum, and slow-transit constipation in which the markers may accumulate in the right colon or may be scattered throughout the colon. Colonic scintigraphy studies can provide similar information after the ingestion of an isotope (indium 111 or technetium 99) and serial measurements with gamma cameras. Scintigraphy studies and wireless motility capsules can be used to assess gastric, small bowel, and colon transit times if whole gut dysmotility is suspected.

COMMON BENIGN DISORDERS OF THE ANUS

Hemorrhoidal Disease

Internal Hemorrhoids

Symptomatic internal hemorrhoids result from enlargement and/or protrusion of the hemorrhoidal cushions in the proximal anal canal, which can lead to bleeding per rectum or prolapse. The most common etiologic factors contributing to the development of symptomatic internal hemorrhoids include constipation, prolonged straining, and excessive toilet time. Increased intraanal pressure leads to abnormal dilatation and engorgement of vascular channels, followed by chronic changes in the supporting connective tissue within the anal cushions.[4] This process can be further exacerbated by normal aging; starting as early as the second or third decade of life, the tissue supporting hemorrhoids can deteriorate or weaken, leading to further distal displacement of the cushions and venous distention, bleeding, and tissue prolapse. Subsequent inflammatory reactions and vascular hyperplasia further contribute to the pathophysiology of symptomatic hemorrhoids.[5,6] Painless bleeding associated with bowel movements with or without intermittent tissue protrusion is the most common complaint of patients with symptomatic internal hemorrhoids.

When eliciting a history from a patient presenting with symptomatic internal hemorrhoids, focus should be on the extent, severity, and duration of symptoms; bleeding and prolapse; difficulty with perineal hygiene; and the presence or absence of pain. Bleeding may be dramatic, “splatter the toilet bowl,” “look like a crime scene,” stain clothing/furniture, or result in anemia, especially for patients taking anticoagulating medications or patients with coagulopathy (e.g., cirrhosis). A detailed review of fiber intake and bowel habits, including frequency, consistency, change in caliber of stool, and difficulty with evacuation, should also be sought. A baseline assessment of fecal continence is important before any anorectal procedure is undertaken. Anorectal examination should include visual inspection of the anus, digital rectal examination, and anoscopy to evaluate the extent of hemorrhoidal disease and evaluate for other abnormalities. Internal hemorrhoids can be assigned a grade based on the classification in Table 97.1.

The initial approach to a patient with symptomatic internal hemorrhoids should always be conservative and focus on optimizing bowel and toilet habits. This usually includes the recommendation to increase fluid intake to at least 64 ounces per day and start on fiber supplementation to achieve at least 20 to 35 g of dietary fiber consumed daily, with the goal of maintaining soft, formed, easy-to-pass stools.[7] Even those patients who regularly consume dietary fiber and report having “normal” bowel movements will benefit from additional fiber intake and hydration. Patients should also be counseled regarding defecation habits, such as avoidance of straining and limiting time on the toilet to no more than 2 to 3 minutes at a time. Patients should be cautioned against reading or using electronic devices while on the toilet because this can significantly increase toileting time.[8]

Sitz baths with warm water can help decrease pain, burning, and itching when performed after bowel movements. Additionally, there are many over-the-counter topical treatments for symptomatic internal hemorrhoids, although there are scarce data to support their efficacy. These therapies generally come in the form of either creams or suppositories and typically include a barrier compound combined with an antiinflammatory agent or astringent. Although there are scarce data to support the efficacy of these agents, some patients may report symptomatic relief.[9] A 6- to 8-week trial of medical management is usually indicated before considering more invasive interventions.

TABLE 97.1 **Classification of Internal Hemorrhoids**

GRADE OF INTERNAL HEMORRHOIDS	DESCRIPTION
Grade I	No prolapse; hemorrhoidal bleeding
Grade II	Hemorrhoids with bleeding and protrusion; reduce spontaneously
Grade III	Hemorrhoids with bleeding and protrusion; manual reduction required
Grade IV	Prolapsed hemorrhoids that cannot be reduced

Most patients with grade I and II (and select patients with grade III) internal hemorrhoidal disease who remain symptomatic despite medical management can be offered an office-based procedure, such as rubber band ligation (RBL), sclerotherapy, or infrared coagulation (IRC).

Hemorrhoidal RBL is the most common and effective option and has been shown to be superior to sclerotherapy and IRC.[10] RBL strangulates hemorrhoidal tissue, which results in ischemia and necrosis of the prolapsing mucosa, followed by scar fixation to the rectal wall. This procedure alleviates symptoms of bleeding and prolapse by decreasing the size of the hemorrhoidal cushion and increasing the fixation of the hemorrhoidal tissue to the rectal wall (Fig. 97.5). RBL is generally well tolerated because the rubber band is placed proximal to the dentate line, in the area of the anus that is devoid of somatic pain fibers. Significant pain after RBL typically results from misplacement of the band below the dentate line and requires immediate band removal. RBL should be avoided (or considered cautiously) in therapeutically anticoagulated patients or in patients taking antiplatelet medications, given an increased risk for serious bleeding from the resultant ulcer when the hemorrhoidal cushion necroses and sloughs off, often days after the procedure.[9]

Sclerotherapy is accomplished by injection of a sclerosing agent directly into the hemorrhoidal cushion, which results in fibrosis of the submucosa and fixation of the hemorrhoidal tissue. The most common sclerosing agents are 5% phenol in almond or vegetable oil and 1% sodium tetradecyl sulfate. Injection is performed into the submucosa at the apex of a hemorrhoidal cushion, using approximately 1 mL of the sclerosing agent. Sclerotherapy is appropriately offered to anticoagulated patients or those receiving antiplatelet therapy, who are often not optimal candidates for RBL or surgical excision.

IRC uses direct application of infrared light, resulting in protein coagulation within the hemorrhoid. This is most commonly used for grade I and II hemorrhoids.

Doppler-guided hemorrhoid artery ligation (HAL) uses the current understanding of the arterial blood supply of hemorrhoids to identify and ligate selected feeding vessels. There is no need for tissue excision, but mucosal pexy is required for patients with symptomatic hemorrhoidal prolapse. Several studies using HAL have demonstrated favorable short-term outcomes. This method, however, is expensive and was not found to be cost-effective compared with RBL in terms of incremental cost per quality-adjusted life-year.[11]

Surgical excision of hemorrhoids is a very effective, albeit painful, approach for patients who did not improve or who are not candidates for an office-based treatment. Excisional hemorrhoidectomy can be offered to patients with symptomatic combined internal and external hemorrhoids with prolapse (grades III–IV).[9] Either open or closed hemorrhoidectomy can be performed. The most commonly used technique is the closed (Ferguson) hemorrhoidectomy. This approach is associated with decreased postoperative pain, faster wound healing, and a reduced risk of postoperative bleeding compared with an open (Milligan-Morgan) hemorrhoidectomy.[12]

The principles of closed hemorrhoidectomy involve removal of only redundant hemorrhoidal tissue and pexy of hemorrhoidal mucosa to the rectal wall. In most instances, removal of the largest or most symptomatic hemorrhoid produces the desired symptomatic relief. Removal of all three hemorrhoidal columns results in larger mucosal defects and can lead to narrowing of the anal canal or stenosis if adequate intervening mucosa is not preserved between the suture lines, or incontinence if the underlying sphincter muscles is injured. The procedure can be performed under general anesthesia, local with monitored anesthesia, or spinal anesthesia in either lithotomy position or prone jackknife position. Prophylactic antibiotics are not indicated.[13] An anal block is induced with local anesthetic, and exposure may be achieved with a Hill-Ferguson or other operating anoscope. The hemorrhoid is excised with a diamond-shaped excision with the distal apex at the base of the external hemorrhoid extending onto the anoderm and then narrowing to the proximal apex at the internal hemorrhoidal pedicle. The hemorrhoidal cushion is then dissected off the internal sphincter in what is typically an avascular plane. The hemorrhoidal pedicle at the proximal apex of the diamond can then be controlled with suture ligation using a braided, absorbable suture.

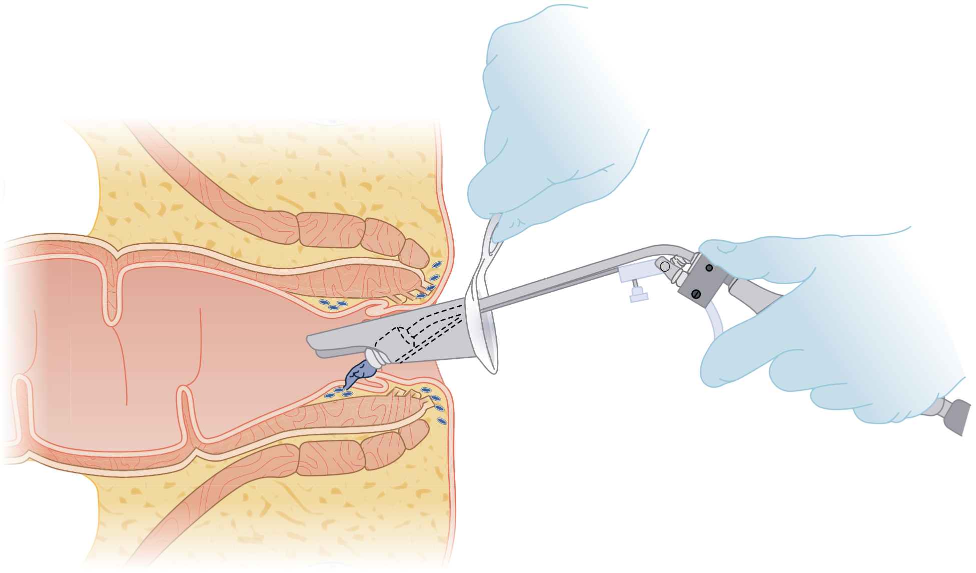

FIGURE 97.5 Diagram of suction ligator. Placement of band on hemorrhoid using specially designed application.

The edges of the hemorrhoidectomy wound are reapproximated with continuous locking stitches of the braided absorbable suture. Complete hemostasis should be achieved with suture closure of the defect. If suture line bleeding is present, additional figure-of-eight sutures can be placed as needed. The use of several bipolar or ultrasonic energy devices during excisional hemorrhoidectomy has also been described. The use of a bipolar energy device has been demonstrated to be faster and to cause less postoperative pain when compared with the traditional closed hemorrhoidectomy described previously.[14,15] Regardless of the excision technique, the internal sphincter fibers should be identified and preserved. There is no benefit in packing the anal canal at the completion of the operation because it is unlikely to stop postoperative bleeding, and large quantities of blood can accumulate above the packing, preventing early diagnosis of a postoperative bleed (Fig. 97.6).

Postoperative care should be aimed at maintaining regular bowel function with liberal use of stool softeners and laxatives to prevent constipation. Sitz baths are an important adjunct that can help with postoperative pain and itching. All patients should be prescribed a multimodal pain regimen to reduce narcotic use and promote a faster recovery.[9]

Complications after surgical hemorrhoidectomy are relatively uncommon; the most common is postoperative hemorrhage, ranging in incidence between 1% and 2%.[12] Acute urinary retention occurs in 1% to 15% of cases. A rare, but feared, complication of hemorrhoidectomy is pelvic sepsis. It can develop after excisional hemorrhoidectomy or office-based procedures. Patients with urinary retention (dysfunction), worsening anal or pelvic pain, or fever must be evaluated emergently for this potentially life-threatening complication. Immediate examination under anesthesia with debridement of any necrotic tissue is required.

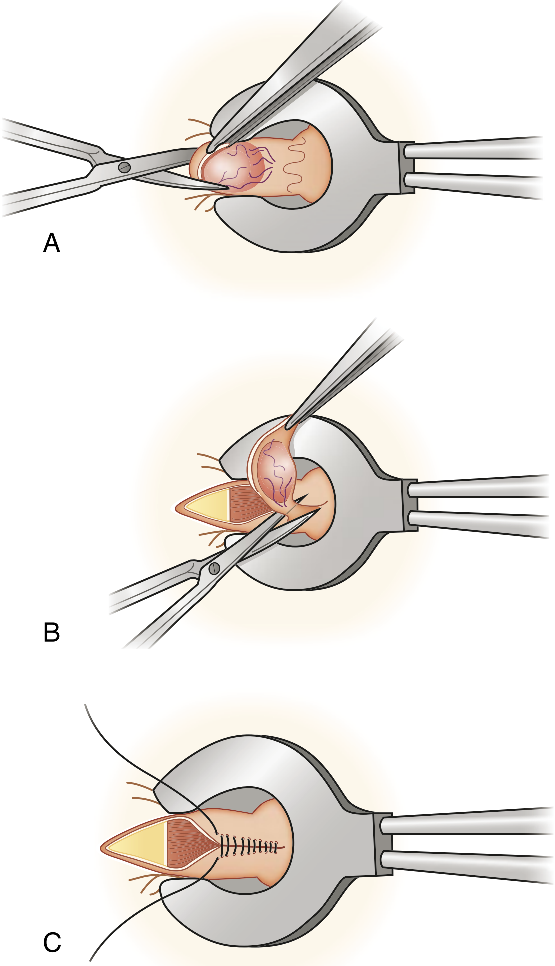

FIGURE 97.6 Open hemorrhoidectomy.

Stapled hemorrhoidopexy uses a specially designed stapling device to create a mucosa-to-mucosa anastomosis while removing redundant mucosa proximal to the dentate line; the procedure also disrupts the feeding hemorrhoidal arteries and displaces the hemorrhoidal cushions into the proximal anal canal. Unlike excisional hemorrhoidectomy, this technique does not address external hemorrhoids. Patients undergoing stapled hemorrhoidopexy generally have less pain, pruritus ani, and fecal urgency but are significantly more likely to have recurrent symptoms requiring additional operative procedures compared with those who undergo excisional hemorrhoidectomy.[16] Stapled hemorrhoidopexy is also associated with several unique complications, such as rectovaginal fistula (RVF), staple line bleeding, chronic pain, and stricture at the staple line. Rectal perforation requiring fecal diversion or low anterior resection has also been reported as a rare, severe complication.[17]

Occasionally, patients may present acutely with strangulated, ischemic, gangrenous, or acutely thrombosed internal hemorrhoids. These patients generally have a previous history of prolapsing hemorrhoids (grade III or IV) and will present with an acute-episode prolapse that is no longer reducible (incarceration). If the presentation is delayed, incarcerated hemorrhoids may become necrotic and drain bloody or malodorous material (Fig. 97.7). For those patients with incarceration without strangulation or signs of sepsis, efforts can focus on reducing the prolapsed hemorrhoids to allow for resolution of the acute crisis and future evaluation if needed for a less invasive treatment modality, such as hemorrhoid banding, or a less extensive resection once the degree of swelling has subsided. Applying table sugar as an osmotic agent and ice packs to the prolapsed, edematous hemorrhoids as well as performing an anal block can facilitate reduction. Use of hyaluronidase injected directly into incarcerated edematous hemorrhoids can result in a prompt and dramatic resolution.[18] Patients who fail a limited trial of nonoperative management or those with strangulation and necrosis on presentation require prompt operation. In patients suffering from circumferential fourth-degree hemorrhoids with extensive thrombosis and inflammation, the anal canal is markedly distorted; special attention must be paid to anatomic planes, internal sphincter preservation, and meticulous hemostasis. Unless the tissue is necrotic, mucosa and anoderm should be preserved as much as possible to prevent postoperative anal stricture or incontinence, which is a very real risk in this setting.

External Hemorrhoids

External hemorrhoids are the portion of the hemorrhoidal vascular plexus located below the dentate line and are therefore covered by anoderm and have somatic innervation. The external hemorrhoids drain mostly via the inferior rectal veins into the pudendal vessels and then into the internal iliac vein. External hemorrhoids commonly become symptomatic when the vessels become acutely dilated, leading to stasis and thrombus formation. Thrombosed hemorrhoids can occur in patients who have had minimal hemorrhoidal symptoms in the past and may be preceded by an episode

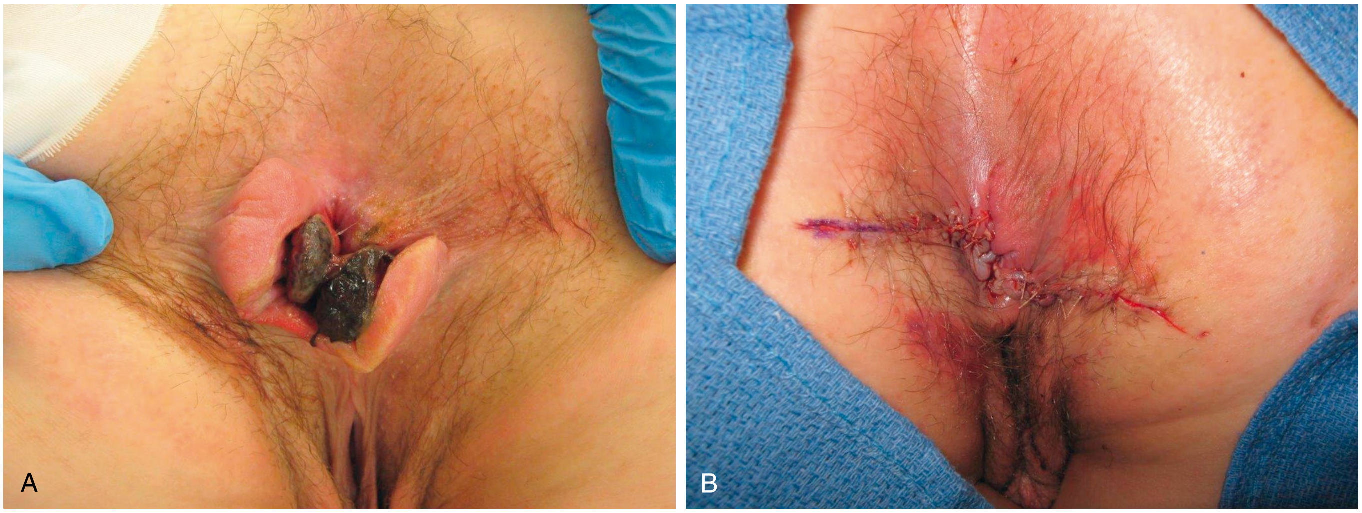

FIGURE 97.7 (A) Strangulated, fourth-degree internal hemorrhoids. (B) Perianal region after urgent excision of strangulated internal hemorrhoids.

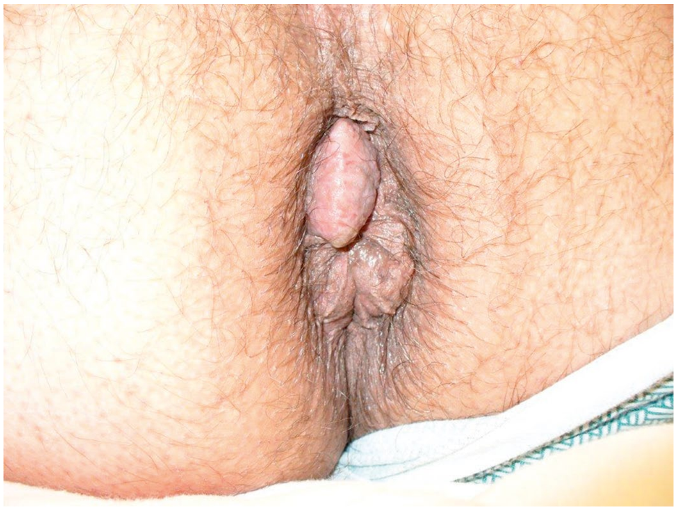

FIGURE 97.8 Thrombosed external hemorrhoid.

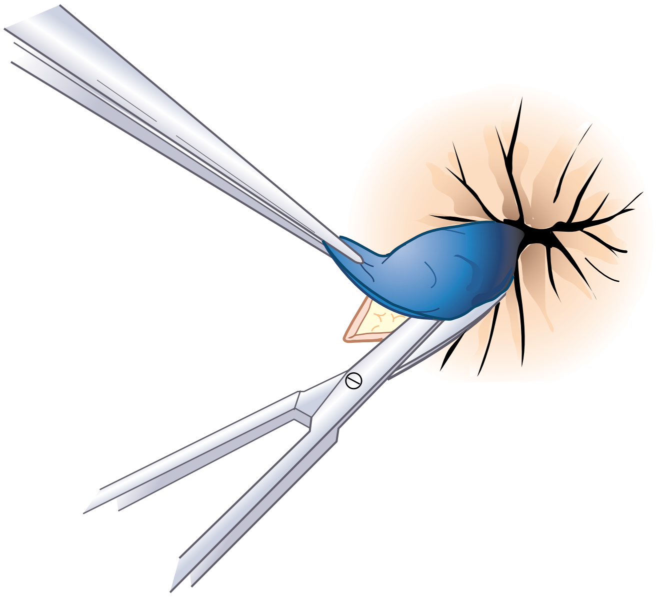

FIGURE 97.9 Excision of thrombosed hemorrhoid.

of constipation or diarrhea. Frequently, they may be associated with antecedent straining during exercise, lifting, or long-distance running. Patients with thrombosed external hemorrhoids typically present with acute onset of severe anal pain that may be exacerbated by sitting or defecation and a palpable round, firm perianal bulge (Fig. 97.8).

Most patients will experience gradual improvement of their symptoms within 48 to 72 hours after the onset with conservative measures, such as sitz baths, application of lidocaine ointment, and stool softeners. Acutely tender, thrombosed external hemorrhoids can be surgically treated when pain is excessive and/or fails to respond to expectant management. Thrombectomy with evacuation of clot is often performed in the emergency setting; however, excision of the hemorrhoid is usually a far better option because it results in faster resolution of symptoms and a greatly decreased chance of recurrence.[19] Both procedures may be readily accomplished with local anesthesia in an outpatient setting (Fig. 97.9).

Hemorrhoidal Skin Tags

Hemorrhoidal skin tags are a common complaint leading to surgical consultation. Hemorrhoidal skin tags are hypertrophied, redundant folds of skin at the anal verge that commonly occur after an underlying external hemorrhoid plexus dilates, stretching the overlying skin. These painless folds of redundant skin must be differentiated from those associated with inflammatory bowel disease or anal fissures, which are discussed elsewhere in this chapter. Although hemorrhoidal skin tags are not of any clinical significance, large skin tags may cause irritation of the perianal skin, interfere with personal hygiene, and cause the patient significant distress related to aesthetic concerns. Removal of anal skin tags can be safely and easily performed in the outpatient setting under local anesthesia. It is important to set realistic

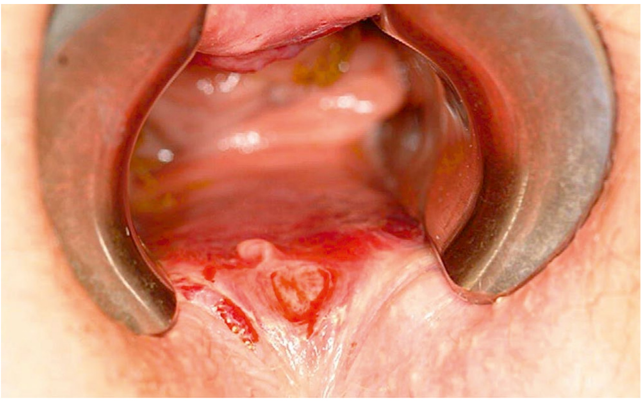

FIGURE 97.10 Acute anal fissure. (From Tiernan JP, Brown SR. Benign anal conditions: haemorrhoids, fissures, perianal abscess, fistula-in-ano and pilonidal sinus. *Surgery.* 2011;29:382-386.)

expectations in terms of postoperative pain (which can be significant) and postoperative aesthetic outcomes because the perianal skin may still not be perfectly smooth after skin tag removal and may recur.

Anal Fissure

An anal fissure is an elliptical or oval-shaped tear in the anal canal starting at the anal verge and extending proximally for a varying length toward the dentate line (Fig. 97.10). Acute fissures appear as a shallow tear in the anoderm. The most common presenting symptom is sharp anal pain with defecation, often described by patients as the feeling of passing "pieces of glass" or "razor blades." The sharp pain can be followed by throbbing and anal spasm, which can persist for minutes to hours after bowel movements. Anal bleeding is typically mild but can present as bright-red blood streaking on the stool or on the toilet paper.

Anal fissures that are present for more than 6 to 8 weeks are considered chronic. Features of a chronic fissure include the presence of exposed internal sphincter fibers at the base, a hypertrophied anal papilla proximally, and a skin tag or sentinel pile distally. Pain with defecation tends to be less severe than with an acute fissure, but the symptoms are nonetheless unrelenting, and in the most severe instances, patients will dread having bowel movements and may avoid oral intake and therefore report associated weight loss.

Fissures may occur as a result of a tear caused by passage of a hard stool, episodes of diarrhea, anal receptive intercourse, or anal trauma. The pain from the fissure leads to anal sphincter spasm, which further decreases blood flow to the anal mucosa, leading to relative ischemia at the site of the fissure. The most common location of an anal fissure is the posterior midline (75%), where there is a relatively less robust blood supply. The anterior midline is also a frequent location for fissures to develop, especially in females. Anal fissures found off the midline are considered atypical, and a broader differential diagnosis should be considered, including Crohn disease, anal cancer, tuberculosis, HIV, syphilis, herpes, and leukemia.

The diagnosis of an anal fissure can often be made based on the patient's reported history alone. Gentle separation of the buttocks can reveal the fissure or the sentinel tag; however, just spreading the buttocks may cause intolerable pain, and the examination may need to be terminated at this point. If the fissure is not clearly visible, focal gentle pressure with the examiner's fingertip or a cotton-tip applicator at the posterior or anterior aspect of the anal canal can reproduce the pain. Digital and anoscopic examinations are often deferred to avoid exacerbating the patient's pain, but if the diagnosis is unclear or the patient has other symptoms concerning for malignancy, an examination under anesthesia should be performed to confirm the diagnosis.

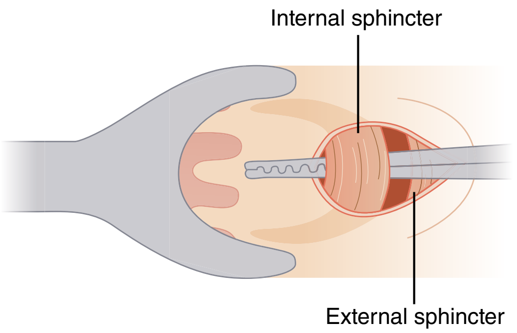
The majority of acute anal fissures resolve with medical management alone. The initial step in management should be to increase fluid and fiber ingestion in order to maintain soft, formed stools as well as sitz baths, which have been demonstrated to provide significant pain relief in over 90% of patients with acute fissures.[20]

Chronic fissures, however, are less likely to heal with exclusively conservative measures. The goals of treatment are aimed at (1) addressing the inciting factors, such as constipation or other causes of anal trauma; (2) addressing the symptoms of pain and bleeding; and (3) relaxation and dilation of the internal anal sphincter to improve blood flow and allow healing.

In addition to maintaining healthy bowel habits, topical nitrates or calcium channel blockers act to relax the internal anal sphincter and promote vasodilation, leading to improved blood flow to the anal mucosa and healing of the fissure. Topical application of nitrates is associated with healing in approximately 50% of chronic fissures, although severe headache is a common side effect that can limit efficacy and leads to cessation of therapy in up to 20% of patients.[21,22] Topical calcium channel blockers, including diltiazem and nifedipine, have demonstrated similar rates of healing chronic fissures when compared with topical nitrates with significantly better side-effect profile regarding headaches, making calcium channel blockers the preferred first-line topical agent.[23] Obtaining topical diltiazem or nifedipine can be challenging, however, because there is no readily available commercial formulation in the United States, and creams or ointments must be sought from specialized compounding pharmacies.

Botulinum toxin (BT) can produce potent and sustained relaxation of the anal sphincter by inducing temporary paralysis of the anal sphincter muscle. BT has similar results compared with topical therapies as first-line therapy for chronic anal fissures and modest improvement in healing rates as second-line therapy after failed treatment with topical therapies.[24] A typical dose of 20 to 100 IU of BT will produce relaxation lasting approximately 3 months. Injection can be done safely in the office or may be performed as an outpatient procedure with sedation. The most common side effects of BT injection are temporary incontinence to flatus. Other side effects include increased urinary residual volume, heart block, skin irritation, and allergic reactions.

A limited, lateral internal sphincterotomy (LIS) induces sustained partial relaxation of the internal anal sphincter and reduces anal sphincter tone, enabling healing of the anal fissure. LIS has shown to be superior to topical nitrates, calcium channel blockers, or BT, with healing rates of 88% to 100%. Reported rates of fecal incontinence after LIS rates range from 8% to 30%, usually limited to minor episodes of incontinence to flatus, most often in the first 30 days after the procedure. LIS is considered the treatment of choice for chronic anal fissure, although care should be taken to identify those patients at higher risk for postoperative fecal incontinence, in whom this procedure should be avoided, including patients with baseline incontinence, females with prior obstetrical injuries, patients who have undergone



Internal sphincter
External sphincter

FIGURE 97.11 Open lateral internal sphincterotomy.

previous anorectal operations, and patients with a documented anal sphincter injury.[24]

LIS can be performed using either an open or a closed technique, with similar results. In the open technique, a radial incision in the anoderm exposes the distal internal sphincter muscle fibers (Fig. 97.11). The distal segment of the internal anal sphincter muscle is divided sharply for the length corresponding to that of the anal fissure. The wound can be left open or closed primarily. A closed LIS can be performed by inserting a narrow-bladed scalpel directly into the intersphincteric groove and dividing a length of the distal internal sphincter corresponding to the length of the fissure laterally to medially toward the surgeon's finger within the anal canal (Fig. 97.12).

Abscess/Fistula

Cryptoglandular Abscesses

The majority of perianal abscesses form as a result of infection arising in anal glands emptying in the crypts at the dentate line, so-called cryptoglandular abscesses. These infections are caused by obstruction of the draining duct by fecal debris, leading to stasis, bacterial overgrowth, and, ultimately, abscesses that expand first into the intersphincteric space.[25] These abscesses commonly expand by caudal extension to the anoderm (perianal abscess) or across the external sphincter into the ischiorectal fossa (ischiorectal abscess). Abscesses that develop in the posterior midline may expand into the deep postanal space, which is a potential space located superficial to the levator muscles but deep to the anococcygeal ligament. The deep postanal space is in direct continuity with the bilateral ischiorectal fossae, and lateral spread of infection in the deep postanal space commonly leads to the formation of a "horseshoe" ischiorectal abscesses. Less common routes of spread are cephalad along the intersphincteric space into supralevator space or within the submucosal plane (Fig. 97.13). Approximately 10% of perianal and perirectal abscesses occur as a result of other etiologies, such as Crohn disease, trauma, HIV, STIs, radiation therapy, or foreign body (Box 97.1).

A patient presenting with a cryptoglandular abscess typically presents with the indolent onset of a constant, throbbing anal pain associated with localized swelling, erythema, and fluctuance. Larger perianal abscesses or delayed presentation can lead to systemic signs and symptoms of infection in some patients, although this is less common. Perianal abscesses can be differentiated from other causes of acute anal pain, such as anal fissure and thrombosed external

hemorrhoid, by history and gentle examination. Thorough digital rectal examination or anoscopic examination is often deferred in the acute setting because of pain. A common error is diagnosing "cellulitis" when patients present with pain, erythema, and tenderness but are not found to have fluctuance. Many of these patients simply have a deeper abscess, making the need for drainage even more compelling; antibiotics alone in this situation will usually be insufficient. Routine use of diagnostic imaging is not typically necessary for patients with anorectal abscesses, but CT of the pelvis can be helpful if the diagnosis is in question (Fig. 97.14).

Perianal abscesses should be treated promptly by incision and drainage.[26] This can be done either in an ambulatory setting under local anesthesia or in the operating room as appropriate. The drainage should be performed starting at the most fluctuant aspect of the abscess, staying as close to the anus as possible to shorten the length of any subsequent fistula tract. The size of the incision should be tailored to the size of the abscess and large enough to ensure adequate drainage. This is accomplished by probing the cavity with the examining finger or an instrument to assess its extent. A cruciate incision with subsequent removal of the corners is a reliable way to ensure ongoing drainage and prevent premature closure of the skin and recurrent abscess accumulation. Loculations within the abscess cavity may be carefully broken up to achieve adequate drainage of the entire cavity. The practice of aggressive digital disruption of loculations, however, should be avoided because this maneuver may cause injury to the sphincter complex or pudendal nerve as well as cause hemorrhage from bridging vessels in the ischiorectal space. If the abscess cavity is larger than 5 cm, one may consider placing counter incisions and bridge them with Penrose drains or vessel loops. This technique avoids large, gaping perineal wounds that may result in prolonged healing, scarring, and distortion of the perianal anatomy. For a deeper abscess cavity, a drainage catheter (e.g., Pezzer or Malecot) can be left in place for several days to weeks until the abscess resolves and then is removed in the outpatient setting.

For those patients presenting with abscesses that do not have obvious external fluctuance, external drainage should be avoided to prevent the iatrogenic creation of a fistula. Low-lying intersphincteric abscesses should be drained through the intersphincteric groove or into the anal canal via an incision of the internal sphincter. Supralevator abscesses originating from the complicated extension of an intersphincteric abscess should also be drained internally by incising the rectal wall.

Horseshoe abscesses can also be challenging to manage. As described previously, these abscesses typically arise from a source at the posterior midline and track in the deep postanal space, extending laterally into one or bilateral ischiorectal spaces, so effective drainage of both the deep postanal space and one or both of the ischiorectal spaces is necessary. A modified Hanley technique involves posterior midline drainage of the deep postanal space by incising the anococcygeal ligament as well as seton placement after identification of a posterior midline fistula tract. Counterincisions are also made to effectively drain the bilateral ischiorectal spaces. Commonly, additional Penrose drains are placed between the posterior midline incision and each of the anterior-lateral counter incisions.

Packing of the abscess cavity is not necessary but can be helpful in selected patients to provide hemostasis of the inflamed, hypervascular tissue. Any packing should be removed when hemostasis is confirmed, when soiled or saturated, when the patient is urinating/defecating or bathing/showering, or the following day. A well-drained abscess cavity does not require wet-to-dry dressing changes or packing to achieve debridement and prevent premature closure of the skin. Packing can be very challenging and uncomfortable for the patient, and patients can unwittingly retain the packing in the abscess cavity for days or weeks, despite being instructed to remove it. Packing does not reduce the risk of abscess recurrence or fistula formation.

A well-drained perirectal abscess also does not typically require treatment with antibiotics because they have not been shown to improve healing times or reduce the recurrence rates.[27] Antibiotics may be used selectively in patients whose abscesses are complicated by cellulitis or systemic illness or in patients with underlying immunosuppression.[26]

After successful drainage of the abscess, the patient should experience immediate improvement in pain. The patient may be instructed to perform warm sitz baths, use bulk-forming fiber supplements, and use multimodal analgesia with sparing narcotic medications only for breakthrough pain. Minor bleeding is common and usually subsides within a few days, but ongoing drainage of serosanguinous fluid is to be expected to continue for 1 to 2 weeks as the cavity heals, with most wounds healing completely within 6 to 8 weeks (depending on the size of the wound). Close surgical follow-up is recommended until complete healing because incomplete healing or a recurrent abscess suggests a persistent underlying fistula-in-ano.

Fistula-in-Ano

Fistula-in-ano results from persistent communication between the inciting cryptoglandular complex in the anal canal (internal opening) and perianal skin (external opening) after spontaneous or surgical drainage of a perianal abscess. Approximately 50% of patients with a history of perianal abscess will ultimately develop fistulae. Patients with fistulae often report chronic drainage or a cyclical pattern of pain and swelling, followed by drainage associated with relief of the symptoms. Physical examination usually identifies one or more chronic wounds with or without granulation tissue. Bilateral external openings should trigger a suspicion for a fistula involving the deep postanal space, and multiple external openings, or a so-called "watering can perineum," should trigger suspicion of perianal Crohn disease. Occasionally, the external opening may be subtle or located at a considerable distance from the anus. Careful inspection of the perianal region with gentle palpation searching for a cordlike subcutaneous structure can help to identify the course of the fistula track. The patient can often assist with identification of the fistula opening by pointing to the location of recurrent pain and drainage. If the course of the fistulous track remains unclear, a pelvic MRI with anal fistula protocol can be useful to delineate the anatomy of the fistula tracks (Fig. 97.15).

Fistula-in-ano can be classified as superficial/subcutaneous, intersphincteric, transsphincteric, suprasphincteric, and extrasphincteric based on the Parks classification (Fig. 97.16). The goals for treatment of an anal fistula are to (1) treat any undrained infection, (2) define fistula anatomy, (3) remove or ablate epithelialized tracts, (4) avoid or minimize the risk of fecal incontinence, and (5) prevent recurrence.

Surgical treatment of fistula-in-ano carries a high risk of impaired continence; however, there is not a perfect linear relationship

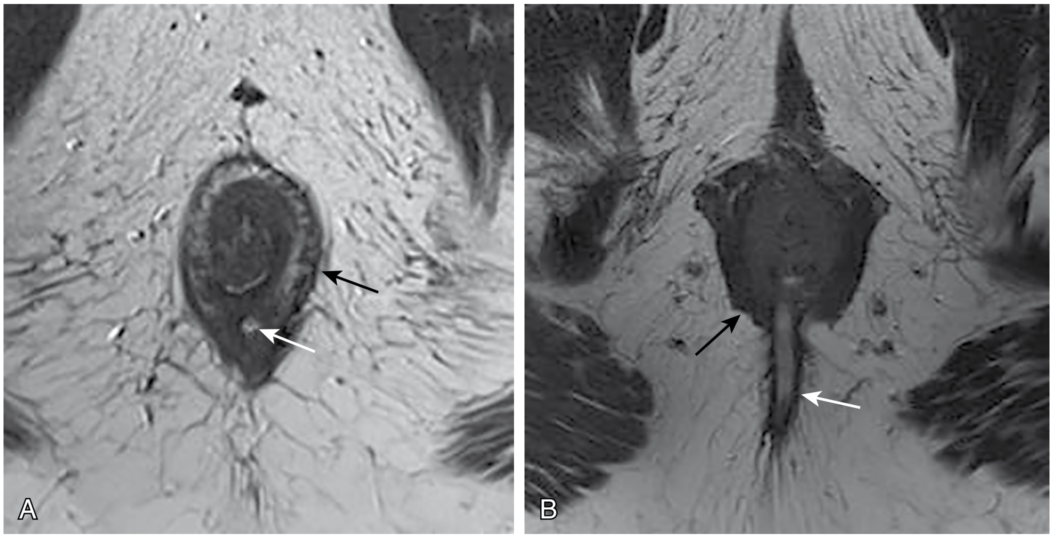

FIGURE 97.15 Anal fistula MRI. (A) Axial T2-weighted scan in a patient with an intersphincteric fistula *(white arrow).* The fistula lies within the intersphincteric plane. The lateral margin of the external sphincter *(black arrow)* is appreciated easily on MRI. (B) Axial T2-weighted scan in a patient with a transsphincteric fistula *(white arrow).* The fistula track clearly lies lateral to the external sphincter boundary *(black arrow)* and penetrates the sphincter to reach a posterior internal opening at 6 o'clock, at dentate-line level. (From Halligan S. Magnetic resonance imaging of fistula-in-ano. *Magn Reson Imaging Clin N Am.* 2020;28[1]:141-151.)

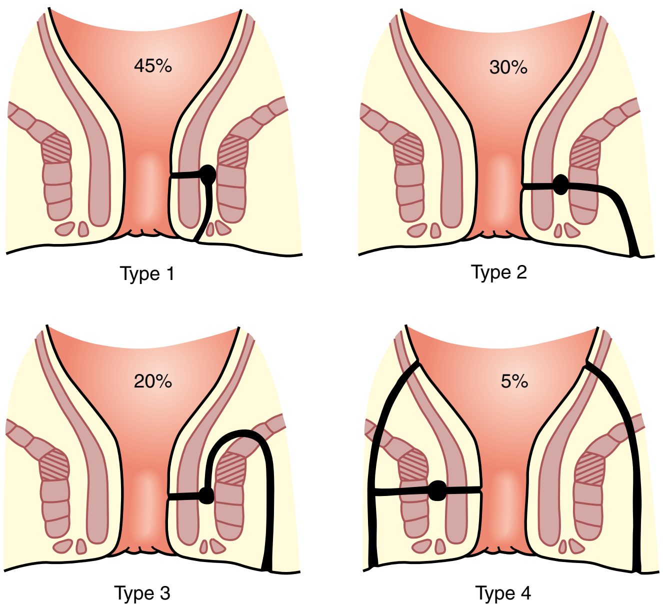

FIGURE 97.16 Park classification of fistula-in-ano: *type 1,* intersphincteric; *type 2,* transsphincteric; *type 3,* suprasphincteric; and *type 4,* extrasphincteric.

between the extent of operative intervention and continence impairment, with some patients reporting no or minimal incontinence despite division of a significant portion of sphincter muscle and some patients reporting significant incontinence despite division of no or minimal sphincter muscle.[28] Preoperative planning should consider preexisting continence, stool consistency, history of sphincter injury or surgery, the amount of sphincter that is likely to be divided, anterior location in females, and the patient's attitude toward potential imperfections in continence.

Intraoperative evaluation begins with identification of the fistula tracks. Goodsall's rule predicts the course of the fistula tract and the location of the internal opening (Fig. 97.17). Fistulas with an external opening anterior to the transverse bisection of the anus typically track in a radial fashion directly into the anal canal, except for those located at a distance greater than 3 cm from the anal verge, which may be an anterior extension of a horseshoe fistula originating posteriorly. Fistulas with an external opening posterior to the transverse bisection of the anus often track in a curvilinear fashion to a posterior midline internal opening.

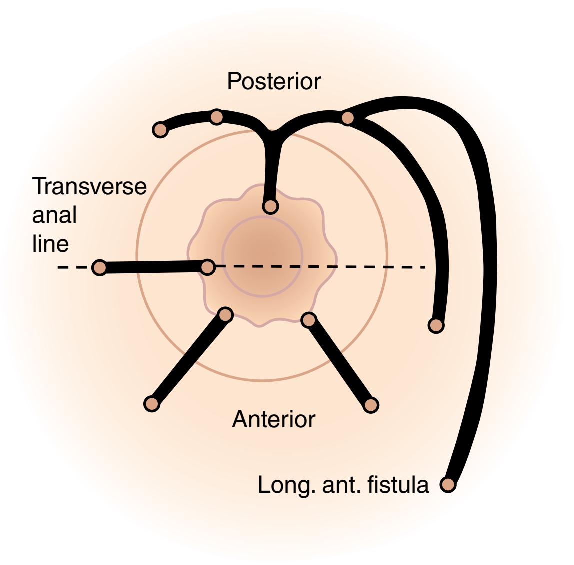

FIGURE 97.17 Goodsall rule of fistula-in-ano tracks extension.

Anoscopy allows direct inspection of the dentate line and may reveal an erythematous crypt or a visible internal opening. Gentle pressure on the skin over the fistula tract may induce drainage from the offending crypt. In the operating room, an anal fistula probe may be passed gently through the external opening into the fistula tract and through the internal opening to demonstrate the anatomy. If the probe does not pass easily, extreme care should be taken to avoid creating a false passage and creating an iatrogenic fistula. The external opening can also be injected with dilute hydrogen peroxide, methylene blue, or milk when identification of the internal opening of the fistula in the anal canal is challenging. The anorectal mucosa should be evaluated to exclude a different origin of the perianal sepsis, such as Crohn disease, atypical ulcers, or cancer.

Simple, low-lying fistulae, commonly defined as those involving less than one-third of the external anal sphincter (intersphincteric or low transsphincteric), may be treated by lay-open fistulotomy (Fig. 97.18).[26] Multiple prospective, multicenter studies have shown that clinically significant fecal incontinence after simple fistulotomy in low-lying fistulae occurs in less than 5% of patients with normal preoperative sphincter function.[29–31] The recurrence rate for treatment of simple anal fistulas with fistulotomy is 2% to 8%.[28,32,33]

For patients in whom a fistula is diagnosed at the time of abscess drainage, primary fistulotomy remains controversial. Although fistulotomy would effectively address the offending crypt and decrease the risk of abscess recurrence and chronic fistula formation, inflammation and edema can make it difficult to accurately assess the anatomy, potentially leading to an underestimation of sphincter involvement.

In fistulas involving larger amounts of sphincter muscle, and in those patients in whom the degree of sphincter involvement cannot be accurately determined because of inflammation, the initial treatment is often focused on controlling the fistula with a draining seton using a silastic vessel loop or a rubber band (Fig. 97.19). This allows for formation of a narrow fistula tract and prevents the recurrent cyclical symptoms of swelling, pain, and drainage from closure of the external opening. This also affords the opportunity to "shorten" a fistula tract by performing a partial fistulotomy through soft tissue, up to the external sphincter. A seton can also be progressively tightened and used in a cutting manner, enabling a slow, controlled division of the fistula tract; alternatively, the cutting seton may shorten the tract over time and allow for a safe lay-open fistulotomy of a more superficial fistula. For a cutting seton to work, the epithelium along the fistula must be divided. Cutting setons should be used with caution because the incidence of incontinence approaches that of lay-open fistulotomy of the tract.[34,35]

The preferred treatment of anal fistulas would ideally result in obliteration of the internal opening and all associated tracts without the need to divide any of the sphincter muscle. Several techniques have been developed in the hopes of achieving this goal, but none has proven to provide a universally reliable cure. The fistula track may be plugged with a bioresorbable substance or filled with a fibrin glue that obliterates the tract and theoretically provides a scaffold on which native tissue can deposit collagen and

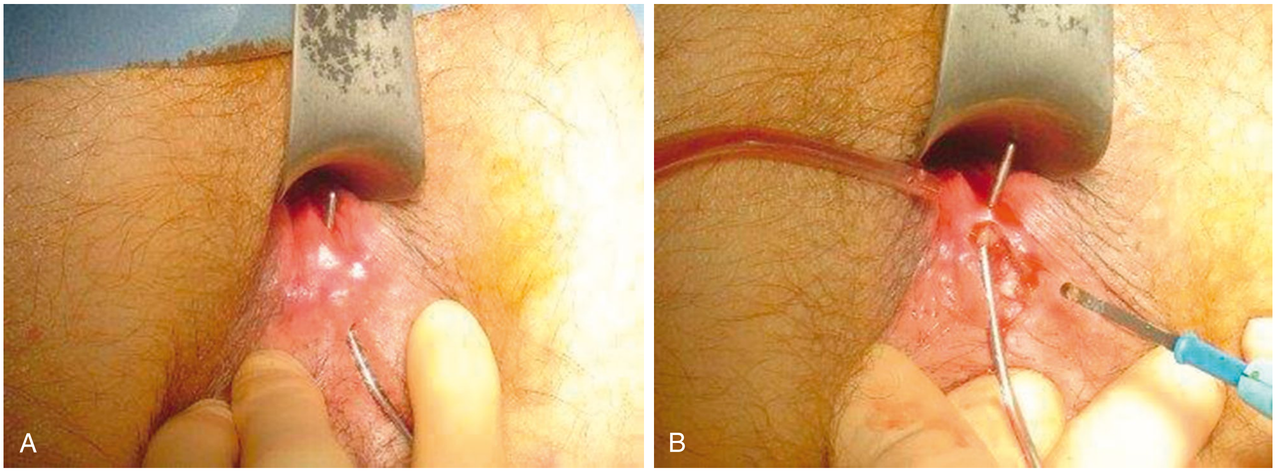

FIGURE 97.18 Lay-open fistulotomy. (A) Fistula probe inserted through the fistula track. (B) Incision over the fistula probe to lay open the fistula track.

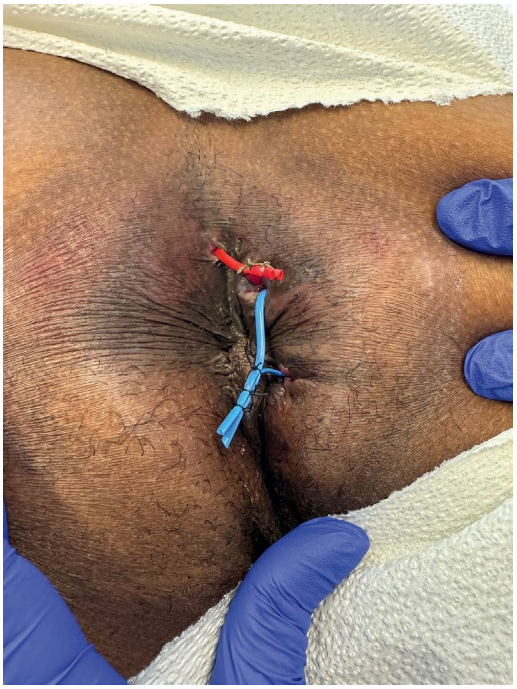

FIGURE 97.19 Seton.

seal the fistula tract. These devices have not been demonstrated to achieve long-term success. Ligation of the intersphincteric fistula tract (LIFT) involves accessing the fistula tract through the intersphincteric plane and ligating/interrupting the fistula tract.[36] Failure of this procedure may favorably result in an intersphincteric fistula that is then amenable to fistulotomy (Fig. 97.20). Endorectal advancement flaps have also been shown to effectively treat cryptoglandular fistula-in-ano, with healing rates between 66% and 87%.[37–39] This repair is often used to treat transsphincteric fistulae. This repair involves excision of the fistula tract and closure of the rectal portion of the fistula with a vascularized mucosal flap from proximal in the rectum (Fig. 97.21). The classic description involves raising a flap containing mucosa and submucosa off the internal sphincter muscle; some surgeons advocate including internal anal sphincter fibers to create a more robust flap and preserve the blood supply, although this approach has been shown to increase rates of mild to moderate incontinence with concomitant decreased manometric resting and squeeze pressures in up to 35% of patients.[40–43]

In recent years there has been significant interest, although scarce robust data, in several minimally invasive approaches to treat fistula-in-ano. Video-assisted anal fistula treatment (VAAFT) uses a specially designed fistulascope that is inserted into the external fistula opening to precisely define the fistula tract and identify any branches. Once precisely identified, the internal opening is closed with suture ligation or stapling. Granulation tissue in the tract is debrided, an electrode is introduced via a working channel in the endoscope, and the fistula tract is ablated under direct vision without dividing any sphincter muscle. The technique has demonstrated encouraging short-term results, with reported healing rates after VAAFT ranging from 71% to 85% and minor or no fecal incontinence reported at a follow-up of up to 2 year.[44–46] The fistula laser closure (FiLaC) uses a conceptually similar technique of ablating the fistula tract along its length from the inside using a radially emitting laser probe rather than an electrode. A recent metanalysis demonstrated similarly promising short-term results, with healing in 65% of patients at a median of 24 months of follow-up.[47] Transplantation of mesenchymal stem cells into the tissue surrounding complex perianal fistulae has shown promising results in small, single-institution studies and is now being investigated with various types of stem cells in randomized control trials by several groups worldwide.[48]

Rectovaginal Fistula

An RVF is an abnormal epithelial-lined communication between the rectum and vagina. Although a misnomer, this term is also often used to encompass what are (and more commonly) anovaginal fistulae as well. The spectrum of presentation is broad, from occasional passage of flatus to continuous drainage of stool through the (sphincterless) vagina, which may cause marked skin irritation and embarrassing symptoms. Anovaginal fistulas may be caused by cryptoglandular anorectal abscesses or Bartholin gland infections that spontaneously drain through the rectovaginal septum, causing a low fistula. Fistulae may also develop as a result of postoperative infections after anorectal surgery. Most commonly, anovaginal fistulae develop after obstetric injuries or postpartum as a result of prolonged labor with necrosis of the rectovaginal septum, traumatic injury from instrumented delivery, third- or

fourth-degree perineal tear, or episiotomy after breakdown of the repair.[49,50]

For RVFs caused by benign disease, especially those related to obstetric injuries, nonoperative management for a period of 3 to 6 months can be considered because spontaneous healing rates ranging from 52% to 65% have been reported.[51,52] Nonoperative management frequently focuses on treating any associated infection or inflammation to optimize healing conditions and includes sitz baths, local wound care, and stool-bulking fiber supplements.[53] For fistulae with significant inflammation or troubling symptoms, draining seton, antibiotics, or fecal diversion may be necessary.

Endorectal advancement flap, as described earlier, is the most common treatment of choice for most anovaginal fistulae, with success rates ranging from 41% to 78%. This procedure is well tolerated by patients and can be repeated if the initial repair is unsuccessful. A diverting stoma is not necessary before performing endorectal advancement flap because it has not been shown to significantly improve outcomes.[26] Nevertheless, it is sometimes considered to address intolerable symptoms or after failed prior attempts at repair. Anovaginal fistulae with a concomitant sphincter defect may be treated with perineal repair with overlapping sphincteroplasty or levatorplasty. Tissue transposition repair adds healthy, well-perfused tissue between the vagina and the anus, increasing the distance and adding new blood supply. The tissue used for interposition is most commonly the gracilis muscle or the bulbocavernosus and labial fat pad (Martius flap).

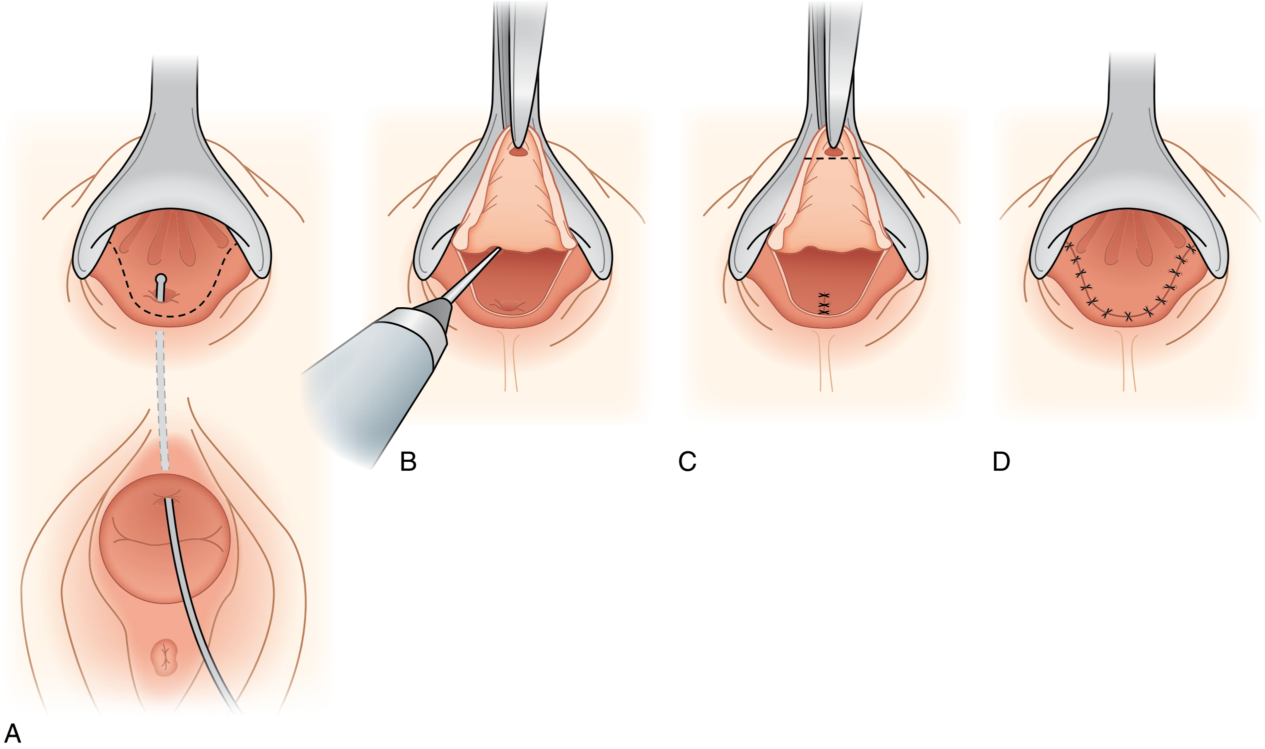

FIGURE 97.21 Mucosal advancement flap for repair of a rectovaginal fistula. (A) Fistula probe inserted to identify fistula track. (B) Broad-based flap is raised. (C) Fistula opening is excised from the tip of the flap. (D) Flap is sutured in place.

Higher true RVFs involving the mid/upper rectum may result postoperatively from iatrogenic injury, such as a stapled colorectal anastomosis that incorporates the posterior vaginal wall, or may occur as a result of a colorectal anastomotic leak complicated by an abscess that drains into the vagina (or vaginal cuff after hysterectomy). Crohn disease may be associated with RVF because it may cause transmural inflammation of the anorectal wall with extension into the rectovaginal septum. Less common causes of RVFs include fecal impaction and stercoral perforation, viral and bacterial infections (in immunocompromised patients), and trauma from sexual assault. Malignancies, particularly anal cancer or rectal cancer, may present as an RVF or may develop a fistula after radiation therapy. If suspicion for an undiagnosed malignancy is present, biopsy of the fistula should be performed. Higher RVFs in the midrectum, involving the fornix of the vagina, are difficult to access via a perineal approach and require a transabdominal repair. Repair typically involves a low anterior resection of the area of the rectum involved in the fistula with a colorectal or coloanal anastomosis and primary closure of the vagina. With limited disease, some have demonstrated successful healing by excision of the fistula with placement of omentum in the rectovaginal septum.[54]

Fournier Gangrene

Severe perianal abscesses and pelvic infections, or infections of the genitourinary tract, can progress to a rare but life-threatening form of necrotizing fasciitis involving the perineal, genital, or perianal regions called *Fournier gangrene* (FG). Less commonly, FG can result from an intrabdominal infection that tracks to the perineum via the inguinal canals.[55] FG has been associated with male sex, diabetes, chronic alcohol abuse, and immunosuppression, although it can also occur in healthy patients without significant comorbidities.

FG initially starts as an area of cellulitis at the initial focus of infection in the perineum or perianal region. The local signs and symptoms may include intense pain and swelling. FG is typically associated with mixed flora, both aerobic and anaerobic. Cultures from the wounds commonly show *Klebsiella,* streptococci, staphylococci, clostridia, *Bacteroides,* and corynebacteria. Crepitus of the inflamed tissues is a common feature because of the presence of gas-forming organisms. Bacterial infection results in microthrombosis of the small subcutaneous vessels, leading to tissue necrosis.

Necrotic patches appear in the overlying skin and progress to more extensive necrosis; purple/black bullae are classically described in FG and other necrotizing infections (Fig. 97.22). The patient is likely to demonstrate signs of severe systemic illness, which are commonly out of proportion to the visible local extent of the disease because the disease progresses deep along the fascial planes. Laboratory values generally demonstrate nonspecific findings of elevated inflammatory markers, making individual lab values largely unhelpful in distinguishing between necrotizing soft tissue infections, such FG, and severe cellulitis. The Laboratory Risk Indicator for Necrotizing Infection (LRINEC) score has been advocated as a clinical tool that can help determine which patients require further diagnostic testing. The scoring system assigns points for abnormalities in six common laboratory values: serum C-reactive protein level (>150 mg/L), white blood cell (WBC) count ($>15{,}000/\mu L$), hemoglobin level (<13.5 g/dL), serum sodium level (<135 mmol/L), serum creatinine level (>1.6 mg/dL), and serum glucose level (>180 mg/dL). A score of 6 points or higher has been shown to have a positive predictive

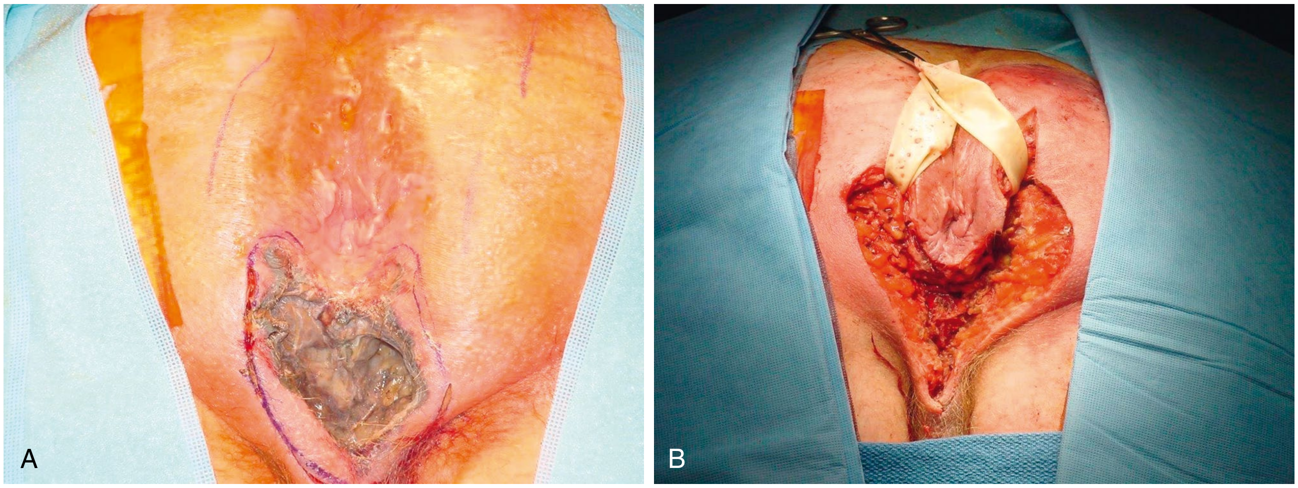

FIGURE 97.22 (A) Fournier gangrene. (B) Perineum after excision of Fournier gangrene.

value of 92% and a negative predictive value of 96% for the presence of a necrotizing infection (Table 97.2).[56,57]

FG is a surgical emergency. It is rapidly progressive and quickly leads to sepsis, potentially with multiple organ failure and even death. Spread of infection occurs along the fascial planes and is usually far more extensive than initially anticipated based on external appearance. Necrotizing fasciitis can extend to involve the scrotum and penis and can spread through the anterior abdominal wall and up all the way to the clavicles.[58] Urogenital infections tend to extend posteriorly along Bucks and Dartos fascia up to the Colles fascia but are often limited from the anal margin by the attachment of the Colles fascia to the perineal body. In contrast, anorectal sources of infection usually involve the perianal skin. The location and the spread of infection can serve as a guide to identifying the initial focus of infection. Regardless of the cause of FG, the testes are usually spared because the blood supply originates intraabdominally.

TABLE 97.2 LRINEC Score

SCORE MARKER	LEVELS	SCORING
C-reactive protein	<150 mg/L	0
	>150 mg/L	4
White blood cells	<15 per mm^3	0
	15–25 per mm	1
	>25 per mm^3	2
Hemoglobin	>13.5 g/dL	0
	11–13.5 g/dL	1
	<11 g/dL	2
Sodium	>135	0
	<135	2
Creatinine	<1.6 mg/dL	0
	>1.6 mg/dL	2
Serum glucose	<180 mg/dL	0
	>180 mg/dL	1
STAGE	**SCORE**	**PROBABILITY OF NECROTIZING FASCIITIS (%)**
Low	<5	50
Moderate	6–7	50–75
High	>8	>75

LRINEC, Laboratory Risk Indicator for Necrotizing Infection.

Treatment of FG requires an aggressive multimodal approach, including hemodynamic stabilization, fluid resuscitation, and broad-spectrum antibiotics; the cornerstone of management, however, is early aggressive surgical debridement. Unnecessary delay in surgical debridement has a negative impact on prognosis. All nonviable and necrotic tissue must be excised until well-perfused, healthy tissue is reached. As noted earlier, the full extent of the disease may be far greater than estimated by the areas of cutaneous involvement. Urinary or fecal diversion may be necessary depending on the location and degree of tissue loss but is seldom necessary at the initial debridement. Multiple trips to the operating room are typically required, with an average of three to four procedures before complete debridement can be achieved. After controlling the infection and preserving healthy viable tissue, healing may be a prolonged course. The use of vacuum-assisted closure systems dressings has markedly improved wound care in these patients and accelerates wound healing. Split-thickness skin grafts can be used to provide coverage of the perineal and scrotal skin defects. Long-term, more extensive tissue coverage techniques may be necessary for reconstruction.

Sexually Transmitted Infections

Anorectal STIs may be transmitted by anoreceptive intercourse, oroanal sexual contact, contiguous spread from a genital infection, or any skin-to-skin contact. Symptoms of STIs are often nonspecific and latent, with some infected (and transmitting) individuals being completely asymptomatic. Complaints may include anal pain, tenesmus, urgency, purulent/mucus drainage, and bleeding. When evaluating a patient with an anorectal complaint, it is important to keep the diagnosis of STI in the differential when abnormalities such as ulcerations, vegetations, and proctitis are seen on examination (Table 97.3).

Human Papillomavirus/Condyloma Acuminata

Human papillomavirus (HPV) is the most common STI in the United States, with 5.5 million new infections occurring every year. The classic lesion is the condyloma acuminatum or anal wart. Serotypes 6 and 11 are found in benign warts, whereas serotypes 16 and 18 are more commonly seen in dysplasia and malignancies, as discussed in the chapter on anorectal malignancy (see Chapter 96).[59]

TABLE 97.3 Etiology and Symptoms of Sexually Transmitted Proctitis

SEXUALLY TRANSMITTED INFECTION	COMMON SIGNS AND SYMPTOMS
Gonorrhea	Asymptomatic. If symptoms present: pruritus ani, constipation, mucopurulent anal discharge, rectal pain, and tenesmus.
Chlamydia	Asymptomatic. If symptoms present: pruritus ani, mucous discharge, anal pain.
Chlamydia (lymphogranuloma venereum)	Generalized illness: fever and malaise. Anal symptoms: purulent or bloody discharge. Anal pain and tenesmus. May mimic inflammatory bowel disease.
Syphilis	Primary: anorectal chancre commonly asymptomatic. If symptomatic: pain or discomfort, itching, bleeding, and/or tenesmus. Secondary: ulcers and mucous patches. Perianal condylomata lata. Generalized manifestations: rash, fever, and lymphadenopathy.
Herpes simplex virus	Vesicular lesions, severe pain, and tenesmus; difficulty with bowel movements. Generalized symptoms: fever and lymphadenopathy.

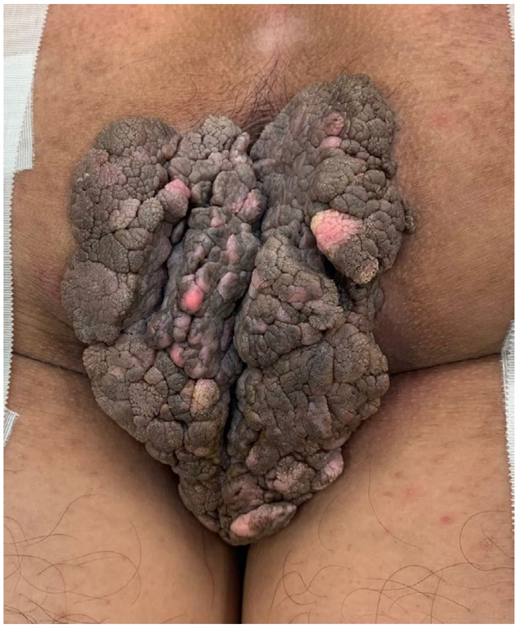

FIGURE 97.23 Buschke-Lowenstein tumor.

Anal HPV is transmitted by anoreceptive intercourse or skin-to-skin contact and may be associated with immunosuppression caused by HIV infection or immunosuppressant medications, especially in solid organ transplantation recipients. The use of condoms lowers the risk of sexual transmission, although infection can still be transmitted through the skin beyond the area covered by a condom. Lesions begin as small, raised, wartlike lesions. Other symptoms are uncommon but may develop as the lesion grows and may include anorectal bleeding or discharge, pain, and itching. Anoscopy may reveal disease present in the anal canal. An aggressive variant of HPV infection, Buschke-Lowenstein disease, results in a giant condyloma (Fig. 97.23). Anal condyloma can be treated by topical agents such as imiquimod, podophyllin, and 5-fluorouracil (5-FU) or surgical methods for excision and destruction of lesions, including tangential excision, cryotherapy, and fulguration (Fig. 97.24). Pathologic analysis of excised condyloma should be performed, especially in patients with HIV or immunosuppression, given the significant co-incidence of low-grade condyloma and high-grade squamous intraepithelial neoplasia in this population. The clearance rate after surgical removal ranges from 60% to 90%, with recurrence rates of 20% to 30%.[60] Anal HPV screening and treatment vary and are mostly extrapolated from the cervical screening guidelines. The HPV vaccine has been demonstrated to provide primary protection against the development of anal condyloma, high-risk lesions, and cervical cancer. Vaccination is recommended for patients with a history of HPV-related infections because the vaccine may protect against HPV strains that the patient has not been exposed to in the past.[61]

Herpes Simplex Virus

Herpes simplex virus (HSV) is highly prevalent in the United States. Both HSV types 1 and 2 (HSV-1 and HSV-2) may cause anogenital herpes infection. Over 90% of patients with genital herpes may be asymptomatic and unaware that they carry the virus.[62] When symptomatic, HSV proctitis is associated with anorectal pain, constipation, tenesmus, anal itching, difficulty with initiating urination, fever, and inguinal adenopathy.[63] Typical lesions are small vesicles that involve the perianal skin and anal canal but may also extend to the rectum. HSV testing can be performed with cell culture or polymerase chain reaction (PCR), although a negative result may be attributed to intermittent viral shedding. Type-specific HSV serologic assays are also available and can be used to evaluate patients with symptoms of anorectal herpes but with negative HSV cultures. Treatment is with acyclovir, famciclovir, or valacyclovir for 7 to 10 days.

Gonorrhea and Chlamydia

Anogenital gonorrhea is transmitted by anoreceptive intercourse with an infected partner. Symptoms may include pruritus ani, constipation, mucopurulent or bloody anal discharge, anal pain, and tenesmus.[64] However, 84% of asymptomatic males who engage in anal receptive intercourse are found to have rectal gonorrhea.[65] On anoscopic examination, the rectal mucosa can appear normal or erythematous and friable with pus. Nucleic acid amplification tests are the preferred testing modality and have significantly higher sensitivity and specificity than bacterial culture.[66] Given a high incidence of coinfection with chlamydia, treatment of patients testing positive for gonorrhea is directed toward both gonorrhea and chlamydia, even if chlamydia testing is negative. The recommended regimen is ceftriaxone 250 mg in a single intramuscular dose plus azithromycin 1 g orally in a single dose, or doxycycline 100 mg orally twice daily for 7 days.

Chlamydial infection can cause a mild form of proctitis, but most infections are asymptomatic. On physical examination, the rectal mucosa can range from normal appearing to erythematous and friable. Patients occasionally present with perirectal abscesses, anal fissures, and fistula formation mimicking Crohn disease. As with gonorrhea, nucleic acid amplification assays are the preferred diagnostic test. Recommended treatment is with azithromycin 1 g orally in a single dose or doxycycline 100 mg orally twice a day for 7 days.

Syphilis

Anorectal syphilis appears within 2 to 10 weeks of exposure after anal intercourse. Infections can be asymptomatic or manifest with

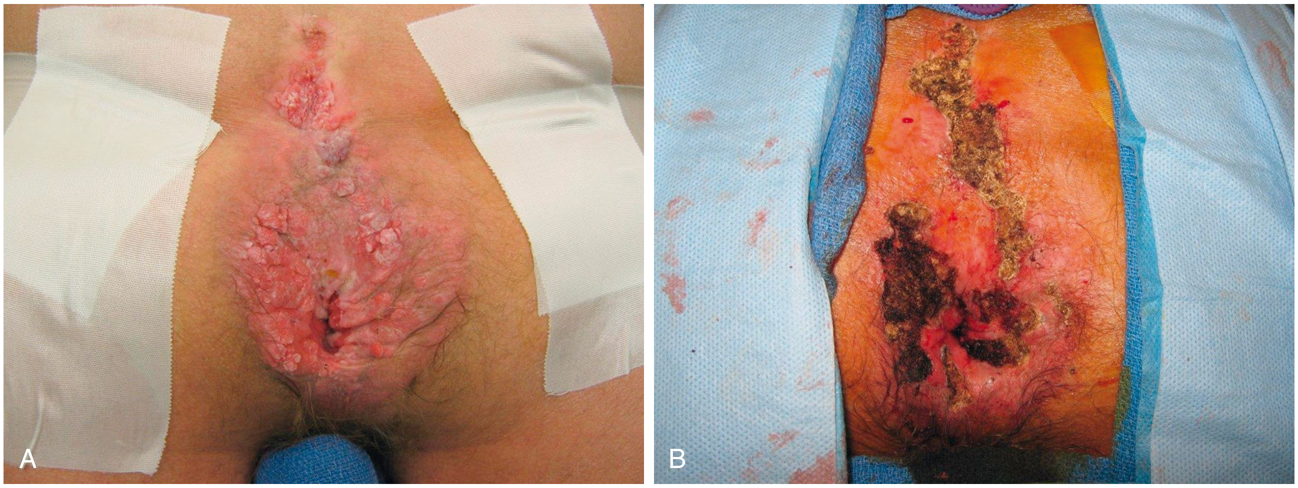

FIGURE 97.24 (A) Extensive anal condyloma. (B) Perianal region after ablation of condyloma.

proctitis, ulcers, and pseudotumors. Anal ulcers are frequently painful, in contrast to the classically described painless genital chancre. Anal lesions usually heal within several weeks, even if untreated. Secondary syphilis may present with a rectal mass, condylomata lata and mucous patches, generalized rash, fever, and lymphadenopathy. Tertiary syphilis presents many years after infection, with debilitating ulcerating gummas as well as damage to other organs and death.

Two types of serologic tests are used to make a presumptive diagnosis of syphilis. The nontreponemal tests, the Venereal Disease Research Laboratory (VDRL) and the rapid plasma reagin (RPR) tests, are used for screening because they become positive within weeks of the primary chancre. Treponemal tests include the fluorescent treponemal antibody absorbed tests, *Treponema pallidum* passive particle agglutination assay, and other immunoassays. These tests usually remain reactive for life in patients who have had a reactive test. Patients with a positive nontreponemal test should undergo a confirmatory treponemal test.

Primary or secondary syphilis is treated with benzathine penicillin G 2.4 million units intramuscularly in a single dose. Doxycycline or tetracycline can be used in patients who have a penicillin allergy.

Human Immunodeficiency Virus

Patients with an STI should be recommended to undergo testing for HIV. STI can coexist, and the immunosuppression associated with HIV can worsen or make patients more susceptible to other STIs. HIV-specific anorectal disorders include idiopathic anal ulcers that are diagnosed after ruling out other STIs and malignancy. Clinical characteristics include a broad-based appearance, localization to the posterior midline and more proximally in the anal canal, erosion into the submucosa, and sphincters with decreased anal sphincter tone. Treatment is with intralesional steroid injection and/or surgical debridement.

Pilonidal Sinus

Pilonidal disease is a common perianal/intergluteal problem affecting young people, typically in their middle to late 20s. Pilonidal disease is estimated to affect approximately 70,000 patients annually in the United States.[67] As the Latin origin of the name suggests—“hair” *(pilus)* and “nest” *(nidus)*—pilonidal disease is caused by shed hair drawn into the natal cleft as a result of the anatomy of the cleft and the motion from the buttocks. This motion creates a vacuum effect, forcing loose hair into the skin through cutaneous pits in the midline of the gluteal cleft. The presence of pits along the midline of the natal cleft and sinus openings is the hallmark finding in pilonidal disease (Fig. 97.25). Some pilonidal pits are noted incidentally without any inflammation or infection. The foreign body reaction produced by trapped hair may lead to local inflammation and may further become superinfected, leading to a hair-filled abscess cavity. The abscess can drain spontaneously through the skin at the midline or to either side of the gluteus through sinus tracts. The location of the abscess is distinctly different from a perirectal abscess,

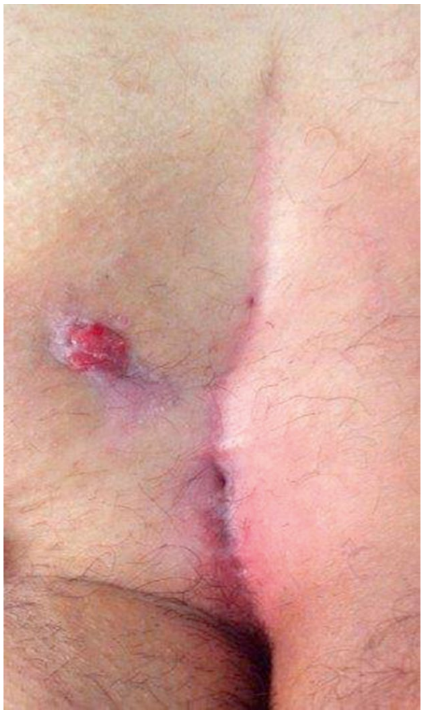

FIGURE 97.25 Pilonidal sinus. (From de Parades V, Bouchard D, Janier M, et al. Pilonidal sinus disease. *J Visc Surg*. 2013;150:237-247.)

which is typically found near the anus. Males are at higher risk because they tend to be more hirsute. Other associations with pilonidal disease are obesity, sedentary occupation, and local irritation or trauma.[67]

Treatment of pilonidal disease should be tailored to the severity of the disease. Antibiotics may be an important adjunct in surgical treatment of pilonidal disease because bacterial colonization was found to range from 50% to 70%, with typical isolates including *Staphylococcus aureus* and anaerobes such as *Bacteroides.* Acute pilonidal abscesses should be treated with incision and drainage. A lateral incision avoiding the midline should be made over the most fluctuant portion of the cavity whenever possible to facilitate the healing of the wound. The cavity should be thoroughly curetted, removing all the embedded hair and devitalized tissue. Hair removal by trimming, shaving, waxing, or laser depilation has been shown to be effective in decreasing recurrence rates.[68]

For recurrent infections or incomplete wound healing, surgical treatment may be considered. Excision of the pilonidal pits and debridement of the abscess cavity and sinus tracts is a less invasive procedure, also known as the *Gips procedure*, developed by Dr. Moshe Gips. Alternatively, the pits and the tracking sinuses may be completely excised. The cavity may then be left open to heal by secondary intention, dressed with a wound vac or negative-pressure dressing, or closed using a variety of different techniques. The importance of avoiding midline closure was popularized by Dr. John Bascom, who advocated lateral incision over the sinus cavity, together with excision of the midline pits and sinus tracts.[69] Complex, extensive pilonidal disease may require transposition of healthy, well-vascularized tissue to close the defect. Several reconstructive techniques have been proposed to cover the defect, including the Bascom cleft lift, Z-plasty, V-to-Y advancement flap, and Limberg flap (Figs. 97.26 and 97.27), note drain left to prevent postoperative seroma/hematoma. As noted, antibiotics may be an important adjunct in surgical treatment of pilonidal disease because bacterial colonization was found to range from 50% to 70%, with typical isolates including *S. aureus* and anaerobes such as *Bacteroides.*

Hidradenitis Suppurativa

Hidradenitis suppurativa (HS) is a chronic recurrent inflammatory skin disorder with chronically draining wounds and sinus tracts that can affect the hair-bearing and apocrine sweat gland–bearing areas of the axillae, perineum, groin, and inframammary regions.[70] Perineal disease is more commonly seen in males. HS typically occurs after puberty, with an incidence peaking between the second and fourth decades of life. The disease is thought to result from occlusion of the apocrine glands or the hair follicular duct. This results in stasis and dilatation of the apocrine gland, followed by bacterial superinfection. When the glands rupture into the subcutaneous space, superficial abscesses form that may lead to complex subcutaneous sinuses and draining tracks (Fig. 97.28). Long-standing inflammation may result in subcutaneous scarring, contractures, and chronic painful induration of the skin. Perianal HS may extend onto the buttocks, to the upper thighs, and medially to the anal verge. Although perianal HS should be differentiated from cryptoglandular abscess and fistula, HS may coexist with other inflammatory disorders, such as Crohn disease.[71]

The differential diagnosis may be challenging, but the distribution of disease, characteristic subcutaneous "pitlike" scarring, distorting contractures, and induration of the skin should be considered pathognomonic for advanced HS. Treatment is based on the Hurley stage of disease at presentation and ranges from medical therapy (antibiotics, antiandrogens, and immunosuppression) to more extensive excision of all affected apocrine sweat gland areas (Table 97.4).

Perianal Crohn Disease

Patients with Crohn disease can have inflammation of the distal rectum that manifests as fistula-in-ano, anal fissure, anal canal stricture, RVF, or abscess. Perianal involvement affects as many as 20% to 35% of patients with Crohn disease.[72,73] For some patients, perianal disease may be the first (or only) site of Crohn disease. The diagnosis should be considered in those patients

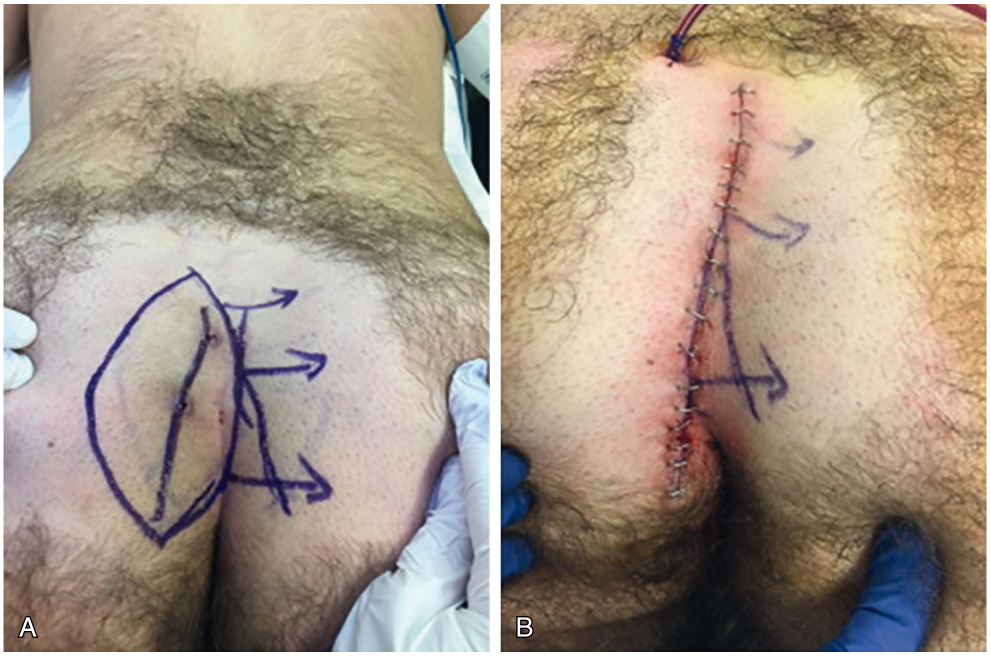

FIGURE 97.27 Bascom cleft lift. (A) The edges of the natal cleft have been marked and an "eccentric" ellipse is planned, which includes all primary midline sinuses and secondary sinuses (two are seen here to left of midline). The skin to the right is undermined in the direction of the arrows. (B) Result at completion of surgery. The ellipse has been excised, the natal cleft is flattened, and the staple line is out of the natal cleft. (From Umesh V, Sussman RH, Smith J, Whyte C. Long term outcome of the Bascom cleft lift procedure for adolescent pilonidal sinus. *J Pediatr Surg*. 2018;53[2]:295-297.)

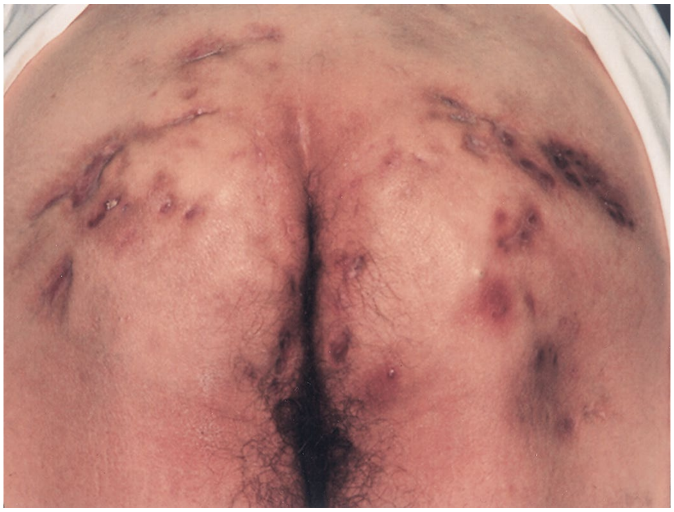

FIGURE 97.28 Hidradenitis suppurativa.

TABLE 97.4 Hurley Stage and Treatment Options

HURLEY STAGE	DISEASE DESCRIPTION	TREATMENT
I	Abscess formation without sinus tracts or scarring	• Lifestyle modifications • Topical/oral antibiotics • Intralesional steroids • Unroofing
II	Recurrent abscesses with skin tunnels and scarring, single or multiple widely separated lesions	• Oral antibiotics • Oral antiandrogenic agents • Oral retinoids • Metformin • Systemic steroids
III	Diffuse involvement or multiple interconnected skin tunnels and abscesses across the entire area	• Anti-TNF • Wide excision

TNF, Tumor necrosis factor.

who have multiple or complex fistulas, especially located bilaterally; large "elephant ear"–type skin tags; or broad-based anal fissures, especially those located off the midline (Fig. 97.29). A history of chronic diarrhea, abdominal pain, and weight loss (or delayed growth in children) should increase the level of suspicion in patients with atypical fistulas/fissures. Colonoscopy with ileal intubation should be performed for all patients presenting with perianal complaints in whom Crohn disease is suspected.

The evaluation of patients with anorectal Crohn disease should include a careful anorectal examination and may be supplemented by MRI. The priority is to address any uncontrolled infection by draining any abscess, with or without placement of draining setons. This should provide control of perineal sepsis and enable medical therapy, which is the mainstay of management in perianal Crohn disease. Medical therapy for perianal Crohn typically includes antibiotics, particularly metronidazole; immunomodulators; and biologic agents. The antitumor necrosis factor-α agents (i.e., infliximab, adalimumab, certolizumab) have been shown to be particularly effective in preventing the progression of fistulizing Crohn disease and, in select cases, may result in successful closure of the fistula tract.[73]

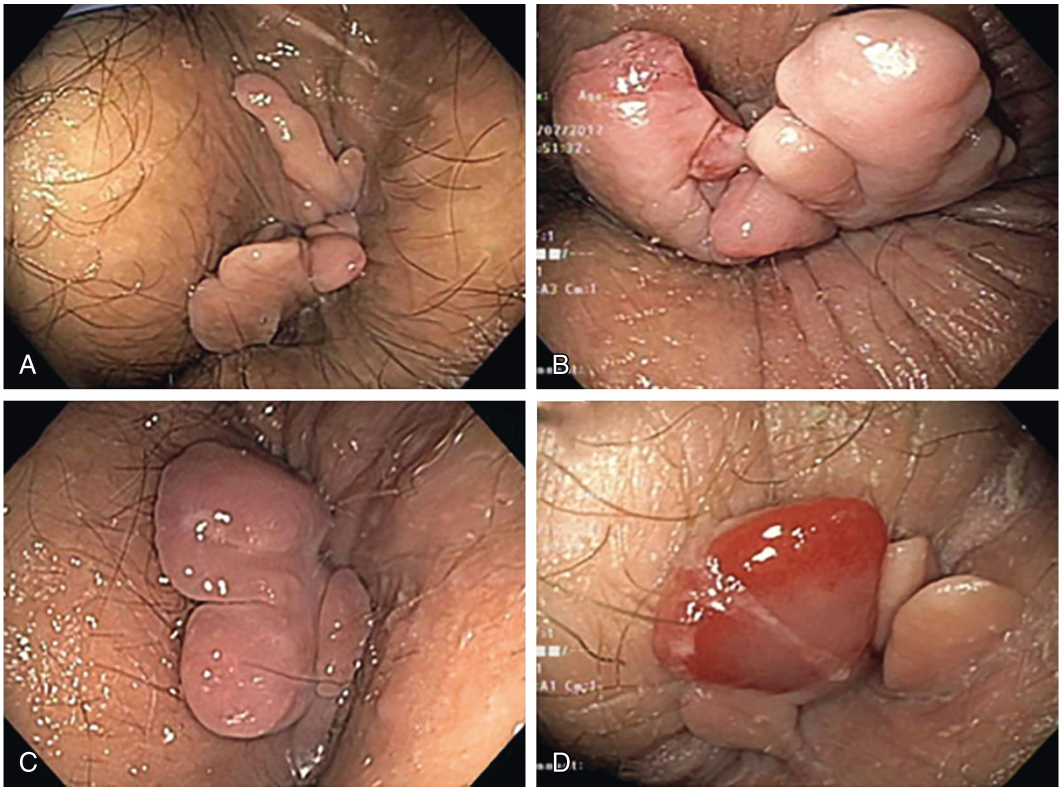

FIGURE 97.29 Crohn disease skin tags. Various forms of skin tags, mostly with an "elephant ear" appearance. (A–D) The skin tags can be single or multiple, thin or thick, flat or cylindrical. The surgical excision of Crohn disease–associated skin tags is not recommended. (From Shen B. Endoscopic evaluation of perianal Crohn's disease. In: Shen B, ed. *Atlas of Endoscopy Imaging in Inflammatory Bowel Disease*. Academic Press; 2020:77-95.)

Surgical management of perianal Crohn disease differs somewhat from the management of pathology not related to inflammatory bowel disease. Because of the risk of poor wound healing and fecal incontinence in these patients, who often suffer from frequent and loose stools, excision of asymptomatic tags and fistulotomy is typically avoided. In patients with long-standing perianal Crohn disease or unusual-appearing fistulas, strictures, or ulcerations, malignancy may develop, and biopsies should be performed. Anovaginal fistula in Crohn disease presents a particularly challenging problem and may require early fecal diversion. An attempt at endoanal mucosal advancement flap repair may be considered when the disease is well controlled and the rectal mucosa appears to be relatively healthy and is without active inflammation. Anal strictures are typically located at the top of anorectal ring and may be dilated if symptomatic. This can be done either by gentle dilation with an examining finger, self-dilation using anal dilators in an outpatient setting, or dilation under anesthesia. Patients with severe perianal disease that does not respond to optimal medical management may ultimately require proctectomy. These patients are often treated in a staged manner, starting with fecal diversion because proctectomy in the setting of significant perianal inflammation may result in a large perineal defect requiring complex reconstruction.[74]

FUNCTIONAL BOWEL AND PELVIC FLOOR DISORDERS

Fecal Incontinence

Fecal incontinence is defined as the uncontrolled passage of feces or gas for greater than 1 month's duration in an individual over 4 years old who had previously achieved control. Fecal incontinence is most common in older female patients, with a prevalence between 9% and 20% in females over the age of 45.[75,76] Obstetric injury is the most common cause of fecal incontinence.[77] Changes in rectal sensation or rectal compliance can result in urgency, diminished capacity of the rectum, and loss of fecal control. Conditions causing inflammation of the anorectum, such as inflammatory bowel disease, can result in urgency and incontinence. Medical conditions such as diabetes, diarrhea, obesity, neurologic diseases, and urinary incontinence may result in or contribute to the symptoms of fecal incontinence.[78]

A comprehensive evaluation of fecal incontinence includes a description of bowel habits, including consistency of stools and frequency of bowel movements, type of incontinence (gas, liquid stool, solid stool, urge, passive, or postdefecation), associated urgency symptoms, awareness of incontinence versus complete lack of sensation, concomitant urinary incontinence, diet, and medications (Fig. 97.30). Patient questionnaires, including the Cleveland Clinic Fecal Incontinence Score and the Fecal Incontinence Severity Index, can help better assess the nature and severity of patient symptoms and can help quantify the response to therapy.[79,80] Patients should be asked about prior anal surgery, anal trauma or sexual instrumentation, obstetric history, prior radiation therapy, and systemic conditions such as diabetes and neurologic diseases. Colorectal cancer must be ruled out in those individuals with a recent change in bowel habits, particularly when blood per rectum is present.

The physical examination should focus on the perineum and perianal region, evaluating for normal musculature, bulk of the

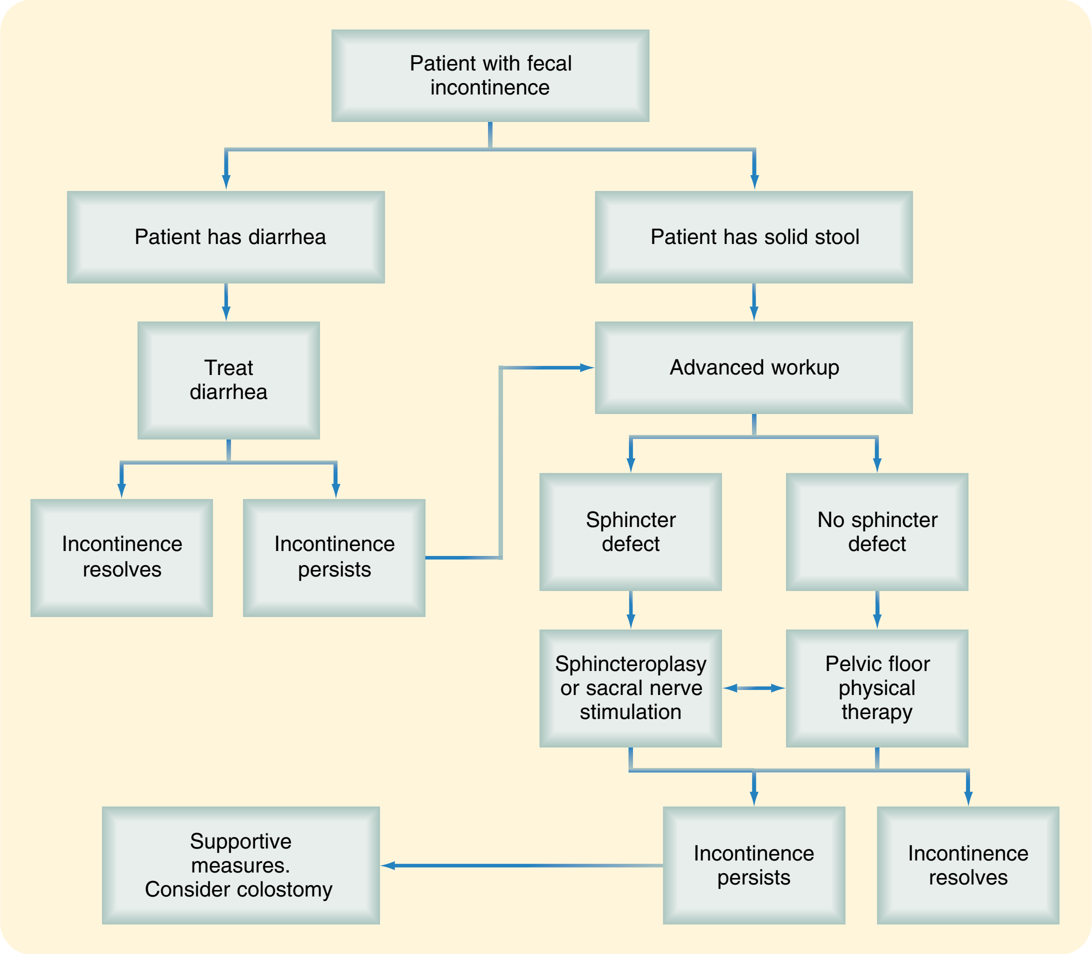

FIGURE 97.30 Evaluation and management of fecal incontinence.

perineal body, the perianal skin, and presence of any prolapsing tissue from the anus. Digital rectal examination may identify fecal impaction and the consistency of the stool and also evaluates resting tone of the anal canal and strength of the squeeze.

Pelvic floor physiologic testing, including anal manometry, anorectal sensation testing, rectal volume tolerance, and compliance testing, can be very helpful in patients when medical management has failed and in those being considered for surgical intervention. Endoanal ultrasound can also be useful to evaluate sphincter anatomy if there is a suspected sphincter injury.

Initial management is typically focused on dietary modification and fiber supplementation, which is used to bulk and firm stool consistency. Medical therapy may include antidiarrheal agents, such as loperamide, which can slow down transit time and decrease the frequency of loose stools. Biofeedback training performed by a pelvic floor physiotherapist is a noninvasive treatment option for patients who have not had sufficient improvement with diet modification and medical therapy. The goals of a comprehensive biofeedback program are to improve sensation, coordination, and strength and provide supportive counseling and practical advice regarding diet, bowel habits, behavior modification, and skin care.[81,82]

Surgical intervention is usually reserved for highly selected patients in whom conservative management has failed. Anal sphincter repair can be beneficial in patients with anal sphincter disruption secondary to traumatic childbirth or prior anal surgery (Fig. 97.31). Although most patients report improvement in continence shortly after surgery, continence may deteriorate again over time. Sacral nerve stimulation has changed the paradigm for the treatment of fecal incontinence and is largely considered a first-line treatment in those patients who have not responded to conservative therapy; although the mechanism of action is not entirely clear, patients report fewer episodes of incontinence and decreased urgency.

Placement of sacral nerve stimulators is generally performed in two stages. The first stage involves placement of an electrode into either the right or left S3 sacral foramen via a posterior approach under fluoroscopic guidance. Adequate placement is confirmed by measuring electrical impedance and observation of robust motor response to stimulation, including dorsiflexion of the ipsilateral great toe and contraction of the perineum and anus, called the *bellows reflex*. The electrode is then connected to an external pulse generator, which is worn externally for a trial period of 7 to 14 days. If a patient experiences at least 50% improvement in fecal incontinence episodes during this trial period, the second stage exchanges the external pulse generator for an internal pulse generator, which is implanted in a subcutaneous pocket in the gluteus. Complications of sacral nerve stimulation include pain, infection, seroma formation, bleeding, and scarring. When alternative therapies are not appropriate or have failed, a colostomy may allow patients with fecal incontinence to resume normal activities and improve their quality of life.[83,84]

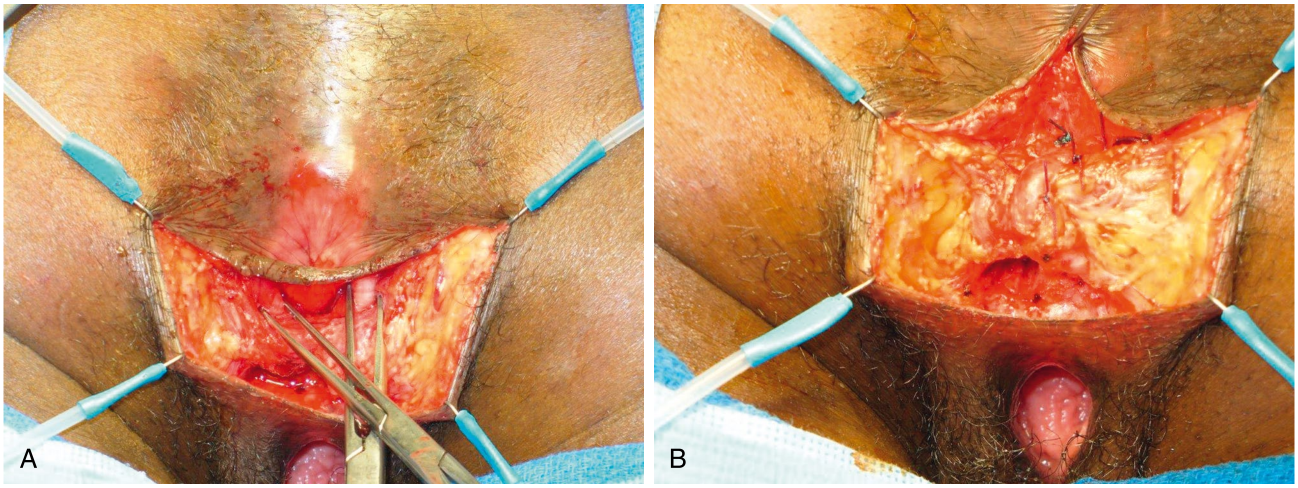

FIGURE 97.31 (A) Surgical repair of anterior anal sphincter defect. Sphincter is dissected. (B) Completed overlapping sphincteroplasty.

Constipation

Constipation is a common symptom, accounting for 8 million annual visits to physicians in the United States. Constipation is commonly secondary to extrinsic factors, including medications, endocrine and neurologic disorders, diet, and lifestyle, many of which are modifiable. Primary constipation, which is the focus of this section, can typically be divided into three broad categories: slow-transit constipation, normal-transit constipation, and pelvic constipation.

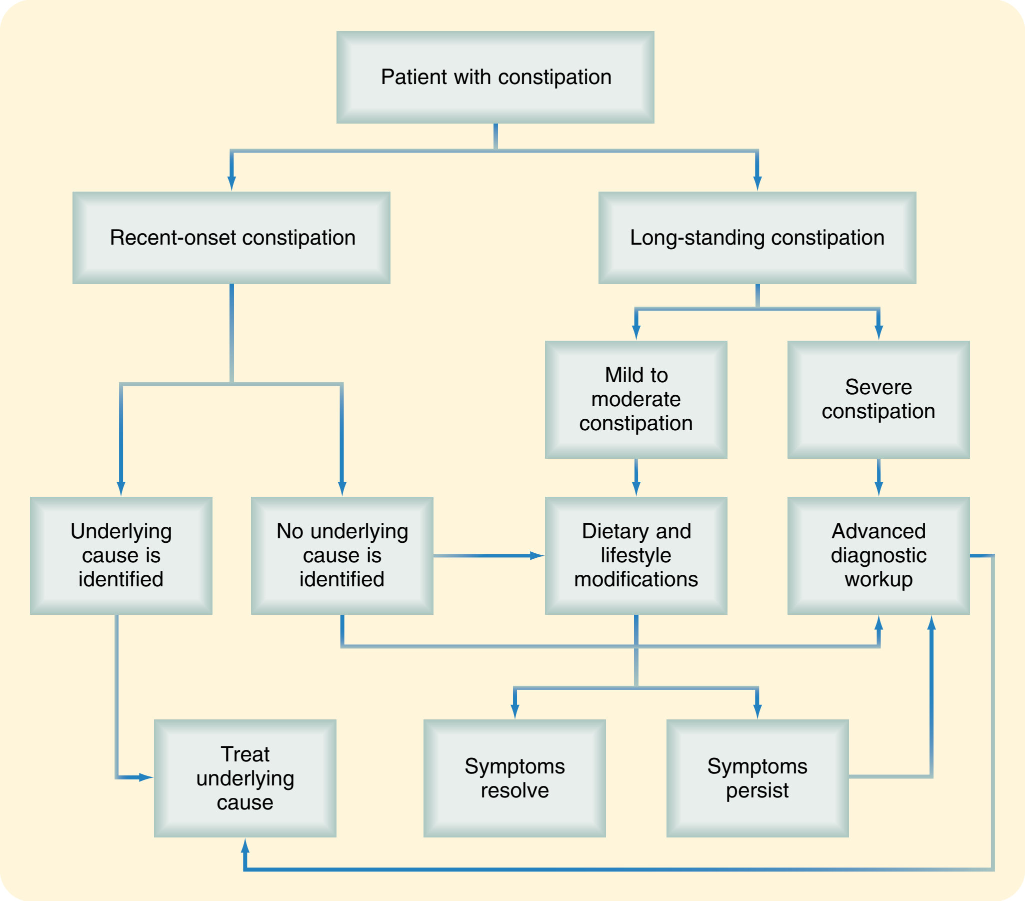
1. Slow-transit constipation results from intrinsic dysmotility of the colon, resulting in significant impairment of propulsive colonic motor activity. In some patients, only the colon is affected, whereas others have involvement of other parts of the GI tract as well. Patients with slow-transit constipation may not have bowel movements for days to weeks at a time despite using laxatives and enemas.
2. In normal-transit constipation, stool traverses the colon at a normal rate, and stool frequency may be normal, but patients feel constipated. Patients typically report that stools are hard and defecation is difficult; these patients may also report bloating, abdominal pain, and discomfort that is relieved by defecation. A significant overlap exists between this subgroup of constipation and constipation-predominant irritable bowel syndrome.
3. Pelvic constipation results from a lack of coordination of the pelvic floor during defecation or constipation from external compression or distortion of the rectum by rectocele, enterocele, and sigmoidocele. Additional causes of pelvic constipation include full-thickness rectal prolapse, rectal intussusception, and solitary rectal ulcer syndrome, all of which can disrupt the coordinated transit of stool through the rectum.

Initial management includes lifestyle modifications, including increased intake of dietary fiber, fiber supplementation, increased fluid intake, and exercise (Fig. 97.32). Use of polyethylene glycol solutions is typically safe and effective when these measures are inadequate. Stimulant laxatives such as senna and bisacodyl may be used judiciously in patients in whom lifestyle modification is inadequate. Prokinetics and secretagogues should be restricted to those not responding to simpler treatments.

For all patients with recent changes in bowel habits or those due for routine screening, colonoscopy is appropriate to rule out a mechanical obstruction from malignancy or strictures related to diverticular disease or inflammatory bowel disease. Anorectal physiology testing and assessment of colorectal transit time are indicated if medical treatment fails and/or symptoms indicate severe slow-transit or pelvic constipation. As detailed in the radiology section, Sitz marker studies or colonic nuclear scintigraphy are the studies of choice to evaluate for slow-transit constipation, and fluoroscopic defecography or magnetic resonance defecography may be helpful to evaluate patients with presumed pelvic constipation. Subtotal colectomy with ileorectal anastomosis is reserved for highly selected patients with severe slow-transit constipation and normal pelvic floor function that has not responded to other methods of treatment. For patients with pelvic constipation, rectopexy may address symptomatic rectocele and internal rectal intussusception (see description of these procedures in the next section). Ventral mesh rectopexy involves mobilization of the rectum anteriorly without division of the lateral ligaments. The pelvic floor musculature and anterior aspect of the rectum are suspended using a mesh sling sutured to the sacrum. Compared with traditional suture rectopexy, which completely circumferentially mobilizes the rectum to the pelvic floor, ventral mesh rectopexy has demonstrated lower rates of postoperative constipation, presumably as a result of preservation of rectal innervation via splanchnic nerves traveling in the lateral rectal stalks.[85]

Rectal Prolapse

Rectal prolapse is characterized by a full-thickness intussusception of the rectal wall that protrudes externally through the anus. Full-thickness rectal prolapse can be identified on physical examination by the characteristic appearance of concentric folds of rectal mucosa compared with the radial invaginations seen in prolapsing internal hemorrhoids and rectal mucosal-only prolapse (Fig. 97.33). Females are six times more likely than males to present with rectal prolapse, with a peak incidence in the seventh decade of life.[86] Symptoms of rectal prolapse may include the feeling of a bulge, mucus drainage, fecal incontinence, constipation, tenesmus, rectal pressure, pelvic pressure and pain, and rectal bleeding. Concomitant anterior compartment prolapse is also common, with 20% to 35% of patients complaining of urinary symptoms and 15% to 30% with vaginal vault or uterine prolapse.[87,88] There are several known anatomic risk factors for rectal prolapse, including laxity of rectal attachments, a



Patient with constipation
Recent-onset constipation
Long-standing constipation
Mild to moderate constipation
Severe constipation

Symptoms persist

FIGURE 97.32 Evaluation and management of constipation.

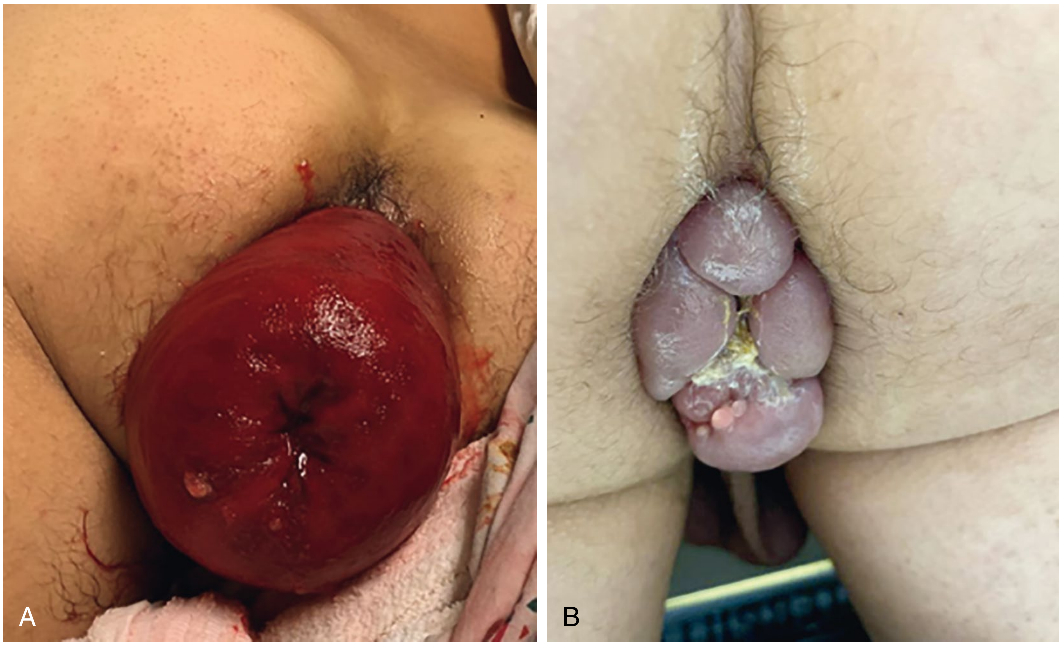

FIGURE 97.33 Rectal prolapse versus prolapsed hemorrhoids (A) Congested rectal prolapse with circumferential fold. (B) Incarcerated prolapse hemorrhoids with radial folds.

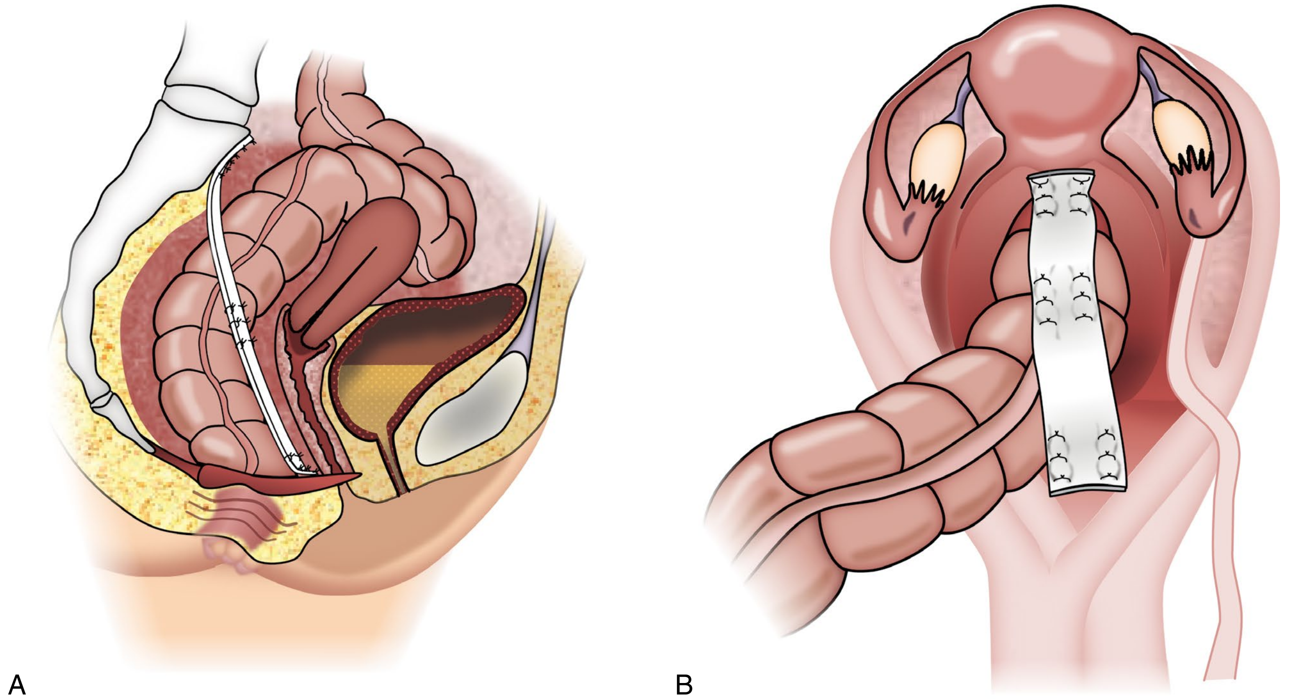

FIGURE 97.34 Ventral mesh rectopexy involves anterior mobilization in the rectovaginal septum down to the pelvic floor between the extraperitoneal rectum and the vagina. The prolapsed rectum is reduced into the abdomen; either permanent or biologic mesh is sutured to the anterior surface of the rectum; and the mesh is suspended to the sacrum, thus elevating the pelvic floor. (A) Lateral view showing ventral mesh affixed to sacrum. (B) Top-down view showing sites of mesh fixation.

deep cul-de-sac, lack of fixation of the rectum to the sacrum, and a large redundant sigmoid colon. Patients with connective tissue disorders (e.g., Marfan syndrome, Ehlers-Danlos syndrome) may present with prolapse at a younger age and may be at higher risk for recurrent prolapse.

The initial evaluation of a patient with rectal prolapse should include a complete history and physical examination, with focus on the prolapse; anal sphincter structure and function; and concomitant symptoms and underlying conditions, including chronic constipation and multiparity. In female patients, symptoms of anterior compartment disorders, including vaginal or uterine prolapse and urinary incontinence, should also be elicited. If the diagnosis of rectal prolapse is suspected but no prolapse is detected on physical examination, the patient can be asked to reproduce the prolapse in the office by straining while on a commode, with or without the use of an enema or a rectal balloon. Rectal examination frequently reveals a patulous anus with decreased sphincter tone.

If prolapse is evident on physical examination, additional confirmatory testing is not required. Fluoroscopic or MRI defecography should be considered in patients with symptoms suggestive of anterior compartment disorders because these studies can demonstrate cystocele, vaginal vault prolapse, and enterocele. Patients with anterior compartment disorders may benefit from urodynamics and urogynecologic examination to complete the evaluation and allow for concomitant surgical intervention to address both the anterior and posterior pelvic compartments. Rarely, a rectal mass may form the lead point to a rectal prolapse, so colonoscopy should be performed before surgery.

Both transabdominal and perineal approaches exist for the surgical correction of rectal prolapse. Abdominal approaches involve varying degrees of rectal mobilization followed by reduction of the prolapse and fixation of the rectum in the pelvis to prevent telescoping of the redundant bowel. The most common operations are posterior suture rectopexy and ventral mesh rectopexy (Fig. 97.34). The most common perineal approaches are the perineal proctosigmoidectomy (Altemeier) and the Delorme procedures (Figs. 97.35 and 97.36). In general, for patients with acceptable surgical risk (able to tolerate general anesthesia and pneumoperitoneum), transabdominal rectal fixation is preferred because of the lower recurrence rates (<10% at 10 years with transabdominal rectal fixation vs. 16%–30% perineal prolapse repair).[89–91]

Occasionally, patients present emergently with incarcerated rectal prolapse. Incarceration typically results from obstruction of venous return from the prolapsed rectum, leading to a bulky edematous rectum that cannot be reduced back into the anal canal. Mucosal ischemia and ulcerations may occur and may progress to full-thickness necrosis of the rectum. Initial conservative methods should be aimed at reducing the edema by the liberal application of sugar as an osmotic agent and relaxation, sedation, perianal nerve block, or general anesthesia to allow for attempts at manual reduction of the prolapse. If the rectal prolapse cannot be reduced or if there is rectal necrosis that should not be reduced, the patient needs to be taken to the operating room without delay for a perineal rectosigmoidectomy (Altemeier procedure) (Fig. 97.37).

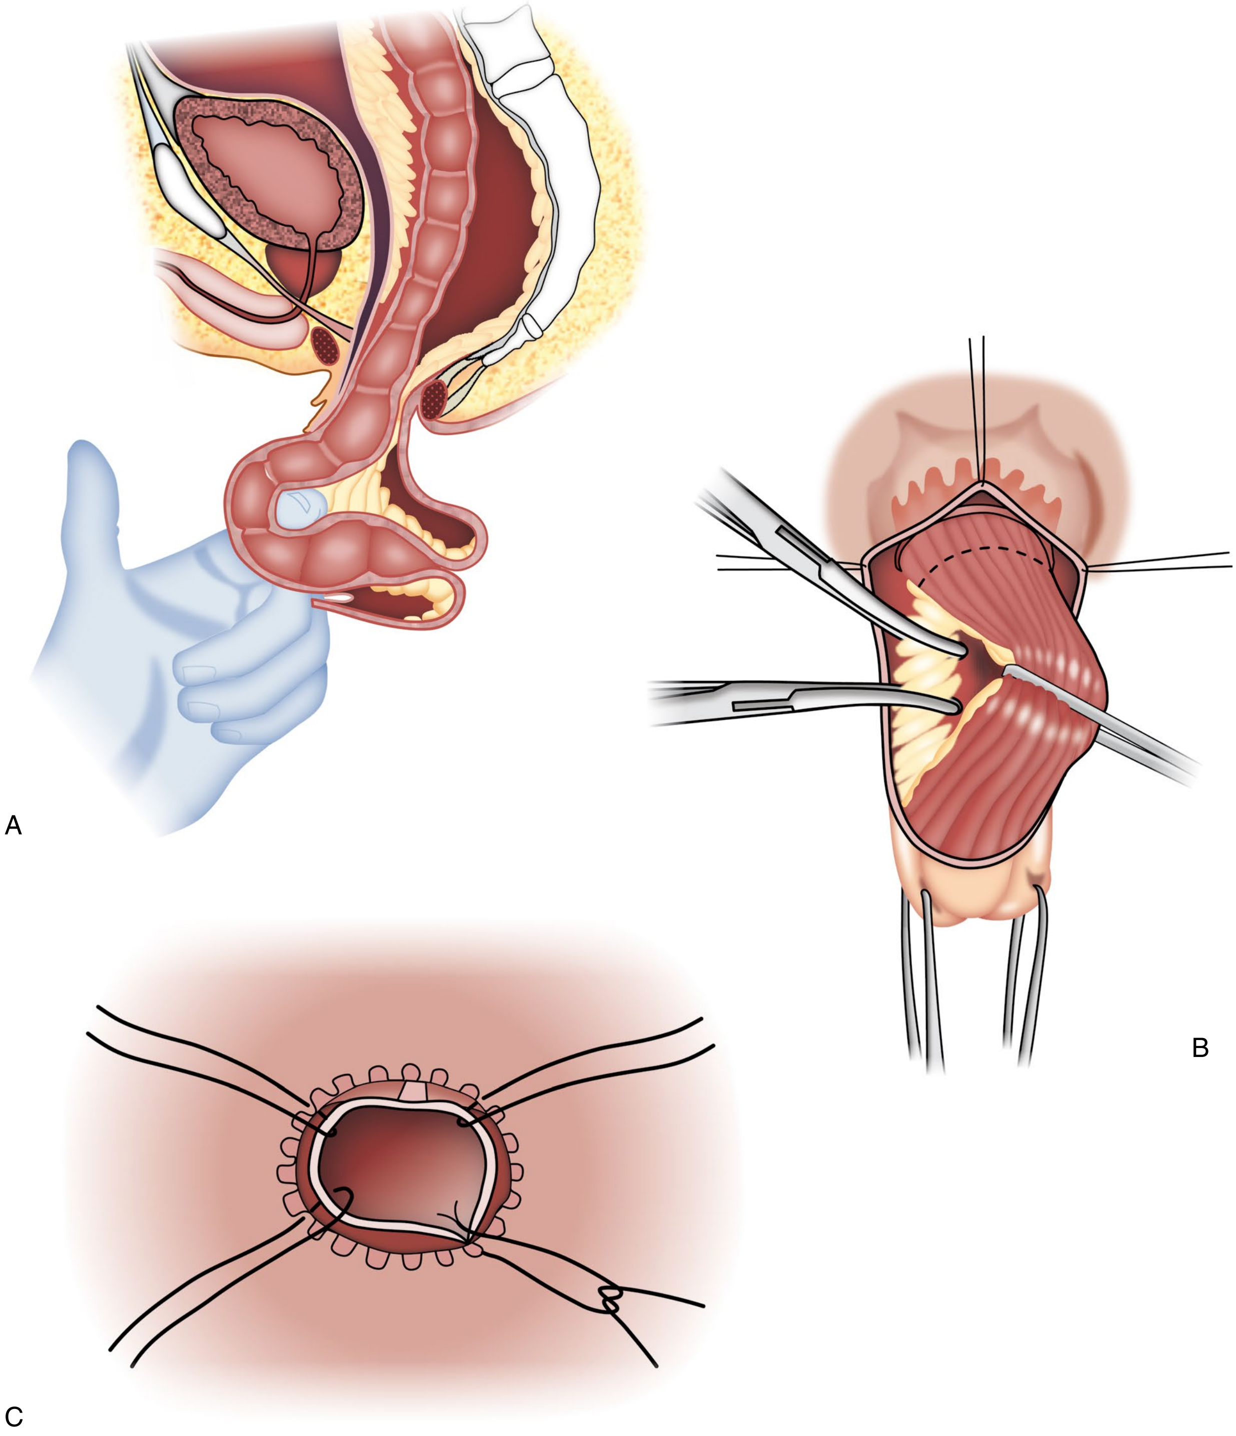

FIGURE 97.35 The perineal proctosigmoidectomy, or Altemeier procedure, involves the full-thickness excision of the prolapsed bowel with a coloanal anastomosis. (A) Sigmoid mesentery in prolapse. (B) Division of sigmoid mesentery adjacent to bowel wall. (C) Completed coloanal anastomosis after transection of redundant rectum and sigmoid.

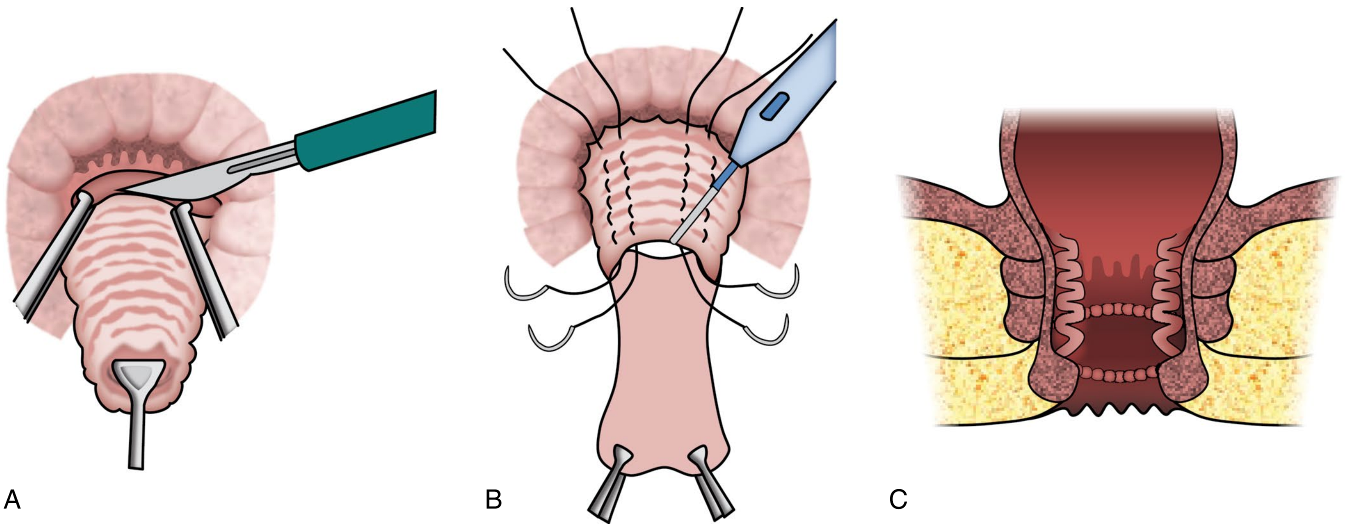

FIGURE 97.36 (A–C) Delorme procedure.

  Surgical Treatment of Lower Gastrointestinal Bleeding
Outcomes in Gastrointestinal Bleeding

INTRODUCTION

Gastrointestinal (GI) diseases account for considerable healthcare use and expenditures. GI bleeding (GIB) is one of the most common GI diagnoses, requiring hospital admission in the United States, with more than 500,000 cases annually.[1] Upper GI bleeding (UGIB) refers to bleeding originating from sites in the esophagus, stomach, or duodenum (GI tract proximal to ligament of Treitz). Nearly 80% of patients visiting emergency departments for UGIB are admitted to the hospital with that principal diagnosis.[1] Lower GI bleeding (LGIB) refers to blood loss of recent onset distal to the ligament of Treitz, most commonly originating from the colon.[2] UGIB, with an incidence of 67 per 100,000 population, is more common than LGIB, which carries an incidence of 36 per 100,000 population.[3] LGIB is more common in males than females because vascular diseases and diverticulosis are more common in males.[2] Although the incidence of GIB increases with age, the overall incidence of GIB is decreasing in the United States annually.

Symptoms and Initial Evaluation of Gastrointestinal Bleeding

Causes of UGIB are as follows:

- Peptic ulcer disease (excess gastric acid, *Helicobacter pylori* infection, NSAID overuse, or physiologic stress)
- Esophagitis
- Gastritis and duodenitis
- Varices
- Portal hypertensive gastropathy
- Angiodysplasia
- Dieulafoy lesion (bleeding dilated vessel that erodes through the GI epithelium but has no primary ulceration)
- Gastric antral valvular ectasia (known as *watermelon stomach*)
- Mallory-Weiss tears
- Cameron lesions (bleeding ulcers occurring at the site of a hiatal hernia)
- Aortoenteric fistulas
- Foreign-body ingestion
- Postsurgical bleeds (postanastomotic bleeding, postpolypectomy bleeding, postsphincterotomy bleeding)
- Upper GI tumors
- Hemobilia (bleeding from the biliary tract)
- Hemosuccus pancreaticus (bleeding from the pancreatic duct)

Patients with acute UGIB commonly present with hematemesis (vomiting of blood or coffee-ground–like material) and/or melena (black, tarry stools). The initial evaluation of a patient with a suspected clinically significant acute UGIB includes a detailed pertinent history and physical examination, including vitals, as well as laboratory tests. The main goal of this initial assessment is to evaluate the severity of bleeding and potentially guide subsequent management (both medical and interventional), such as triage, hemodynamic stability, appropriate resuscitation, empiric medical therapy, and diagnostic testing.

A thorough history and physical examination are of critical importance because they can provide clinically important information in the setting of suspected UGIB that can help guide the appropriate diagnostic approach and management. Symptoms such as patient-reported melena (likelihood ratio [LR] 5.1–5.9), melenic stool on examination (LR 25), blood detected during nasogastric lavage (LR 9.6), and prerenal acute kidney injury (ratio of blood urea nitrogen to serum creatinine greater than 30, LR 7.5) are commonly encountered. Conversely, the presence of blood clots in the stool makes an upper GI source less likely (LR 0.05).

Hematemesis (either red blood or coffee-ground emesis) suggests bleeding proximal to the ligament of Treitz. The presence of frankly bloody emesis suggests moderate to severe bleeding that may be ongoing, whereas coffee-ground emesis suggests more limited bleeding that may have already stopped. Similarly, the presence of melena indicates bleeding originating proximal to the ligament of Treitz (90%), although it may also originate from the oropharynx or nasopharynx, small bowel, or colon.[4] Melena may be seen with variable degrees of blood loss, being seen with as little as 50 mL of blood.[5] Finally, hematochezia (red or maroon blood in the stool) is usually due to LGIB. However, it can occur with massive UGIB,[6] which is typically associated with orthostatic hypotension.

A thorough assessment of the patient's past medical history can also provide important information to help determine potential causes of bleeding. Patients should be asked about prior episodes of UGIB because up to 60% of patients with a history of UGIB are bleeding from the same lesion.[7] In addition, the patient's past medical history should be reviewed to identify important comorbid conditions that may lead to UGIB or may influence the patient's subsequent management, such as gastritis or peptic ulcer disease (*H. pylori*, NSAIDs, smoking, steroids), portal hypertension (varices), prior aortic aneurysm repair (aortoenteric fistula), angiodysplasia (in the setting of renal failure, aortic stenosis a patient with renal disease and aortic stenosis), malignancy (weight loss, obstruction, perforation in the setting of smoking or excess alcohol use), and marginal ulcers (in the setting of known bariatric surgery or prior gastroenteric anastomosis).[8] Finally, medications such as antiplatelets (e.g., P2Y12 inhibitors and aspirin), anticoagulants (including warfarin and direct oral anticoagulants), selective serotonin reuptake inhibitors (SSRIs), calcium channel blockers, and aldosterone antagonists can increase the bleeding diathesis and risk. Moreover, medications such as iron, licorice, charcoal, and bismuth can turn stool black and might alter the clinical presentation.

The presence of accompanying symptoms can facilitate the evaluation of the severity of bleeding. For example, orthostatic lightheadedness, altered mental status (confusion), and clammy extremities can indicate hemodynamically significant and potentially life-threatening bleeding. Abdominal pain, with rebound or guarding, might indicate perforation of hollow viscus in the setting of peptic ulcer disease. Dysphagia or odynophagia can indicate esophageal disease as the source of bleeding, whereas the presence of emesis or retching before hematemesis can be seen in Mallory-Weiss tears. A history of ascites, jaundice, and clinical findings of liver failure can be found in cases of hemorrhage due to esophageal varices and portal hypertensive gastropathy. A history of cachexia, weight loss, early satiety, or obstructive symptoms can be seen in the setting of malignancy.[9]

Physical examination is a key component of the assessment of hemodynamic stability and the estimated blood loss. Patients with less than 15% of blood volume lost (up to 750 mL) might have normal vitals. In patients with blood volume loss of 15% to 30% (750–1500 mL), pulse pressure will be widened, urine output will be decreased (<30 mL/h), and patients will very likely be tachycardic (heart rate >100 beats/minute). When the estimated blood loss is 30% to 40% of the total blood volume (1500–2000 mL), patients are generally hypotensive, tachycardic to 120 beats/minute, and confused, with low urine output (<20 mL/h). Finally, when more than 40% of the total blood volume is lost (>2000 mL), patients are hypotensive, tachycardic to 140 beats/minute, tachypneic, and lethargic, with negligible urine output.[10]

Laboratory tests that should be obtained in patients with acute UGIB include a complete blood count, serum chemistries, type and screen, liver tests, and coagulation studies. In addition, electrocardiogram and cardiac enzymes may be indicated in patients who are at risk for a cardiac event. The initial hemoglobin level in a patient with acute UGIB may be similar to the patient's baseline because the patient is losing whole blood and will take time to equilibrate. With time, the hemoglobin level will decline as the blood is diluted by the influx of extravascular fluid into the vascular space and by fluid administered during resuscitation. The hemoglobin level should initially be monitored every 2 to 8 hours, depending on the severity of the bleed. On the contrary, active hemorrhage will not change the mean corpuscular volume (MCV). If the MCV is low, it may suggest iron deficiency, which could be caused by chronic bleeding. Because blood is absorbed as it passes through the small bowel and patients may have decreased renal perfusion, patients with acute UGIB typically have an elevated blood urea nitrogen (BUN)-to-creatinine or urea-to-creatinine ratio. Values of this ratio >30:1 or >100:1, respectively, suggest UGIB as the cause,[11,12] and the higher the ratio, the more likely the bleeding is from an upper GI source.[11]

Causes of LGIB are as follows:

- Diverticulosis
- Angiodysplasia
- Infectious colitis
- Ischemic colitis
- Inflammatory bowel disease
- Colon cancer
- Hemorrhoids
- Anal fissures
- Rectal varices
- Radiation-induced damage after treatment of abdominal or pelvic cancers
- Postsurgical (postpolypectomy bleeding, postbiopsy bleeding)

Patients with acute LGIB typically present with hematochezia (passage of maroon or bright-red blood or blood clots per rectum), although hematochezia may also be seen in patients with massive upper GI or small bowel bleeding. Although bleeding originating in the colon tends to present with the passage of bright-red blood per rectum, rarely, patients with right-sided colonic bleeding will present with melena. LGIB will stop spontaneously in 80% to 85% of patients, and the mortality rate is 2% to 4%.[13] The causes of acute LGIB may be grouped into several categories: anatomic (diverticulosis), vascular (angiodysplasia, ischemic, radiation induced), inflammatory (infectious, inflammatory bowel disease), and neoplastic. In addition, acute LGIB can occur after therapeutic interventions such as polypectomy. In patients suspected of having acute LGIB, the initial management is similar to the one in UGIB (obtaining adequate intravenous [IV] access, triaging the patient to the appropriate level of care, and providing supportive measures such as supplemental oxygen and resuscitation). Also, exclusion of acute UGIB is also required (e.g., in a patient with massive hematochezia and signs of hemodynamic compromise) because an upper GI source can be the cause of hematochezia in 10% to 15% of cases.[14] Past medical history, including prior episodes of LGIB, medications, and concomitant symptoms that may suggest the underlying etiology of the LGIB (e.g., painless hematochezia with diverticular bleeding, change in bowel habits with malignancy, abdominal pain with colitis), should be evaluated.

DIAGNOSIS AND MANAGEMENT OF GASTROINTESTINAL BLEEDING

Nonsurgical Management of Upper Gastrointestinal Bleeding

Although the principles behind the management of all patients with UGIB are similar, there are some special considerations when it comes to patients presenting with hemodynamic instability (shock, orthostatic hypotension). Of paramount importance is the establishment of adequate peripheral access, which should be attained with either two 18-gauge or larger IV catheters and/or a large-bore, single-lumen central cordis. Elective endotracheal intubation in patients with ongoing hematemesis or altered respiratory or mental status may facilitate endoscopy and decrease the risk of aspiration. However, among patients who are critically ill, elective endotracheal intubation has been associated with worse outcomes.[15] All patients with hemodynamic instability or active bleeding (manifested by hematemesis, bright-red blood per nasogastric tube [NGT], or hematochezia) should be admitted to an intensive care unit for resuscitation and close observation. Fluid resuscitation should begin immediately and should not be delayed pending transfer of the patient to an intensive care unit. For patients with active/brisk bleeding and hypovolemia, transfusion should be guided by hemodynamic parameters, the pace of the bleeding, estimated blood loss, and the ability to stop the bleeding, rather than by serial hemoglobin measurements. If the initial hemoglobin level is low (<7 g/dL), transfusions should be initiated.[16,17] In a patient with acute and ongoing hemorrhage, however, transfusion support should not be delayed while awaiting laboratory test results and should begin at the time of evaluation. Patients without active bleeding who become hemodynamically stable with fluid resuscitation alone may be managed without an initial transfusion but should be watched closely because the need for transfusion may develop as they clinically equilibrate. For most stable patients, a restrictive transfusion strategy is appropriate (transfuse if hemoglobin is <7 g/dL rather than at a higher hemoglobin) because it has been shown to be related to lower all-cause mortality and rebleeding rates compared with a liberal transfusion strategy.[18,19] Another crucial component of the management of UGIB is acid suppression, such as proton pump inhibitors (PPIs). Options include giving IV PPIs every 12 hours or starting a continuous infusion. For patients who may have stopped bleeding (e.g., patients who are hemodynamically stable), IV PPIs every 12 hours are preferred. In the setting of active UGIB from an ulcer, acid-suppressive therapy with H_2 receptor antagonists has not been shown to significantly lower the rate of ulcer rebleeding.[20–22] On the contrary, high-dose antisecretory therapy with an IV infusion of PPIs significantly reduces the rate of rebleeding compared with standard treatment in patients with bleeding ulcers.[23] Oral and IV PPI therapy also decreases the length of hospital stay, rebleeding rate, and need for blood transfusion in patients with high-risk ulcers treated with endoscopic therapy. PPIs may also promote hemostasis in patients with lesions other than ulcers. This likely occurs because neutralization of gastric acid leads to the stabilization of blood clots.[24]

Prokinetics, such as erythromycin and metoclopramide, have been studied in patients with acute UGIB. The goal of using a prokinetic agent is to improve gastric visualization at the time of endoscopy by clearing the stomach of blood, clots, and food residue. A reasonable dose is 250 mg intravenously over 20 to 30 minutes. Endoscopy is performed 20 to 90 minutes after completion of the erythromycin infusion. Patients receiving erythromycin need to be monitored for QTc prolongation. In addition, drug-drug interactions should be evaluated before giving erythromycin because it is a cytochrome P4503A inhibitor. Erythromycin promotes gastric emptying based on its ability to be an agonist of motilin receptors. The use of erythromycin was found to improve gastric visualization (77% vs. 51%, odds ratio [OR] 4.14, 95% CI 2.01–8.53), was less likely to require second-look endoscopy (15% vs. 26%, OR 0.51, 95% CI 0.34–0.77), and resulted in shorter hospital stays (mean difference –1.75 days, 95% CI –2.43 to –1.06). There were no differences in units of blood transfused, endoscopy duration, or need for emergent surgery between those who received erythromycin and those who did not.[25,26]

Vasoactive medications, such as somatostatin (analog octreotide) and terlipressin, are used in the treatment of variceal bleeding and may also reduce the risk of bleeding resulting from nonvariceal causes. In patients with suspected variceal bleeding, octreotide is given as an IV bolus of 50 μg, followed by a continuous infusion at a rate of 50 μg/h. Octreotide is not recommended for routine use in patients with acute nonvariceal UGIB, but it can be used as adjunctive therapy in some cases. Its role is generally limited to settings in which endoscopy is unavailable or to help stabilize patients before definitive therapy can be performed.[27] In patients with cirrhosis, a special consideration is the use of prophylactic antibiotics because bacterial infections are present in up to 20% of patients with cirrhosis who are hospitalized with GIB. Even for those cirrhotic patients who do not present initially with an infectious source, up to an additional 50% develop an infection while hospitalized. Not surprisingly, these patients have an increased rate of mortality. Multiple trials evaluating the effectiveness of prophylactic antibiotics in cirrhotic patients hospitalized for GIB suggest an overall reduction in infectious complications and possibly decreased mortality.[28] Antibiotics may also reduce the risk of recurrent bleeding in hospitalized patients who bled from esophageal varices.[29,30]

As a general rule, the management of UGIB should be primarily medical (gastroenterology) and should begin with an upper endoscopy. Surgical and interventional radiology consultation should be considered if endoscopic therapy is found to be unsuccessful; if the patient is deemed to be at high risk for rebleeding or there are complications associated with endoscopy; if there is concern that the patient may have a complicated intraabdominal process, such an aorto-enteric fistula; and in all patients with severe UGIB, such as those presenting with hemodynamic instability that fails to respond to resuscitation.[31] The role of routine use of NGT placement in patients with suspected acute UGIB is not recommended because studies have failed to demonstrate a benefit regarding clinical outcomes.[32–34] Early NGT placement is associated with shorter time to endoscopy but offers no benefit in terms of mortality, length of hospital stay, surgery, or transfusion requirement. It might be considered in cases of unclear diagnosis or unclear acuity of bleeding where patients might benefit from an early endoscopy. In addition, NGT lavage can be used to remove particulate matter, fresh blood, and clots from the stomach to facilitate endoscopy. An alternative to NGT lavage in this situation is to use prokinetics such as erythromycin or metoclopramide. The presence of red blood or coffee-ground material in the nasogastric aspirate also confirms an upper GI source of bleeding and predicts whether the bleeding is caused by a lesion at increased risk for ongoing or recurrent bleeding.[35] However, lavage may not be positive if bleeding has ceased or arises beyond a closed pylorus. Nasogastric aspiration of nonbloody bilious fluid suggests that the pylorus is open and that there is no active UGIB distal to the pylorus (Table 98.1).

Upper endoscopy is the diagnostic modality of choice for acute UGIB,[36] and early endoscopy (within 24 hours) is recommended for most patients with acute UGIB. Endoscopy has a high sensitivity and specificity for locating and identifying bleeding lesions in the upper GI tract. In addition, once a bleeding lesion has been identified, therapeutic endoscopy can achieve acute hemostasis and prevent recurrent bleeding in most patients. For patients with suspected variceal bleeding, endoscopy should be performed within 12 hours of presentation. Endoscopic findings in patients with bleeding peptic ulcers are described using the modified Forrest classification.[37] Findings include spurting hemorrhage (class Ia), oozing hemorrhage (class Ib), a nonbleeding visible vessel (class IIa), an adherent clot (class IIb), a flat pigmented spot (class IIc), and a clean ulcer base (class III). The endoscopic

TABLE 98.1 Overview of Upper Gastrointestinal Bleeding

Causes

Peptic ulcer, esophagogastric varices, arteriovenous malformation, tumor, Mallory-Weiss tear

Clinical Features

History: Medications (NSAIDs, aspirin, anticoagulants/antiplatelets), previous GI bleed, liver failure, coagulopathy
Symptoms and signs: Abdominal pain, hematemesis or coffee-ground emesis, passing melena/tarry stool
Examination: Tachycardia, orthostatic blood pressure, hypotension, rectal exam, abdominal tenderness, peritonitis

Diagnostic Testing

Type and screen, CBC, coagulation screen, LFTs, BUN, Cr
Nasogastric lavage may be helpful if the source of bleeding is unclear (upper or lower GI tract) or to clean the stomach before endoscopy.

Treatment

Continuous monitoring, resuscitation, oxygen, transfusion

- For severe, ongoing bleeding, immediately transfuse blood products in 1:1:1 ratio of RBCs, plasma, and platelets, as for trauma patients.
- For hemodynamic instability despite crystalloid resuscitation, transfuse 1 to 2 units RBCs.
- For hemoglobin <8 g/dL (80 g/L) in high-risk patients (e.g., older adult, coronary artery disease), transfuse 1 unit RBCs and reassess the patient's clinical condition.
- For hemoglobin <7 g/dL (70 g/L) in low-risk patients, transfuse 1 unit RBCs and reassess the patient's clinical condition.

Consult with gastroenterologist; obtain surgical and interventional radiology consultation for any large-scale bleeding.

Give a proton pump inhibitor:

If evidence of active bleeding (e.g., hematemesis, hemodynamic instability), give esomeprazole or pantoprazole, 80 mg IV.
If no evidence of active bleeding, give esomeprazole or pantoprazole, 40 mg IV.
If endoscopy is delayed beyond 12 hours, give second dose of esomeprazole or pantoprazole, 40 mg IV.

Known or suspected esophagogastric variceal bleeding and/or cirrhosis: Somatostatin or an analog (e.g., octreotide 50 μg IV bolus followed by 50 μg/h continuous IV infusion)

Give an IV antibiotic (e.g., ceftriaxone or fluoroquinolone).
Balloon tamponade may be performed as a temporizing measure for patients with uncontrollable hemorrhage likely due to varices using any of several devices (e.g., Sengstaken-Blakemore tube, Minnesota tube); tracheal intubation is necessary if such a device is to be placed; ensure proper device placement before inflation to avoid esophageal rupture.

BUN, Blood urea nitrogen; *CBC,* complete blood count; *Cr,* creatinine; *GI,* gastrointestinal; *IV,* intravenous; *LFT,* liver function test; *RBC,* red blood cell.

TABLE 98.2 Endoscopic Predictors of Recurrent Peptic Ulcer Hemorrhage

FORREST CLASSIFICATION	PREVALENCE (%)	RISK OF REBLEEDING ON MEDICAL MANAGEMENT (%)
Forrest Ia (active arterial bleeding)	12% (arterial bleeding + oozing)	55 (arterial bleeding + oozing)
Forrest Ib (oozing without visible vessel)		
Forrest IIa (nonbleeding visible vessel)	8	43
Forrest IIb (adherent clot)	8	22
Forrest IIc (flat spot)	16	10
Forrest III (clean ulcer base)	55	5

appearance helps determine which lesions may require further management beyond endoscopic therapy (Table 98.2). In patients in whom blood obscures the source of bleeding, a second endoscopy may be required to establish a diagnosis and to potentially apply therapy, but routine second-look endoscopy is not recommended.

Other diagnostic tests for acute UGIB include CT angiography (CTA; using an occult GIB protocol) and angiography, which can detect active bleeding[38,39]; deep small bowel enteroscopy; and rarely, intraoperative enteroscopy. Upper GI barium studies are contraindicated in the setting of acute UGIB because they will interfere with subsequent endoscopy, angiography, or surgery.[40] There is also interest in using wireless capsule endoscopy for patients who have presented to the emergency department with suspected UGIB. An esophageal capsule (which has a recording time of 20 minutes) can be given in the emergency department and reviewed immediately for evidence of bleeding. Confirming the presence of blood in the stomach or duodenum may aid with patient triage and identify patients more likely to benefit from early endoscopy.[41,42] Small bowel capsule endoscopy has also been employed to help localize bleeding in patients with acute GIB without hematemesis. A colonoscopy is generally required for patients with hematochezia and a negative upper endoscopy unless an alternative source for the bleeding has been identified. In addition, patients with melena and a negative upper endoscopy frequently undergo colonoscopy to rule out a colonic source for the bleeding because right-sided lesions may present with melena (Fig. 98.1).

Surgical Management of Upper Gastrointestinal Bleeding

The surgical management of UGIB will depend entirely on the source of the UGIB and the failure of nonsurgical options to

control bleeding. In the case of malignancies, the management has dual intent, both controlling the bleeding and performing an appropriate oncologic procedure.

For Mallory-Weiss tears, surgery is rarely necessary and is considered only after the failure of endoscopic or angiographic procedures. Laparoscopic or open oversewing of the tear under endoscopic guidance has been performed with excellent results.[43]

In patients with esophageal varices who had failed medical/endoscopic management (unsuccessful 10%–20% of cases), the next step should be rescue therapy in the form of emergent transjugular intrahepatic portosystemic shunt (TIPS) or surgical portocaval shunt creation.[44] TIPS is typically preferred over surgery because operative mortality may be high in cirrhotic patients, although acute emergent variceal hemorrhage may be associated with significant mortality irrespective of treatment modality.[45] Surgical management of esophageal varices includes shunting and nonshunting operations. Nonshunting operations include esophagogastric devascularization, esophageal transection, and splenectomy. The idea of transthoracic ligation of esophageal varices was first proposed by Crile (1950), with many modifications of the procedure after its initial conception. In 1973, Sugiura and Futagawa formulated the Sugiura procedure, which included extensive transthoracic paraesophageal devascularization, esophageal transection combined with an abdominal component consisting of splenectomy, devascularization of the upper stomach, vagotomy, and pyloroplasty.[46] Devascularization procedures are rarely the treatment of choice in the emergency setting; the operative mortality has been as high as 100% in Child C patients in some series. Nevertheless, when nonsurgical procedures fail, devascularization procedures can salvage critical situations of variceal bleeding. Also, in the elective setting, when the vascular anatomy is unsuitable for shunt procedures because of extensive portal, splenic, and superior mesenteric vein thrombosis and when other modalities have failed, devascularization procedures should be considered.[47] These procedures are related to a perioperative mortality of 12.7%. Long-term survival rates are dependent on the Child-Pugh classification at the time of the procedure. The survival rate was 44% in Child A patients, 22.5% in Child B patients, and 0% in Child C patients. In other series, the 5-year overall survival rate ranged from 58% to 93%.[48,49]

Shunting operations include total or portosystemic shunts, and they can be classified as nonselective or selective.[50] Total shunts may be an end-to-side shunt where the portal vein is divided at its bifurcation and the proximal end anastomosed to the inferior vena cava or a side-to-side anastomosis between the portal vein or a tributary greater than 10 mm in diameter and the inferior vena cava. All diverted-portal-flow and side-to-side shunts also decompress the liver sinusoids. Bleeding control is excellent, but portal flow is diverted, which may cause hepatocellular dysfunction. Partial portal systemic shunt is achieved with a portacaval anastomosis. This reduces portal pressure to 12 mm Hg while maintaining forward portal flow in 83% of patients.[51] The operative exposure is similar to that of total portal systemic shunts.

The selective shunts are further classified as follows:

- Distal splenorenal shunt (distal splenic vein to the left renal vein, with or without spleno-pancreatic and spleno-gastric connection).
- Small-diameter H-graft shunt (8-mm polytetrafluorethylene reinforced grafts anastomosing the superior mesenteric vein or portal vein to inferior vena cava)

The nonselective shunts are further classified as follows:

- Portocaval shunt (portal vein to the inferior vena cava directly)
- Mesocaval shunt (superior mesenteric vein to the inferior vena cava directly)
- Central (proximal) splenorenal shunt (proximal splenic vein to the left renal vein, with or without spleno-pancreatic and spleno-gastric connection or splenectomy)
- Large-diameter H-graft shunt (16-mm polytetrafluorethylene reinforced grafts anastomosing superior mesenteric vein or portal vein to the inferior vena cava)

Overall, the literature showed a superiority of selective shunts in terms of controlling bleeding (and bleeding prevention), maintaining portal flow, maintaining liver function, decreased postoperative encephalopathy, and overall survival, especially in nonalcoholics.[52]

In cases of bleeding gastric ulcer, the primary goal of any operation is hemorrhage control, with a secondary goal of definitively treating the underlying ulcer pathology. Bleeding gastric ulcers are generally best treated by excision of the ulcer and repair of the stomach. Excision or biopsy of the ulcer is important because 4% to 5% of benign-appearing ulcers are malignant ulcers.[53] For ulcers along the greater curvature of the stomach, antrum, or body of the stomach, wedge resection and primary closure can easily be achieved in most cases. For distal gastric ulcers along the lesser curvature in the area of the incisura angularis, a distal gastrectomy with reconstruction (Billroth I or Billroth II or Roux-en-Y [RY]) is often the easiest method of excising the ulcer and restoring GI continuity. In cases of gastroesophageal junction (GEJ) bleeding, wedge resection will often result in compromise of the GEJ and leak; thus, anterior gastrotomy with biopsy and oversewing of the ulcer from inside the gastric lumen is effective and relatively straightforward. In the event that ulcer excision is necessary, a Csendes procedure, a distal gastrectomy with tongue-shaped extension of the lesser curve resection margin to include the ulcer and subsequent RY esophagogastrojejunostomy, is an excellent option.[54]

In cases of bleeding duodenal ulcer, the standard approach is to perform an anterior longitudinal duodenotomy extending across the pylorus to the distal stomach. The bleeding vessel, often the gastroduodenal artery, is ligated in the ulcer crater by placing a figure-of-eight suture at the top and the bottom of the ulcer crater to control the artery proximally and distally. A third suture is placed as a U-stitch underneath the ulcer to control the transverse pancreatic branches that enter the gastroduodenal artery posteriorly. The transverse duodenal incision is then closed vertically to construct a Heineke-Mikulicz pyloroplasty. Classically, a truncal vagotomy is then performed to reduce the risk of recurrent ulceration if the patient is hemodynamically stable.[55,56] More extensive operation that includes gastric resection combined with ulcer resection is found to have lower rebleeding rates without significant differences in overall mortality. However, morbidity rates, mostly duodenal leaks, are significantly higher after gastric resection.[57]

Nonsurgical Management of Lower Gastrointestinal Bleeding

Similar to UGIB management, the goals are to determine if the bleeding is coming from the lower GI tract, determine the severity of bleeding, triage patients to the appropriate level of care, provide general supportive measures, and initiate resuscitation. Once these steps are complete, additional diagnostic studies can be obtained.[14] The approach to subsequent treatment depends on the source of the bleeding. If bleeding or stigmata of recent hemorrhage are identified during colonoscopy or angiography, attempts can be made to control the bleeding. However, frequently, active bleeding is not seen, and a presumptive diagnosis is made regarding the source of the bleeding (e.g., diverticular bleeding in a patient with diverticula). In those cases, the management approach will vary depending on the type of lesion (e.g., endoscopic treatment is appropriate for angiodysplasia but not for nonbleeding diverticula). If no source is identified, the patient may need to be evaluated for upper and mid-GI bleeding. In cases of blood per rectum, evaluation is warranted that includes gastroenterology consultation.[58] General surgery and interventional radiology consults are required in cases of massive hematochezia or those who are at high risk for complications. Other diagnostic procedures that may be useful include radionuclide imaging, CTA (multidetector row helical CT), and mesenteric angiography. These radiographic procedures require active bleeding at the time of examination in order to identify a bleeding source and are, therefore, reserved for the subset of patients with severe, ongoing bleeding.

Colonoscopy is the diagnostic test of choice for hemodynamically stable patients with LGIB because it allows the precise localization of the bleeding site as well as the ability to collect biopsy and provide therapeutic interventions. However, high-quality colonoscopy (colonic mucosa evaluation during both insertion and withdrawal, terminal ileum intubation, etc.) requires adequate bowel preparation and anesthesia, with its attendant risks, and incurs the risk of postprocedural bleeding or perforation.[59,60] Colonoscopy may not be needed in patients with previous presumptive or definitive diverticular bleeding who present with modest blood loss that stops spontaneously and who have had a high-quality colonoscopy within 12 months with adequate bowel preparation and no colorectal neoplasia.[59,60] A definitive or potential bleeding source is visualized in 45% to 90% of patients undergoing colonoscopy for LGIB.[61] Visualization of a potential bleeding site that is not actively bleeding does not exclude the presence of a more proximal source. The identification of more than one potential bleeding site is common (e.g., diverticulosis and hemorrhoids). Furthermore, a bleeding site is not always identified.[62] Colonoscopy should be performed on a next-available basis after adequate colon preparation because there is no difference in identification of stigmata of recent hemorrhage, rebleeding, or blood transfusions in patients undergoing colonoscopy in less than 24 hours of presentation versus within 24 to 96 hours (Table 98.3).[63]

TABLE 98.3 Overview of Lower Gastrointestinal Bleeding

Causes

Diverticular disease (most common), angiodysplasias, colon polyps, tumors (benign or malignant), inflammatory bowel disease, hemorrhoids, anal fissures

Clinical Features

History: Medications (NSAIDs, aspirin, anticoagulants/antiplatelets), previous GI bleed, liver failure, coagulopathy
Symptoms and signs: Abdominal pain, hematochezia
Examination: Tachycardia, orthostatic blood pressure, hypotension, rectal exam, abdominal tenderness, peritonitis

Diagnostic Testing

Type and screen, CBC, coagulation screen, LFTs, BUN, Cr
Nasogastric lavage may be helpful if the source of bleeding is unclear (upper or lower GI tract).

Treatment

Continuous monitoring, resuscitation, oxygen, transfusion

- For severe, ongoing bleeding, immediately transfuse blood products in 1:1:1 ratio of RBCs, plasma, and platelets, as for trauma patients.
- For hemodynamic instability despite crystalloid resuscitation, transfuse 1 to 2 units RBCs.
- For hemoglobin <8 g/dL (80 g/L) in high-risk patients (e.g., older adult, coronary artery disease), transfuse 1 unit RBCs and reassess the patient's clinical condition.
- For hemoglobin <7 g/dL (70 g/L) in low-risk patients, transfuse 1 unit RBCs and reassess the patient's clinical condition.

Consult with gastroenterologist; obtain surgical and interventional radiology consultation for any large-scale bleeding.

Colonoscopy

Computed tomographic angiography, angiography, radionuclide scan, push enteroscopy for small bowel bleeding

BUN, Blood urea nitrogen; *CBC,* complete blood count; *Cr,* creatinine; *GI,* gastrointestinal; *LFT,* liver function test; *RBC,* red blood cell.

Imaging for GIB can facilitate the diagnosis of bleeding throughout the GI tract, including small bowel sources. In addition, treatment of the bleeding site can be attempted during angiography (but not radionuclide imaging or CTA). However, these studies all require active bleeding at the time of the study to detect a bleeding site. In patients with severe bleeding who are unstable for colonoscopy or those with ongoing bleeding despite colonoscopy, CTA may be used to select patients with active bleeding for subsequent angiography or, less commonly, to localize the source before surgery. It is important that angiography be performed promptly after a positive CTA.[64] Otherwise, the patient may stop bleeding by the time the angiography is completed, thereby missing the opportunity for embolization. In patients with ongoing hemodynamically significant hematochezia, CTA is the initial diagnostic test of choice.[59] Patients with extravasation on a CTA should undergo prompt (ideally within 90 minutes) transcatheter arteriography and possible embolization.[65] CTA is an appealing diagnostic modality because it is widely available, fast, and minimally invasive. In addition, it provides anatomic detail that may be helpful for subsequent interventions such as angiography. Bleeding at a rate of 0.3 to 0.5 mL/minute can be detected with CTA.[66] CTA has a sensitivity of 85% and a specificity of 92% for detecting active GIB, and the accuracy of CTA is almost 100%.[67] CTA was found to be similar to radionuclide imaging for detecting bleeding on subsequent angiography (sensitivity of 90%, specificity of 20%), but it was more precise when it came to localizing the site of the bleeding. However, CTA lacks therapeutic capability, requires radiation exposure, and uses IV contrast, which can be associated with nephropathy and allergic reactions.[68] Like the other radiographic tests for GI bleeding, a positive scan requires active bleeding. Angiography requires active blood loss of 0.5 to 1.0 mL/minute under optimal conditions for a bleeding site to be visualized.[69] Angiography is typically reserved for patients in whom endoscopy is not feasible because of severe bleeding with hemodynamic instability. CTA is commonly used to identify and localize the bleeding source before angiography.[64] Angiographies performed within 90 minutes of positive CT angiograms are more likely to detect bleeding than those that are delayed beyond this time frame. In the absence of prior localization (e.g., radionuclide imaging), the superior mesenteric artery is generally examined first in patients with presumed LGIB because bleeding sources tend to occur in bowel supplied by this artery.[70] If this test is negative, the inferior mesenteric and celiac vessels are studied. The success rate varies widely from 25% to 70%, depending on the timing relative to the episode of bleeding and local expertise.[71] The advantages of angiography over other tests for LGIB are that it does not require bowel preparation, and anatomic localization is accurate. Additionally, angiography also permits the opportunity for therapeutic intervention. Transcatheter embolization is a means of controlling hemorrhage and has largely replaced other temporizing interventions, such as vasopressin infusion. Superselective embolization of distal vessels using coaxial catheters decreases the risk of bowel infarction. A meta-analysis found that in patients with active bleeding, superselective embolization is feasible in 98%, and complications occur in 4.6%, most commonly bowel infarction or ulceration.[71,72] Radionuclide scanning detects bleeding that is occurring at a rate of 0.1 to 0.5 mL/minute, and it is the most sensitive radiographic test for GI bleeding.[73] It is important that angiography be performed promptly after a positive radionuclide scan to localize the source of bleeding. However, a major disadvantage of radionuclide imaging is that it can only localize bleeding to a general area of the abdomen. Accuracy rates have varied substantially across reports, ranging from 24% to 91%.[74] Poor localization occurs because blood can move in either a peristaltic or antiperistaltic direction.

TABLE 98.4 Procedures Used for Evaluation of Lower Gastrointestinal Bleeding

TECHNIQUE	ADVANTAGES	DISADVANTAGES
Radionuclide imaging	• Noninvasive • Sensitive to low rates of bleeding	• Has to be performed during active bleeding • Poor localization of bleeding site • Not therapeutic • Not widely available
CT angiography	• Noninvasive • Accurately localizes bleeding source • Provides anatomic detail • Widely available	• Has to be performed during active bleeding • Not therapeutic • Radiation and IV contrast exposure
Angiography	• Accurately localizes bleeding source • Therapy possible with superselective embolization • Does not require bowel preparation	• Has to be performed during active bleeding • Invasive
Colonoscopy	• Precise diagnosis and localization regardless of active bleeding or type of lesion • Allows endoscopic therapy	• Need colon preparation for optimal visualization • Risk of sedation and perforation in acutely bleeding patient • Definite bleeding source (stigmata) infrequently identified

CT, Computed tomographic; *IV*, intravenous.

A bleeding site may not be evident in some patients despite lower GI evaluation. If not already done, an upper endoscopy or push enteroscopy should be considered in those with severe, ongoing bleeding because up to 15% of such patients have a bleeding site in the upper digestive tract.[75] Push enteroscopy (endoscopy using a pediatric colonoscope or a dedicated enteroscope) allows visualization of approximately the proximal 60 cm of the jejunum.[76] Bleeding sites can also arise in more distal segments of the small bowel. There are several methods to evaluate the small intestine, such as capsule endoscopy and deep small bowel enteroscopy. In some patients, bleeding may have stopped, making efforts to identify the site more difficult. Such patients should be observed for 24 to 48 hours. An urgent CT angiogram/tagged red blood cell scan can be obtained to localize the region of bleeding if bleeding resumes (Table 98.4). Provocative challenges with vasodilators, anticoagulants, and/or thrombolytics have been reported to aid in the diagnosis of elusive bleeding. However, the risk of serious complications, including refractory bleeding and death, is substantial, and these methods should be used extremely rarely and only by expert centers after careful planning.[77]

Surgical Treatment of Lower Gastrointestinal Bleeding

The surgical treatment of LGIB depends on the source of the bleeding. In many cases, the bleeding can be controlled with therapies applied at the time of colonoscopy or angiography. Rarely, patients with exsanguinating LGIB will need immediate surgery. The morbidity and mortality associated with colectomy in the absence of preoperative localization of a bleeding site are higher than those in patients who have a bleeding site identified before surgery.[78] Thus, all efforts should be made to identify the bleeding source before surgery. In patients with significant, early (during the initial hospitalization) recurrent LGIB, a repeat colonoscopy should be performed with endoscopic hemostasis if indicated.[2]

The indications for surgery in LGIB include persistent hemodynamic instability with active bleeding; persistent, recurrent bleeding; and transfusion of more than 4 units of packed red bloods cells in a 24-hour period with active or recurrent bleeding. In these patients, the operation type is dependent on the patient's hemodynamic and overall performance status, the background preexisting disease, and the preoperative successful localization. Segmental bowel resection after precise localization of the bleeding point is a well-accepted surgical practice in hemodynamically stable patients. Subtotal colectomy is the procedure of choice in patients who are actively bleeding from an unknown source. The latter has an associated morbidity rate of around 37% and a mortality rate of about 11% to 33%. In those patients who have nonlocalized disease and are unstable, a two-stage procedure is preferred: temporary end ileostomy and delayed ileoproctostomy. In those patients who are hemodynamically stable with minimal medical comorbidities, this procedure can be performed as a single-stage procedure with ileoproctostomy (Fig. 98.2).[79]

OUTCOMES IN GASTROINTESTINAL BLEEDING

UGIB in-hospital mortality reaches 10%. This rate holds steady up to 1 month after hospitalization for GIB. Long-term follow-up of patients with UGIB shows that at 3 years after admission, mortality rates from all causes approach 37%. Mortality rates are higher in females than in males. Patients with multiple hospitalizations for GIB carry higher mortality rates. The long-term prognosis was the worst in patients who suffered from malignancies and variceal bleeding.[80]

For LGIB, all-cause in-hospital mortality is less than 4%. Death from LGIB itself is rare, with most in-hospital mortality occurring from other comorbid conditions. Increased risk of death corresponded to increasing age and comorbid conditions. Other negative prognostic factors include secondary bleeding (onset of bleed after being hospitalized for a different condition), patients with preexisting coagulopathies, hypovolemia, transfusion requirement, and male sex. The lowest risks of mortality are associated with more benign causes of LGIB, such as hemorrhoids, anal fissures, and colon polyps.[81]

Morbid Obesity

Alfonso Torquati, Nicholas J. Skertich, Philip Omotosho, and William O. Richards

OUTLINE

Obesity: The Magnitude of the Problem
Pathophysiology and Associated Medical Problems
Medical Versus Surgical Therapy
- Metabolic Surgery Versus Medical Therapy for Diabetes
- Glucagon-Like Peptide-1 Receptor Agonists

Bariatric Surgery Mechanism of Action
- Enteroencephalic Endocrine Axis
- Enteroinsular Endocrine Axis

Preoperative Evaluation and Selection
- Eligibility
- General Bariatric Preoperative Evaluation and Preparation
- Evaluation of Specific Comorbid Conditions
- Special Equipment

Operative Procedures
- Laparoscopic Adjustable Gastric Banding
- Roux-en-Y Gastric Bypass
- Biliopancreatic Diversion
- Biliopancreatic Diversion With Duodenal Switch
- Single Anastomosis Duodenal-Ileal Bypass With Sleeve Gastrectomy
- Laparoscopic Sleeve Gastrectomy

Postoperative Care and Follow-Up
- Laparoscopic Adjustable Gastric Banding
- Roux-en-Y Gastric Bypass, Biliopancreatic Diversion With Duodenal Switch, Single Anastomosis Duodenal-Ileal Bypass With Sleeve Gastrectomy, and Laparoscopic Sleeve Gastrectomy

Bariatric Surgery Results
- Laparoscopic Adjustable Gastric Banding
- Roux-en-Y Gastric Bypass
- Biliopancreatic Diversion With Duodenal Switch and Single Anastomosis Duodenal-Ileal Bypass With Sleeve Gastrectomy
- Laparoscopic Sleeve Gastrectomy

Complications of Bariatric Surgery
- Laparoscopic Adjustable Gastric Banding
- Roux-en-Y Gastric Bypass
- Biliopancreatic Diversion With Duodenal Switch and Single Anastomosis Duodenal-Ileal Bypass With Sleeve Gastrectomy
- Laparoscopic Sleeve Gastrectomy

Reoperative Surgery
Endoscopic Procedures in Bariatric Surgery
- Preoperative Use of Endoscopy
- Intraoperative Endoscopy
- Postoperative Endoscopy
- Primary Endoscopic Weight Loss Procedures

Conclusion

OBESITY: THE MAGNITUDE OF THE PROBLEM

Until very recently, obesity was not recognized as a disease, which confounded the ability of physicians to be compensated for treatment they delivered and to treat the condition effectively. The American Medical Association (AMA) officially recognized obesity as a disease in 2013 and, in 2014, voted to approve the resolution "that our AMA, advocate for patient access to the full continuum of care of evidence-based obesity treatment modalities (including surgical interventions)."

Morbid obesity is defined as being 100 lb above ideal body weight, twice ideal body weight, or body mass index (BMI; measured as weight in kilograms divided by height in meters squared) of 40 kg/m^2 or greater. The last definition is more accepted internationally and has essentially replaced the former ones for all practical and scientific purposes. A consensus conference by the National Institutes of Health (NIH) in 1991 suggested that the term *severe obesity* as perhaps a more appropriate terminology. This term is used interchangeably with *morbid obesity* in the remainder of this chapter.

The obesity epidemic in the United States is evidenced by the fact that over 40% of the US adult population is considered obese, and the prevalence of obesity in adolescents has increased to 22.2% in the most recent National Health and Nutrition Examination Survey (NHANES). The percentage of obese adults (BMI >30) in the United States increased 16% from 1980–2000 and by another 9% from 2000–16.[1] There are also significant differences in the prevalence of obesity in adults by sex, race, and Hispanic origin. Non-Hispanic Asians (16.1%) had significantly lower rates of obesity than all other race and non–Hispanic-origin groups. Non-Hispanic Whites (41.4%) had a lower prevalence of obesity than non-Hispanic Blacks (49.9%) and Hispanic adults (45.6%). Hispanic males (45.2%) had a greater prevalence of obesity compared with non-Hispanic Asian (17.6%) and non-Hispanic Black males (40.4%).[1]

The prevalence of morbidly obese adults (BMI ≥40 kg/m^2) has increased to 9.2% of the adult population, and morbid obesity is the second leading cause of preventable death in the United States. Morbid obesity is second only to smoking on the list of preventable factors responsible for increased healthcare costs. It is a sobering thought to realize that a 40-year-old male with morbid obesity has a 12.4% reduction in life expectancy, or 9.1 years of life lost, compared with a male who is nonobese. Moreover, the cost of care is staggering and may be as high as 9% of annual medical expenditures, or $147 billion per year. There appears to be significant population heterogeneity between BMI and mortality that is attenuated by increasing age of the individual. Mortality also increases significantly even for individuals with minimal increases in BMI greater than 30.0. Thus, it appears that age, sex, race, and income level all play a role in the development of obesity and obesity-related mortality.[2]

PATHOPHYSIOLOGY AND ASSOCIATED MEDICAL PROBLEMS

The pathophysiology of severe obesity is multifactorial and has as its basis a genetic predisposition. There is a clear familial predisposition, and it is rare for a single family member to have severe obesity. Specific genes associated with obesity have been identified, including the *FTO* gene (fat mass and obesity related), which plays a role in controlling feeding behavior and energy expenditure, and the *MC4R* deficiency gene (melanocortin 4 receptor), which is associated with obesity, increased fat mass, and insulin resistance.[3]

Single gene mutations causing obesity are rare and are expressed during early childhood (Table 99.1). The most common single gene etiology of severe obesity is the *MC4R* gene, which induces appetite-suppression (anorexigenic) effects on the hypothalamus in the regulation of energy homeostasis.[3] Recent studies have suggested that the cilium of MC4R neurons in the hypothalamus is the most common pathway underlying the genetic causes of human obesity (see Table 99.1).[3]

Another theory suggests that bacteria within the gut, known as the *microbiome,* play an essential role in the metabolism and immune system. Simply giving subtherapeutic antibiotic treatment to mice for 4 weeks increases adiposity and plasma levels of insulin, leptin, and triglycerides when the mice are later fed a high-fat diet. The predilection to obesity is transferrable to other mice when the low-dose penicillin-selected gut bacteria are transferred to germ-free hosts, thus identifying that it is the action of the altered gut bacteria, not the antibiotics, that causes the obesity.[4] Recent studies have demonstrated that the gut microbiome circadian rhythm is disrupted by lifestyle differences in developed countries (shift work or jet lag), which provokes the development of altered microbial community, thus predisposing the host to obesity and glucose intolerance. Other studies have shown that degradation of dietary flavonoids through the altered microbiome results in diminished energy expenditure, which leads to obesity. It is fascinating to hypothesize that the current epidemic of obesity relates to changes in the microbiome created by the lifestyle changes and increased use of antibiotics in childhood seen in people who reside in developed countries.

Although there is no definitive answer to the pathophysiology of severe obesity, it is clear that a severely obese individual has, in general, persistent hunger that is not satiated by amounts of food that satisfy the nonobese. This lack of satiety or maintenance of hunger with corresponding increases in calorie intake may be the single most important factor in the process. There appear to be fundamental differences in the satiety and appetite hormonal control of eating that have created the current epidemic. This is hypothesized to occur when the brain's energy "set point" rises to increase energy intake through modulation of the individual's appetite.

We know that hormones, peptides, and vagal afferents to the brain have a major influence on satiety, appetite, and energy intake. Ghrelin, the only known orexigenic gut hormone, is also known as the *hunger hormone* and is secreted by P/D1 cells of the gastric fundus. Ghrelin stimulates release of various neuropeptides, such as neuropeptide Y (NPY) and growth hormone, from the hypothalamus, which creates an orexigenic, or increased appetite, state.[5] Increased levels of ghrelin produce increased food intake, and increased levels of ghrelin develop in individuals after low-calorie diets, thus suggesting that one possible mechanism for the failure of most diets after 6 months is the increase in the appetite hormone ghrelin.

One evolving concept is that the environment causes heritable change in gene function without modification of DNA sequences, termed *gene-environment interactions*. The changes in the epigenome lead to the development of obesity and are much more common than either the monogenetic or the syndromic forms of obesity.[5]

Morbid obesity is a metabolic disease associated with numerous medical problems, some of which are virtually unknown in the absence of obesity. Box 99.1 lists the most common. These problems must be carefully considered when one is contemplating offering a patient weight-reduction surgery. The most frequent problem is the combination of arthritis and degenerative joint disease, present in at least 50% of patients seeking surgery for severe obesity. The incidence of sleep apnea is high. Asthma is present in more than 25%, hypertension in more than 30%,

TABLE 99.1 **Gene Mutations Associated With Obesity**

GENE	EFFECT	ACTION ON	INHERITANCE	LINKED TO
Leptin/leptin receptor	Appetite stimulant	Hypothalamus	Autosomal recessive	Severe childhood obesity
Ghrelin receptor	Appetite stimulant	Hypothalamus	Autosomal recessive	Short stature and obesity
Melanocortin 4 receptor	Appetite inhibitor	Hypothalamus	Autosomal dominant	Increased fat mass, insulin resistance
Proopiomelanocortin (POMC)	Appetite inhibitor	Melanocortin 4 receptor in hypothalamus	Autosomal recessive	Severe early-onset obesity by age 1 and excessive eating caused by insatiable hunger
Neuropeptide Y (NPY)	Appetite stimulant	Hypothalamus	Autosomal recessive	Hypertension, high low-density lipoprotein cholesterol and triglycerides, increased food intake and hunger

BOX 99.1 Medical Conditions Associated With Severe Obesity

Cardiovascular
Hypertension
Sudden cardiac death myocardial infarction
Cardiomyopathy
Venous stasis disease
Deep venous thrombosis
Pulmonary hypertension
Right-sided heart failure

Pulmonary
Obstructive sleep apnea
Hypoventilation syndrome of obesity
Asthma

Metabolic
Metabolic syndrome (abdominal obesity, hypertension, dyslipidemia, insulin resistance)
Type 2 diabetes mellitus
Hyperlipidemia
Hypercholesterolemia
Nonalcoholic steatotic hepatitis (NASH) or nonalcoholic fatty liver disease (NAFLD)

Gastrointestinal
Gastroesophageal reflux disease
Cholelithiasis

Musculoskeletal
Degenerative joint disease
Lumbar disk disease
Osteoarthritis
Ventral hernias

Genitourinary
Stress urinary incontinence
End-stage renal disease (secondary to diabetes and hypertension)

Gynecologic
Menstrual irregularities

Skin/Integumentary System
Fungal infections
Boils, abscesses

Oncologic
Cancer of the thyroid, prostate, esophagus, kidney, stomach, colon, rectum, gallbladder, pancreas, female cancers of the breast, ovaries, cervix, and endometrium

Neurologic/Psychiatric
Pseudotumor cerebri
Depression
Low self-esteem
Stroke

Social/Societal
History of physical abuse
History of sexual abuse
Discrimination for employment
Social discrimination

diabetes in more than 20%, and gastroesophageal reflux in 20% to 30% of patients. The incidence of these conditions increases with age and the severity and duration of severe obesity.

The *metabolic syndrome* includes type 2 diabetes mellitus (insulin resistance), dyslipidemia, and hypertension. Patients with this constellation of problems are obese, with central body obesity being the primary essential feature (waist circumference >35 inches in females or >40 inches in males). The syndrome is characterized by impaired hepatic uptake of insulin, systemic hyperinsulinemia, and tissue resistance to insulin. Patients with metabolic syndrome are at high risk for early cardiovascular death.

Obesity has been shown to increase the risk of developing cancer of the thyroid, colon, rectum, esophagus, stomach, kidney, prostate, gallbladder, pancreas, breast (postmenopausal), endometrium, ovaries, and cervix.[5] There are several mechanisms that may be responsible for the increased risk of cancer. Obesity increases chronic inflammation, which is linked to the development of esophageal adenocarcinoma through chronic inflammation from gastroesophageal reflux disease (GERD). Fat produces excess levels of estrogen, which is linked to increased risk of endometrial, ovarian, and postmenopausal breast cancer. Increased levels of insulin and insulin-like growth factor-1 are hypothesized to be linked to the development of colon, prostate, kidney, endometrial, and postmenopausal breast cancer.[5]

Not listed in Box 99.1 are the associated societal discriminatory problems that severely obese individuals face. Public facilities, in terms of seating, doorways, and restroom facilities, often make access to events held in such settings unavailable to a severely obese person. Travel on public transportation is sometimes difficult, if not impossible. Employment discrimination clearly exists for these individuals. Finally, low self-esteem, a frequent history of sexual or physical abuse, and these social difficulties coalesce to create a very high incidence of depression in the population of patients with morbid obesity.

MEDICAL VERSUS SURGICAL THERAPY

Medical therapy for severe obesity historically has had limited short-term success and almost nonexistent long-term success. However, with the introduction of incretin-based therapies, which are becoming rapidly available, that may change. Nevertheless, once severely obese, the likelihood that a person will lose enough weight by dietary means alone and remain at a BMI below 35 kg/m^2 is estimated at 3% or less. The 1991 NIH consensus conference recognized that for this population of patients, medical therapy has been largely unsuccessful in treating the problem. Review of the clinical trials of lifestyle interventions for prevention of obesity demonstrated that the majority of trials were completely ineffective, and the few that were marginally effective had an extremely small impact on BMI. As the understanding of the disease of obesity has changed, and due to significant advances in medicine, the leadership of the American Society of Metabolic and Bariatric Surgery (ASMBS) and the International Federation for Surgery of Obesity and Metabolic Disorders (IFSO) reconvened in

TABLE 99.2 Results of Bariatric Surgery Compared With Medically Treated Controls

STUDY	SURGERY MORTALITY RATE	MEDICAL MORTALITY RATE	HAZARD RATIO SURGICAL REDUCTION IN MORTALITY	NOTES
Adams[10]	2.7%	4.1%	0.63 HR	Retrospective matched cohort of 7925 RYGB and 7925 severely obese control patients, mean follow-up 7.1 years
Aminian[9]	10.0%	17.8%	0.59 HR	Retrospective matched cohort of patients with diabetes, 2287 bariatric surgery and 11,435 matched control patients, 10-year follow-up
Arteburn[11]	13.8%	23.9%	0.47 HR	Veterans Affairs multisite cohort of 2500 bariatric surgery patients and 74,62 matched control patients, 10-year follow-up
Kauppilia[12]	3.6%	15.2%	0.74 HR	5 Nordic countries, population-based study of 49,977 bariatric surgery patients and 494,842 who did not have surgery, 15-year follow-up
Swedish Obesity Study[8]	22.8%	26.4%	0.77 HR	Prospective trial of 2007 bariatric surgery and 2040 matched control patients, with median 24- and 22-year follow-up, respectively

HR, Hazard ratio; *RYGB*, Roux-en-Y gastric bypass.

2022 to revise the criteria for surgery. Based on the large volume of new trials available, ASMBS and IFSO reasserted the safety, efficacy, durability, and resultant decrease in mortality associated with metabolic and bariatric surgery compared with nonoperative treatments.[6]

Although medical treatments are significantly improving, one of the most remarkable stories in modern medicine has been the absolute superiority of bariatric surgery over medical therapy for the treatment of morbid obesity and its comorbidities. In a 2021 meta-analysis, metabolic-bariatric surgery was associated with a reduction in the hazard rate of death of 49.2%, and median life expectancy increased by 6.1 years.[7] Multiple long-term follow-up trials comparing patients with morbid obesity who underwent bariatric surgery with those who did not have shown decreased mortality long term (Table 99.2).

The Swedish Obese Subjects (SOS) study is the first prospective controlled trial to provide long-term data on the effects of bariatric surgery on diabetes, cardiovascular events, cancer, and overall mortality. The study enrolled 2010 bariatric surgery patients (gastric bypass, 13%; banding, 19%; vertical banded gastroplasty, 68%) and 2037 matched controls who received standard medical treatment, and the subjects have now been observed for over 20 years. The SOS study was able to obtain follow-up on nearly 100% of the patients and found that at 20 years after initiation of the surgery, patients had a BMI reduction of 7 compared with baseline versus a small gain in the control group. The long-term sustained weight loss and reduction in comorbid conditions after bariatric surgery resulted in a 30% reduction in mortality in the bariatric surgery patients (adjusted hazard ratio [HR] = 0.70, 95% confidence interval [CI] 0.61–0.81, $p < 0.001$). The most common cause of death in the SOS study was cardiovascular diseases and cancers. The incidence of myocardial infarction was significantly reduced in the surgery group compared with the control group (HR = 0.51), and the surgery group had a lower number of first-time cardiovascular events (HR = 0.70).[8] As can be seen in Table 99.2, there are multiple studies with long-term follow-up comparing bariatric surgery to matched control groups, and these studies have found that the surgical groups have significant survival advantage (all cause, cancer, cardiovascular), associated with improvement in diabetes, obstructive sleep apnea, dyslipidemia, and hypertension.[8–12] These studies are convincing evidence that bariatric surgery provides long-term weight loss, resolution of comorbidities, and improvement in mortality. Although the SOS study found improvement in all-cause mortality after 20 years of follow-up, most procedures performed were vertical banded gastroplasty, whereas only 13% were the much more effective Roux-en-Y gastric bypass (RYGB).[8] Therefore, it is not surprising that the Adams[7] and Aminian[9] studies, which compared RYGB to medical treatment, showed convincing mortality differences as early as 3 to 5 years after surgery, much earlier than the SOS.[8] Similarly, Kauppila[12] studied 49,977 patients undergoing bariatric surgery, of which RYGB made up 73.4% of the operative procedures, compared with a cohort of obese persons in five Nordic countries and found that all-cause mortality was reduced by 4 years and improved further at 15 years. Moreover, the Arterburn study[11] was from the Veterans Affairs (VA) hospitals in the United States, so it had a predominance of males (74% male) as opposed to all of the other reported trials having a majority of females, but it also identified a reduction in all-cause mortality at 5 years. These results also hold true for older patients, who may have a higher operative mortality and shorter time to see long-term benefits (HR = 0.75, 95% CI 0.65–0.85 for patients 55–80 years of age).[13]

The driving force behind the improved mortality is likely a reduction in health-related comorbidities, particularly cardiovascular disease, cancer, and diabetes, as discussed later. A large, retrospective cohort study with 5-year postoperative follow-up demonstrated significantly lower rates of lung, ovarian, and uterine cancer in obese patients undergoing sleeve gastrectomy or RYGB compared with bariatric patients without any surgical intervention (odds ratio [OR] 0.74, 95% CI 0.643–0.859; OR 0.778, 95% CI 0.674–0.898 for sleeve gastrectomy and gastric bypass, respectively).[14] Similarly, a large retrospective study with a matched cohort of nearly 15,000 patients demonstrated that at a median follow-up of 3.9 years, surgical intervention had an absolute risk reduction in composite all-cause mortality, coronary artery events, cerebrovascular events, heart failure, nephropathy, and atrial fibrillation of 16.9% (adjusted HR = 0.61, 95% CI 0.55–0.69). On secondary analysis, the composite of all-cause mortality, myocardial infarction, and ischemic stroke was also significantly lower in the surgical group, 17.0% versus 27.6% (HR = 0.62, $p < 0.001$).[9]

Despite the objective health benefits, one perception of bariatric surgery is that it may induce profound, unalterable changes in eating that negatively affect the patients' health-related quality of life (HRQOL). A well-done 12-year prospective study by

Kolotkin et al. evaluated HRQOL changes after gastric bypass surgery compared with two nonsurgical groups matched for similar demographics. The patients who underwent bariatric surgery had greatly improved quality of life (QOL) in the physical component compared with before surgery. There were also significant differences between the surgery patients and both nonsurgical groups for both the weight-related HRQOL and the physical HRQOL. The magnitude of improvement 12 years after gastric bypass surgery compared with before surgery and between matched control groups supports the conclusion that bariatric surgery improves the patients' QOL.[15] These QOL improvements were also seen in the Swiss Multicenter Bypass or Sleeve Study (SM-BOSS) and SLEEVEPASS trials.[16,17]

However, the Kolotkin study,[15] SOS,[8] and Utah long-term study[13] all identified an increase in suicides and self-harm in patients undergoing bariatric surgery. In all studies, the numbers remain low, and the authors concluded that the absolute risk and numbers of patients do not support not offering bariatric surgery to patients. We recommend that preoperative psychiatric mental health assessment and postoperative monitoring for mental health, particularly substance abuse, are needed.

Metabolic Surgery Versus Medical Therapy for Diabetes

The Surgical Treatment and Medications Potentially Eradicate Diabetes Efficiently (STAMPEDE) trial[18] is the preeminent randomized controlled trial (RCT) to demonstrate the superiority of bariatric surgery over intensive medical therapy in type 2 diabetes mellitus. However, multiple trials have shown bariatric surgery to be more effective in glycemic control, weight loss, medication reduction, improvement in lipids, and QOL, as shown in Fig. 99.1 and summarized in Table 99.3.[18–20] Metabolic surgery reduced hemoglobin A1c (HgbA1c) by 2% to 3.5%, whereas medical therapy was only able to reduce HgbA1c by 1% to 1.5%. The short- and long-term (2- to 5- year) results shown in Table 99.3 demonstrate that a significant number of patients (29%–43%) undergoing laparoscopic RYGB (LRYGB) achieved HgbA1c levels of less than 6 compared with only 5% to 7% of medically treated patients.[18–20] These results were further corroborated in the Alliance of Randomized Trials of Medicine Versus Metabolic Surgery in Type 2 Diabetes (ARMMS-T2D) study, which included patients from multiple prior randomized trials.[21] It again demonstrated superior glycemic control, more diabetes remission, and greater change in BMI than medical/lifestyle intervention. It is even more remarkable that the medically treated patients still required intensive medical therapy, whereas the surgery patients had reduced or eliminated diabetic medications. Weight loss for both LRYGB and laparoscopic sleeve gastrectomy (LSG) was far superior to that for medical therapy.

LRYGB also improves the other associated medical conditions of the metabolic syndrome, including improvements in hypertension and high-density lipoprotein (HDL) cholesterol, which results in reduced cardiovascular events/deaths. Specifically, diabetic patients who undergo bariatric surgery have a lower rate of developing microvascular diseases. The reduced incidence of microvascular disease was largest in the reduction of retinopathy (71% reduction, OR 0.29), followed by end-stage renal disease (ESRD; 69% reduction, OR 0.31) and nephropathy (59% reduction, adjusted odds ratio [AOR] 0.31). In pooled analysis, it did not reduce diabetic neuropathy.[22] The authors of this systematic review and meta-analysis concluded that bariatric surgery significantly reduced the incidence of microvascular disease, specifically retinopathy, ESRD, and nephropathy. We argue that the additional evidence of improvement in microvascular disease encourages primary care providers to discuss the benefits of bariatric surgery with their patients with diabetes and obesity.

Glucagon-Like Peptide-1 Receptor Agonists

Medical treatment of obesity is rapidly evolving with the introduction of incretin-mimetic–based treatments, which include glucagon-like peptide-1 receptor agonists (GLP-1 RAs). These medications were initially developed to treat diabetes because they were found to stimulate insulin release in the pancreas while increasing the insulin sensitivity of pancreatic cells and inhibiting glucagon secretion. Incidentally, they have increased appetite suppression via slowed gastric emptying and act on the hypothalamus, which is involved in regulation of appetite.[23] As of May 2024, 13 GLP-1 RAs are FDA approved, 3 of which are approved specifically for obesity (liraglutide, semaglutide, and tirzepatide). Tirzepatide is also a glucose-dependent insulinotropic polypeptide (GIP) receptor agonist that can also stimulate insulin release.

Incretin-based therapies, compared with placebo, have shown promise for the treatment of obesity, with semaglutide and tirzepatide faring best. In a systematic review and meta-analysis that included the Semaglutide Treatment Effect in People with Obesity (STEP) and Study of Tirzepatide in Participants With Obesity or Overweight (SURMOUNT) trials, the placebo-subtracted difference on body weight was –15.0%; it was –12.9% with semaglutide (95% CI –14.7 to –11.1) and –19.2% (95% CI –22.2 to –16.2) with tirzepatide.[24] It is important to note that these trials were industry sponsored; that weight regain occurs after stopping medications (two-thirds of prior weight loss within 1 year); and that these medications do have side effects, most commonly nausea, vomiting, and diarrhea.[24]

The place of incretin-mimetics in our armamentarium against obesity has yet to be fully elucidated. They are indeed an excellent option in nonsurgical candidates who meet indications for use or for patients who do not desire surgery. In our practice, they are also advantageous in bridging high-BMI patients to surgery as well as in postoperative patients with inadequate weight loss or recurrent weight gain.

A recent meta-analysis evaluating liraglutide and semaglutide in post–bariatric surgery patients found that postoperative GLP-1 RA use can lead to additional weight loss. This adjuvant effect is superior with semaglutide compared with liraglutide. Semaglutide led to a mean weight loss of nearly 10%, with over 60% of patients achieving greater than 10% weight loss at 12 months.[25] As GLP-1 RA continue to get FDA approval for treatment of obesity and as new drugs hit the market, additional and improved studies will be needed to further elucidate the benefits of perioperative use of GLP-1 RA.

BARIATRIC SURGERY MECHANISM OF ACTION

The first study reporting on the effectiveness of surgery in treating obesity and related comorbid conditions, published in 1955, reported observing "the amelioration of diabetes mellitus following subtotal gastrectomy." A few decades later, the wide acceptance of bariatric surgery as treatment for severe obesity has given significant momentum to study the physiology of bariatric surgery. The initial prevailing theory behind bariatric surgery was based on two primary mechanisms for surgically induced weight loss: caloric restriction and nutrient malabsorption. There is little question that the reduction in caloric intake and resulting postoperative energy deficit is one of the factors responsible for the

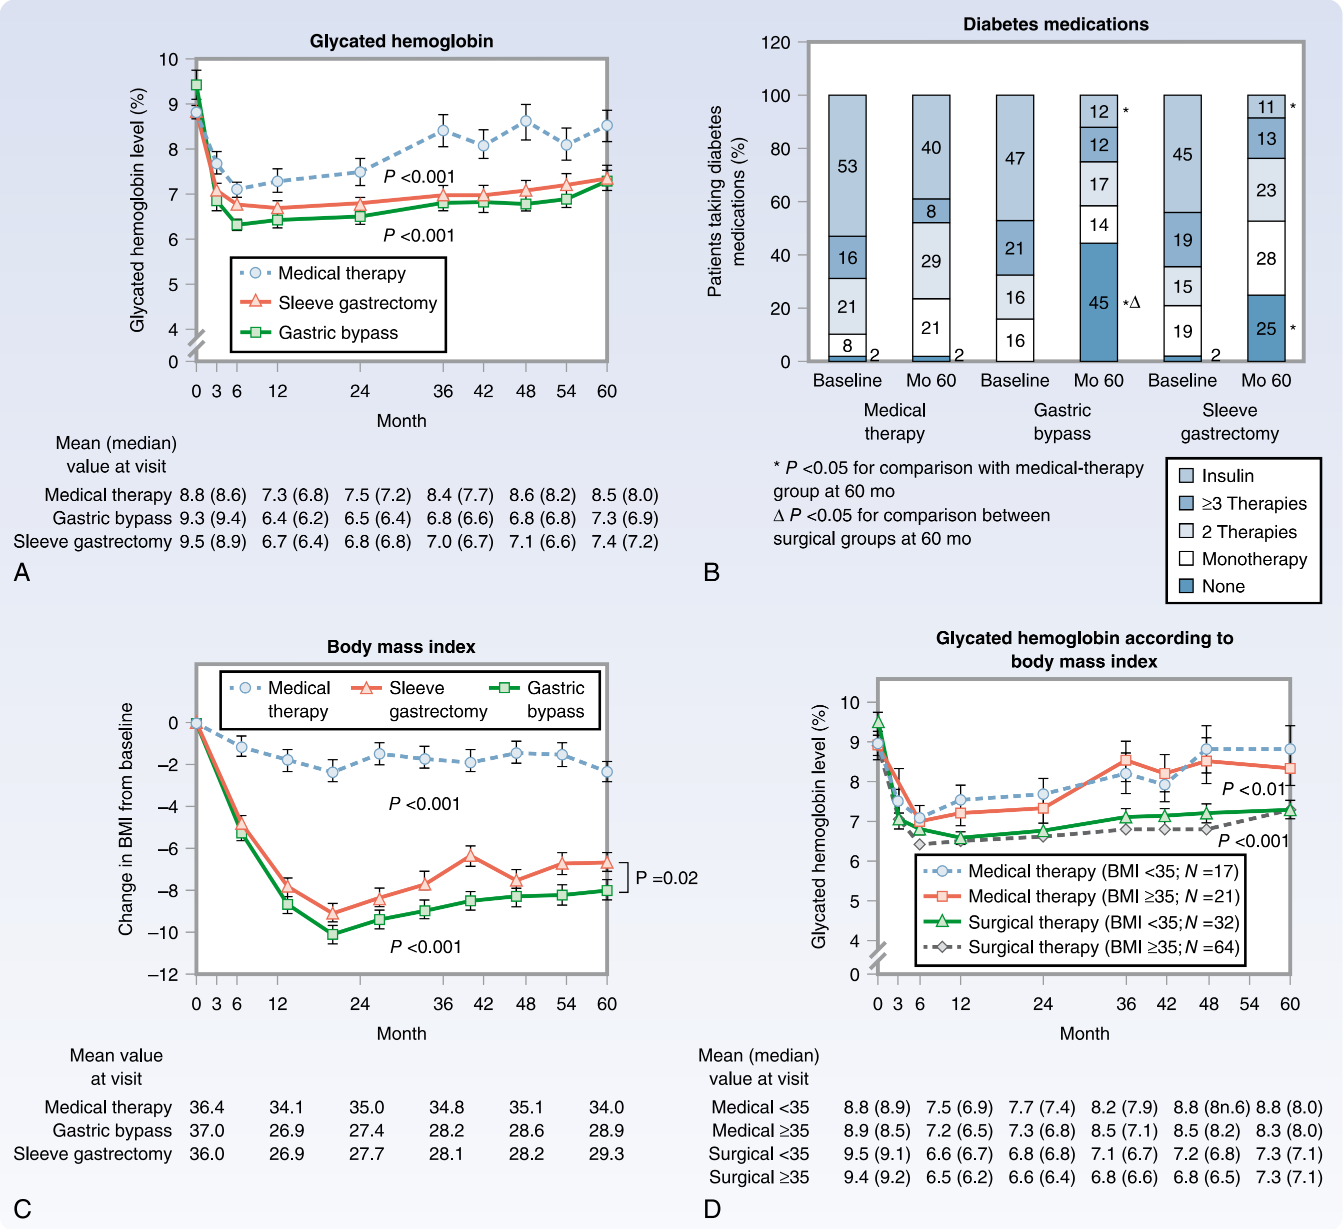

FIGURE 99.1 Mean changes in measures of diabetes control from baseline to 5 years in medical and surgically treated subjects. Shown are the mean glycated hemoglobin levels (A), the percent change in diabetes medications during the study period (B), the changes in body-mass index (BMI, the weight in kilograms divided by the square of the height in meters) (C), and the mean glycated hemoglobin levels according to BMI (D) over a 5-year period among patients receiving intensive medical therapy alone, those who underwent sleeve gastrectomy, and those who underwent a gastric bypass procedure. I bars indicate standard errors. Mean values in each group are provided below the graphs; in A and D, median values are also provided in parentheses. P values for the comparison between each surgical group and the medical-therapy group in A, C, and D were derived from overall treatment effect in the repeated measurements model. In D, $P<0.001$ for the comparison between the surgical groups and the medical-therapy group for the subgroup of patients with a BMI of less than 35; $P<0.01$ for the comparison for the subgroup with a BMI of 35 or more. *BMI*, Body mass index. (From Schauer PR, Bhatt DL, Kirwan JP, et al. Bariatric surgery versus intensive medical therapy for diabetes—5-year outcomes. *N Engl J Med.* 2017;376:641-651.)

rapid improvement in insulin sensitivity observed after RYGB and LSG. However, after taking into account the more recent scientific evidence, the concepts of restriction and malabsorption do not fully explain the metabolic effects of bariatric surgery. In fact, the mechanisms seem to extend beyond the magnitude of weight loss alone to include effects on central nervous system regulation of appetite and metabolism and improvements in insulin secretion and insulin sensitivity. Long-term weight loss, improvement in glucose metabolism, and other metabolic effects clearly result from significant postoperative changes in the **enteroencephalic** and the **enteroinsular** endocrine axes, as shown in Table 99.4.

Enteroencephalic Endocrine Axis

RYGB and LSG are known to increase satiety and reduce hunger. During the periprandial phase, the interplay between the gastrointestinal (GI) tract and the regulatory centers of the brain has been shown to activate complex neural networks to modulate food intake. In the central nervous system, the hypothalamus is the key area involved in the regulation of appetite. The hypothalamus regulates energy intake using a complex system of anorexic and orexigenic neuronal signaling. NPY is the dominant hormonal signal regulating energy intake. Release of NPY is modulated by hormones secreted into the circulation by GI cells, such as ghrelin and peptide YY (PYY).

Ghrelin is secreted into the circulation by P/D1 cells located in the fundus of the stomach. Ghrelin levels increase significantly before a meal, and levels quickly diminish postprandially. Ghrelin activates receptors in the arcuate nucleus and the lateral hypothalamus, stimulating the synthesis of NPY and agouti-related protein. This activation creates an orexigenic signal. The role of ghrelin in the post–bariatric surgery regulation of appetite has been extensively studied, sometimes with controversial results. Most studies show that ghrelin levels fall significantly after LSG. In patients who undergo RYGB, the results of various studies are contradictory, especially when they compare fasting levels. A recent cross-sectional study performed by Svane and colleagues[26] has finally provided more definitive data regarding ghrelin levels during the periprandial period in post–bariatric surgery patients. In this study, the postprandial areas under the curve (AUCs) for total and acylated ghrelin were significantly lower after LSG as compared with RYGB and controls. In addition, total ghrelin AUC was significantly lower after RYGB as compared with controls. This study provides significant evidence that anatomic changes after bariatric surgery reduce the postprandial secretion of ghrelin and thereby reduce hunger signals.

PYY is another hormone that acts on NPY neurons. L-cells found throughout the small and large intestines secrete PYY in response to the presence of nutrients within the lumen of the distal gut. PYY exerts an anorexigenic effect on NPY neurons. Svane and colleagues[26] showed that postprandial PYY levels are significantly affected by bariatric surgery. Patients after RYGB have significantly higher PYY peaks and AUCs than patients after LSG and matched controls. No difference in PYY or AUCs was observed between LSG and matched obese controls.[26]

Enteroinsular Endocrine Axis

The remission/amelioration of type 2 diabetes mellitus is considered one of the major benefits after bariatric surgery. Although the mechanisms involved in type 2 diabetes mellitus remission are not completely understood, the improved insulin action, β-cell function, and modulative effect of gut hormones in the enteroinsular axis appear to play a significant role. Among these hormones, glucagon-like peptide-1 (GLP-1) appears to be the major player. GLP-1 is released by L-cells in the distal GI tract, and levels increase in response to the presence of nutrients in the lumen of the distal or hindgut intestines. In obese subjects, there is a delay in the postprandial release of GLP-1 and, overall, significantly reduced circulating levels of the peptide.[27] GLP-1 is known to exert anorexigenic effects in obese subjects secondary to a reduction in gastric emptying. However, GLP-1 action is more predominant in the enteroinsular axis. GLP-1 is part of a family of peptides involved in the synthesis, secretion, and regulation of insulin: the incretins. In the enteroinsular axis, GLP-1 has many physiologic functions, including the stimulation of insulin secretion by the pancreas, an increase in the insulin sensitivity of pancreatic cells (α cells and β cells), and inhibition of glucagon secretion. Many studies have shown that GLP-1 is a major driver of insulin secretion after bariatric surgery. GLP-1 has been found to be consistently elevated (peak and postprandial AUC) in response to both RYGB and LSG, with significantly higher magnitude in RYGB than LSG. More important, the effect of both RYGB and LSG on postprandial GLP-1 secretion is not observed in subjects with an equivalent degree of weight loss achieved only by caloric restriction.[23] The pivotal role of GLP-1 in the metabolic changes observed after bariatric surgery was reaffirmed in a recent study focused on mechanisms of recurrent weight gain after RYGB.[28] The study demonstrated that the weight-regain group had less augmented postprandial GLP-1 response but exaggerated hyperinsulinemia compared with the sustained weight loss group. These results provide further evidence of a metabolic effect for bariatric surgery that is independent of weight loss.

PREOPERATIVE EVALUATION AND SELECTION

Eligibility

Selection of patients for bariatric surgery is based on currently accepted NIH and American Heart Association/American College of Cardiology/Obesity Society (AHA/ACC/OS) guidelines. Patients must have a BMI greater than 40 kg/m^2 without associated comorbid medical conditions or a BMI greater than 35 kg/m^2 with an associated comorbid medical problem. The ASMBS and IFSO recently updated their recommendations in 2022 to include all individuals with a BMI greater than 35 kg/m^2 regardless of presence, absence, or severity of comorbidities and noted that it should be considered in patients with a BMI of 30 to 34.9 kg/m^2 with associated comorbidity, although insurance companies have yet to adopt approval based on these newly recommended BMI parameters.[6]

In addition to BMI and comorbidities, patients must have also failed dietary and behavioral therapy. Several criteria must also be used as guidelines for indications for surgery, including psychiatric stability, motivated attitude, and ability to comprehend the nature of the operation and its resultant changes in eating behavior and lifestyle. Criteria for eligibility for bariatric surgery are given in Box 99.2. An inability to fulfill these criteria is a contraindication to bariatric surgery.

One criterion not listed in Box 99.2 that, unfortunately, is often a significant issue for a severely obese patient is insurance coverage for the operation. The Affordable Care Act (ACA) mandates that patients covered under the ACA Marketplace health plans must receive obesity screening and counseling without charging of copayment or coinsurance even if the patient has not met the yearly deductible. Remarkably, the ACA does not mandate coverage for bariatric surgery, and most federal Marketplace insurance coverage does not cover bariatric surgery, despite that the writers of the ACA wanted to prevent bias against preexisting conditions and the overwhelming evidence that bariatric surgery is the only effective modality of long-term treatment in this population. Meanwhile, medical societies recognize the need to refer severely obese individuals to bariatric surgeons, particularly for the care of patients with type 2 diabetes mellitus. In the most recent guidelines, the American Diabetes Association states: “Consider metabolic surgery as a weight and glycemic management approach in patients with BMI > 30.0 kg/m^2.”[29]

BOX 99.2 Indications for Bariatric Surgery

Patients must meet the following criteria for consideration for bariatric surgery:

- Body mass index (BMI) >35 kg/m^2 or BMI >30 kg/m^2 with an associated medical comorbidity worsened by obesity
- Failed dietary therapy
- Psychiatrically stable and without alcohol dependence or illegal drug use
- Knowledgeable about the operation and its sequelae
- Motivated individual
- Medical problems not precluding probable survival from surgery

The Centers for Medicare and Medicaid Services (CMS), the federal agency that sets Medicare guidelines, established criteria for coverage of bariatric surgery in 2006. The ruling required that only surgeons in hospitals that are designated Centers of Excellence perform bariatric surgery. As outcomes improved, in 2013 CMS removed this requirement. Yet today, the majority of bariatric procedures are performed at Metabolic and Bariatric Accredited and Quality Improvement Programs (MBSAQIPs). Accreditation, improvement in communication, and structured quality programs have been important in the improvements in quality of care. The ASMBS has recently published recommendations on credentialing of bariatric surgeons by hospitals that include the need for active participation within a structured bariatric surgery program and quality improvement program. Although hospital-wide coordination of care, communication, and multidisciplinary teams must function well to achieve best results in bariatric surgery, the technical skill of the individual surgeon is highly correlated with significantly fewer complications, readmissions, reoperations, and visits to the emergency department as well. Overall, bariatric operative mortality has declined around the world to remarkably low levels, and mortality in the United States is only 0.07%.[30] In summary, these studies show that the surgeon not only must achieve technical proficiency but also must engage the entire operative and hospital team to achieve excellent outcomes.

Medical contraindications to bariatric surgery are relative, and all patients with comorbid conditions are at greater risk. The surgeon must ensure that these risks are well understood by all patients before bariatric surgery, especially those at high risk. Ideally, several family members are included in these discussions. Surgery is also contraindicated in patients who are unable to ambulate because their level of debility precludes recovery during the phase of rapid weight loss after surgery. Prader-Willi syndrome is another absolute contraindication because no surgical therapy affects the hyperphagia that often characterizes this syndrome.

Patients who weigh more than 500 lb are at increased risk for mortality and have more complications. Many options for diagnostic testing, such as computed tomography (CT), are exceeded by this weight limit. At this weight, operating room tables, moving and lift equipment and teams, blood pressure cuffs, sequential compression device (SCD) boots, and any sort of invasive bedside procedures such as central venous catheters become extraordinarily difficult. It has been our practice to require patients weighing more than 500 lb to lose weight down to that level by nonoperative methods.

Age is a controversial consideration in bariatric surgery. For adolescents, most pediatric and bariatric surgeons recommend that the operation be performed after the major growth spurt (mid- to late teens), thus allowing increased maturity on the part of the patient. The Teen–Longitudinal Assessment of Bariatric Surgery (Teen-LABS) and multiple other studies demonstrated that severely obese teens ($<$19 years) had multiple comorbid conditions and could undergo one of three commonly performed operations (LRYGB, LSG, and laparoscopic adjustable gastric banding [LAGB]) with no mortality and a favorable short-term complication profile. Follow-up after LRYGB or LSG in the Teen-LABS study showed excellent and sustained weight loss and resolution of diabetes in 88% of patients who had type 2 diabetes mellitus at baseline at 5 years, a figure far higher than the 50% to 70% of adult bariatric surgery patients. The authors hypothesize that adults accumulate pounds-years that are less reversible than in the adolescent population. They conclude that bariatric surgery is effective at 5 years in adolescents.[31]

Although, in our practice, we have generally set the age of 65 years as a rough cutoff for performing gastric bypass and 70 years for LSG, patients older than 70 years have been individually evaluated. Such evaluations focus on the patient's level of frailty and potential for longevity rather than chronologic age. The duration and degree of obesity are the most important factors in evaluating an older patient. In general, the duration and the severity of obesity and the number of comorbid medical problems that exist lower the potential for such individuals to benefit from bariatric surgery.

General Bariatric Preoperative Evaluation and Preparation

Preoperative assessment of a bariatric surgical patient involves two distinct areas. One is a specific preoperative assessment of candidacy for bariatric surgery and evaluation for comorbid conditions. The second is a general assessment and preoperative preparation, just as for any major abdominal surgery, which is discussed in depth in Chapter 19. A team approach is required for optimal care of the patient, as shown in Box 99.3. Box 99.4 summarizes the steps and tests routinely performed for the preoperative evaluation of bariatric patients in the authors' clinics. Proper preoperative patient education is essential, and attendance at educational sessions is mandatory. After preoperative testing is completed, a final counseling session with the surgeon and an education session with the nurse educator and dietician are held.

Data support the use of preoperative antibiotics and deep venous thrombosis (DVT) prophylaxis. A first-generation cephalosporin, in a dose appropriate for weight, is given preoperatively. Bariatric surgery patients are at moderate to high risk for venous thromboembolism (VTE), and they should receive mechanical prophylaxis, such as early ambulation and use of SCDs. Most patients are at moderate or high risk for VTE, and the preponderance of data suggests that both chemoprophylaxis and mechanical measures be used based on individual assessment of clinical judgment and risk of bleeding. The Michigan Bariatric Surgery Collaborative (MBSC) identified that preoperative and postoperative use of low-molecular-weight heparin was associated with significantly lower rates of VTE compared with patients given unfractionated heparin. High-risk patients (e.g., those with history of DVT, venous stasis ulcers, known or highly suspected pulmonary hypertension, hypoventilation syndrome of obesity, or need for reoperation during the initial hospitalization) are given low-molecular-weight heparin administered twice daily for a full 2-week course.

BOX 99.3 The Bariatric Multidisciplinary Team

- Surgeon
- Assisting surgeon
- Nutritionist
- Anesthesiologist
- Operating room nurse
- Operating room scrub tech or nurse
- Nurse care coordinator or educator
- Secretary/administrator
- Psychiatrist/psychologist
- Primary care physician
- Medical specialists for cardiac, pulmonary, gastrointestinal, endocrine, musculoskeletal, and neurologic conditions as indicated

BOX 99.4 Preoperative Evaluation and Postoperative Care

Before the Clinic Visit

- Documented, medically supervised diet
- Counseling and referral from the primary care physician
- Reading a comprehensive written brochure and/or attendance at a seminar regarding operative procedures, expected results, and potential complications

Initial Clinic Visit

- Group presentation on information in the booklet
- Group presentation on preoperative and postoperative nutritional issues by the nutritionist
- Individual assessment by the surgeon's team
- Individual counseling session with the surgeon
- Individual counseling session with the nutritionist
- Screening blood tests

Subsequent Events/Evaluations

- Full psychological assessment and evaluation as indicated
- Medical specialist evaluations as indicated
- Insurance approval for coverage of the procedure
- Screening flexible upper endoscopy as indicated
- Screening ultrasound of the gallbladder (if present) as indicated
- Arterial blood gas analysis as indicated

Subsequent Clinic Visits

- Counseling session with the surgeon (including selection of the date for surgery)
- Education session with the nurse educator
- Preoperative evaluation by the anesthesiologist
- Final paperwork by the preadmissions center

Evaluation of Specific Comorbid Conditions

Cardiovascular evaluation of a bariatric patient must include a history of recent chest pain and functional assessment of activity in relation to cardiac function. Patients with a history of recent chest pain or a change in exercise tolerance need to undergo a formal cardiology assessment, including stress testing as indicated.

The prevalence of obstructive sleep apnea diagnosed using sleep studies in patients with morbid obesity ranges between 35% and 94%, and the majority of the studies identified a prevalence of greater than 60%. A history of falling asleep while driving or while at work or a history of feeling tired after a night's sleep, coupled with a history of snoring or even witnessed apnea, is strongly suggestive of the condition. Patients with suggestive histories of clinically significant sleep apnea should undergo a preoperative sleep study. If the patient is found to have sleep apnea, use of a continuous or bilevel positive airway pressure apparatus postoperatively while sleeping can eliminate the stressful periods of hypoxia that would otherwise result and has been found to reduce perioperative complications. Although tolerated under normal circumstances, these hypoxic episodes in the immediate postoperative period are more treacherous because of the enhanced effect of narcotic pain medications and postoperative fluid shifts that affect hemodynamic stability.

Reactive asthma is another common problem in this patient population and one that is underrecognized. It requires less preoperative preparation in terms of testing than sleep apnea does and is less dangerous.

Because there is an increased incidence of hypertension and diabetes in patients with concomitant renal disease, the serum creatinine value is an excellent preoperative screening test for baseline renal function.

Musculoskeletal conditions, especially arthritis and degenerative joint disease, are the most common group of comorbid diseases found in patients with severe obesity. More than half the patients have some form of these conditions, often to an advanced degree. Limited ambulation, joint replacement, severe back pain, and other sequelae are not uncommon. Before surgery, it is important for patients to understand that any preexisting structural damage cannot be reversed by weight loss. Fortunately, significant weight loss often alleviates or even eliminates the chronic pain or disability from such conditions. Significant weight loss after bariatric surgery will make subsequent knee and hip replacement surgery more effective and safer.

Metabolic problems are common in severely obese patients, particularly hyperlipidemia, hypercholesterolemia, and type 2 diabetes mellitus. All are easily screened for by simple blood tests. Of patients undergoing bariatric surgery, 20% to 30% have clinically significant type 2 diabetes mellitus. Diabetes needs to be controlled preoperatively to reduce the risk of perioperative morbidity.

The skin must be examined for fungal infection and venous stasis changes, which are associated with a greatly increased incidence of postoperative DVT. Umbilical or ventral hernias may be present. It has been our practice to postpone repair of ventral and incisional hernias until after significant weight loss. Repair of the hernias at the time of abdominoplasty enables the surgeon to complete physical reconstruction of the abdominal wall and to place prosthetic mesh to reinforce the abdominal wall, something that often cannot be accomplished during the initial bariatric procedure.

Cholelithiasis is the most prevalent of the several GI conditions, and if a history of symptomatic cholelithiasis is present, most surgeons agree that cholecystectomy needs to be performed simultaneously with the bariatric surgery. However, we do not routinely perform screening ultrasounds. Of note, the incidence of gallstone or sludge formation after gastric bypass is approximately 30%. Ursodeoxycholic acid, 300 mg twice daily for 6 months postoperatively, reduces the incidence of gallstone formation to 3% in patients who follow this treatment plan. Our current recommendations for patients undergoing laparoscopic bariatric surgery are simultaneous cholecystectomy if a history of symptomatic gallstones is present and ursodiol therapy for 6 months after surgery if the gallbladder is normal.

GERD is also common in these patients because of the increased abdominal pressure and shortened lower esophageal sphincter. Preoperative upper endoscopy is indicated in all patients who have GERD symptoms to detect Barrett esophagus and the presence of hiatal hernias and to evaluate the distal stomach in patients undergoing RYGB.

A patient with nonalcoholic steatotic hepatitis (NASH) presents a potential problem. The size of the left lobe of the liver often interferes with the surgeon's ability to complete an operation laparoscopically. Patients with known enlarged fatty livers may benefit from calorie restriction, especially carbohydrate restriction, for a period of 5 to 10 days preoperatively. Bariatric surgery is beneficial for NASH because weight loss improves the prognosis. NASH is not a contraindication to bariatric surgery if there is no cirrhosis and portal hypertension or hepatocellular decompensation. Liver biopsy should be performed at the time of bariatric surgery in any patient whose liver appears abnormal.

Special Equipment

Clinic

The clinic for evaluating bariatric patients must be constructed with the needs of the patient in mind. The waiting area must contain comfortable benches with backs, not standard-size chairs. Doorways must be extra wide to accommodate wheelchairs. This is true for bathrooms as well, which must be equipped with toilets on the floor, not mounted on the wall. A scale that can weigh up to 800 lb is necessary. Large-sized gowns, wide examining tables stable enough for large patients, and wide blood pressure cuffs are needed. A large room with appropriate seating is needed for the patient group education session.

Operating Room

The operating room should contain a hydraulically operated table that can accommodate up to 800 lb. Side attachments to widen the table as needed are required. Foam cushioning, extra-large SCD stockings, wide and secure padded straps for the abdomen and legs, and a footboard for the operating room table are all essential to safely secure the patient for placement in a steep reverse Trendelenburg position during surgery. Video telescopic equipment, as used for any laparoscopic abdominal procedure, is necessary. Two monitors, one near each shoulder, and high-flow insufflators able to maintain pneumoperitoneum are essential.

A 45-degree telescope, extra-long staplers, atraumatic graspers, extra-long trocars, and ultrasonic scalpel or other energy source instruments are essential for laparoscopic operations. A fixed retractor device secured to the operating room table for clamping and holding the liver retractor is essential. This can pose one of the most difficult technical challenges in patients with a large, thick liver.

OPERATIVE PROCEDURES

Laparoscopic Adjustable Gastric Banding

The LAGB procedure may be performed with any of multiple types of adjustable bands with similar technique; only the locking mechanisms, band shape and configuration, and adjustment schedules vary somewhat for the different types of bands. Their advantage over other bariatric procedures is individualized adjustability and a markedly lower initial operative morbidity and mortality.

Trocar placement for LAGB may vary, but typically, an 11-mm trocar is placed supraumbilically, a 15-mm trocar in the left upper quadrant, a 5-mm trocar in the left upper quadrant, and a 12-mm trocar in the right upper quadrant, with a Nathanson retractor in the epigastric region. The surgeon stands to the patient's right; the assistant and the camera operator are to the patient's left. Most surgeons place the patient in the supine position, but some prefer to have the patient's legs spread so that the surgeon can stand between the legs. The peritoneum at the angle of His is divided to create an opening in the peritoneum between the angle of His and the top of the spleen.

The pars flaccida technique has become the approach of choice for placing the adjustable band; it begins with dividing the gastrohepatic ligament in its thin area just over the caudate lobe of the liver. The anterior branch of the vagus nerve is spared, and any aberrant left hepatic artery is preserved. The base of the right crus of the diaphragm is identified. Care must be taken to definitively identify the crus because, occasionally, the vena cava can lie close to the caudate lobe. The surgeon gently follows the surface of the right crus posterior and inferior to the esophagus while aiming for the angle of His (Fig. 99.2A). A gentle spreading and pushing technique is used to create a tunnel along this generally avascular plane. Once the tip of the tunneling instrument is seen near the superior pole of the spleen, it is gently pushed through any remaining peritoneal layers to complete the tunnel. The adjustable band has already been placed in the peritoneal cavity through the large 15-mm trocar located in the right upper quadrant before dissection of the pars flaccida. The narrow end of the band itself is grasped by the tunneling instrument and pulled through the tunnel from the greater to the lesser side of the stomach (see Fig. 99.2B). That end is then threaded through the locking mechanism of the band, after which the band is locked. Once the band has been locked in place, the buckle is adjusted to lie on the lesser curvature side of the stomach (see Fig. 99.2C). A 5-mm grasper inserted between the band and stomach ensures that the band is not too tight.

The anterior gastric wall is plicated over the band with three or four interrupted, nonabsorbable sutures (see Fig. 99.2D). There needs to be just enough stomach above the level of the band for incorporating that tissue into the suture. Suturing is carried as far posterolaterally as possible because this region has been the most frequent area of fundus herniation through the band. The band is thus ideally secured about 1 cm below the gastroesophageal junction with this technique.

The Silastic tubing leading from the band is pulled through the 15-mm trocar site in the right upper quadrant paramedian area to complete the laparoscopic portion of the operation. The trocar site incision is enlarged to reveal the anterior rectus fascia, which is exposed approximately 2 to 4 cm lateral to the existing fascial defect for the trocar, and the access port is connected to the inflation tubing. Four sutures inserted through the four holes on the access port are placed in the fascia, after which the port is tied to the fascia. The redundant tubing is replaced in the abdominal cavity, with care taken to avoid kinking.

Roux-en-Y Gastric Bypass

The gastric bypass first described by Mason and Ito in 1969 incorporated a loop of jejunum anastomosed to a proximal gastric pouch.

This operation proved unacceptable because of bile reflux, and RYGB, which eliminates bile reflux, has become one of the most commonly performed bariatric operations in the United States.

Described here is one technique that incorporates many of these modifications. There are certainly many variations of this technique, and many, if not most, will give excellent results. The essential principles of the operation are listed in Table 99.5.

The left subcostal region, near the midclavicular line, is an ideal location for the first trocar. Either a bladed trocar (United States Surgical Corporation, Norwalk, CT) or an optical trocar (Optiview, Ethicon Endo-Surgery, Cincinnati, OH) that dilates a tract under direct vision is placed. Subsequent trocars are placed under laparoscopic vision to achieve the configuration shown in Fig. 99.3.

Once the omentum is mobilized, the ligament of Treitz is identified. A location approximately 50 cm distal to the ligament is chosen for division of the jejunum with an endoscopic stapler (Fig. 99.4). The mesentery is then further divided with staples or a harmonic scalpel.

The length of the Roux limb is influenced in our practices by the patient's weight. Patients with a BMI in the 40s will be well served with a Roux limb of 100 cm, whereas a Roux limb of approximately 150 cm is constructed for patients with a BMI in excess of 50. The

TABLE 99.5 Technical Considerations During Laparoscopic Roux-en-Y Gastric Bypass

TECHNIQUE	RECOMMENDATION	RATIONALE
Pouch size	15–20 mL	Smaller pouch reduces marginal ulceration and is associated with improved long-term weight loss
Method of gastrojejunostomy	No difference in techniques between circular stapler, linear cutter, or hand-sewn	Although the circular stapler is the most common technique, all have similar outcomes. Biggest difference is skill and efficiency of the surgeon.
Operative time	Faster surgical procedures associated with reduced complications	Surgical skill and efficiency trump all other factors when comparing, adjusting for patient characteristics.
Mesenteric defects	Closure of all mesenteric defects with nonabsorbable sutures	Marked reduction in internal hernia formation requiring surgical correction
Antecolic or retrocolic Roux limb	Antecolic	The antecolic is technically easier and reduces the number of mesenteric defects from three to one; the Roux limb is at least 75 cm in length
Fibrin sealant	Use fibrin sealant	Associated in some studies with reduced leak rates

proximal jejunum is left to lay to the patient's right side, and the Roux limb is lifted cephalad and coiled in the curve of the transverse colon mesentery (Fig. 99.5). This technique allows the proximal jejunum to be aligned directly alongside the designated point on the Roux limb for the distal anastomosis. The stapler is placed through the surgeon's right-hand port because the bowel segments are easily aligned to facilitate placement of the stapler into enterotomies created in each segment of bowel at the desired location of the anastomosis (Fig. 99.6). Another firing of the stapler, this time from the left side of the patient, creates a large side-to-side anastomosis. Once the anastomosis is created, the stapler defect is closed with another fire of the stapler.

The left lobe liver retractor is now placed, and the patient is placed in the reverse Trendelenburg position. Exposure of the angle of His allows division of the peritoneum between the top of the spleen and the gastroesophageal junction with the ultrasonic scalpel. The lesser sac is entered through the gastrohepatic ligament, 3 to 4 cm below the gastroesophageal junction. The linear stapler is now fired multiple times to create a 20- to 30-mL proximal gastric pouch based on the upper lesser curvature of the stomach (Fig. 99.7). Once the gastric pouch is created, the Roux limb may be passed toward the proximal gastric pouch through a retrocolic or antecolic pathway. The antecolic, antegastric approach is preferred to prevent the risk of an internal hernia through the transverse mesocolon or a hernia formed by the transverse mesocolon and the mesentery of the Roux limb in the retrocolic approach. The gastrojejunostomy may be performed with a circular stapler (Fig. 99.8), a hand-sutured technique, or a linear stapler oversewing the common enterotomy. The entire anastomosis is irrigated with saline, and a member of the operative team uses the endoscope to monitor occlusion of the Roux limb with an atraumatic 10-mm bowel clamp. Even the smallest leaks of air can be identified and closed with this technique. Studies have shown that use of this technique can dramatically reduce the incidence of postoperative leaks to very low levels. The mesenteric defect in the jejunojejunostomy is closed with a purse-string suture of 2-0 polypropylene, and Petersen's defect (between the Roux limb mesentery and the transverse mesocolon) is closed

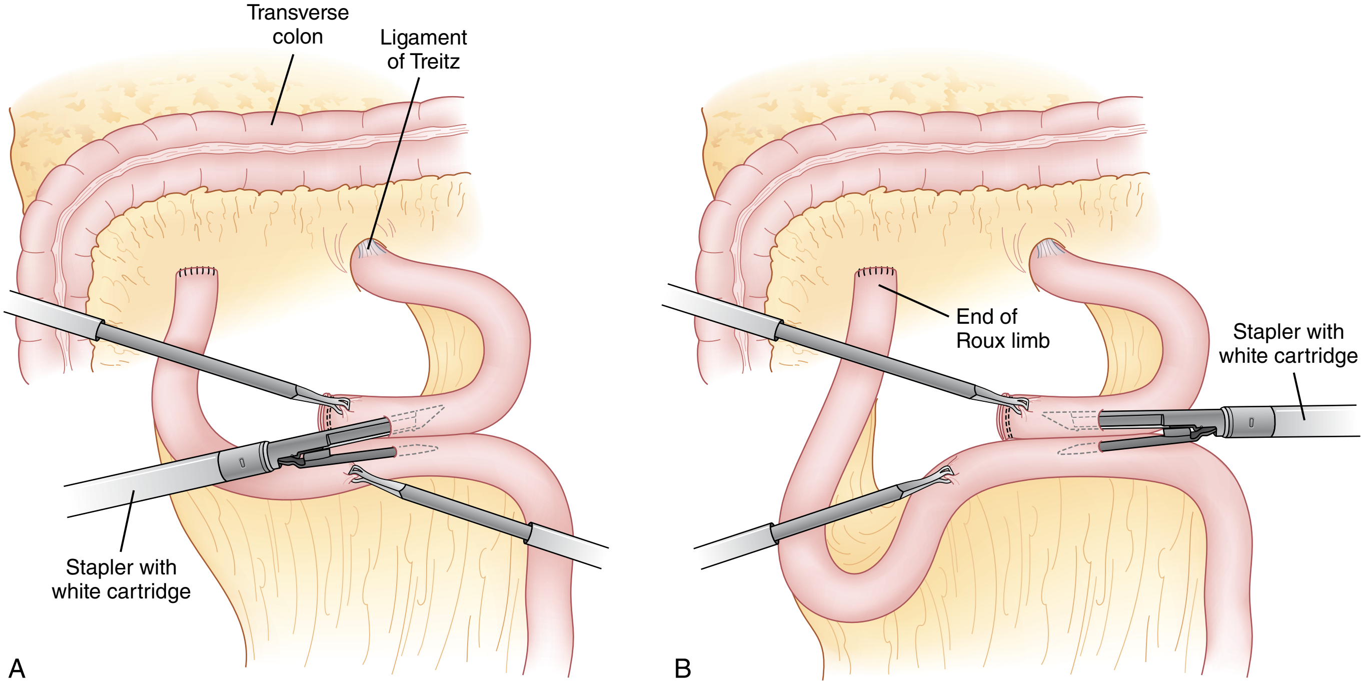

FIGURE 99.6 Placing the stapler to create an enteroenterostomy. (A) The surgeon uses the 60-mm linear stapler to create the jejunojejunostomy between the biliopancreatic limb and the Roux limb. (B) The first assistant uses the 60-mm linear stapler to create a larger jejunojejunostomy. Not shown is the closure of the enterotomy using the 60-mm linear cutter as the final step.

with a purse-string suture of 2-0 silk; defect closure has significantly reduced internal hernia rates (Fig. 99.9; see Table 99.5).

Biliopancreatic Diversion

Biliopancreatic diversion (BPD), like most bariatric operations that had been performed through an open approach, can be performed through a laparoscopic approach. BPD produces weight loss primarily based on malabsorption, but it does have a restrictive component as well.

The anatomic configuration of BPD is shown in Fig. 99.10. The intestinal tract is reconstructed to allow only a short, so-called common channel of the distal 50 cm of terminal ileum for absorption of fat and protein. The alimentary tract beyond the proximal part of the stomach is rearranged to include only the distal 200 cm of ileum, including the common channel. The proximal end of this ileum is anastomosed to the proximal end of the stomach after a distal hemigastrectomy is performed. The ileum proximal to the end that is anastomosed to the stomach is in turn anastomosed to the terminal ileum within the 50- to 100-cm distance from the ileocecal valve, depending on the surgeon's preference and the patient's size. This procedure is very rarely performed today and is included for historical and educational context.

Biliopancreatic Diversion With Duodenal Switch

The biliopancreatic diversion with duodenal switch (BPD-DS) configuration is shown in Fig. 99.11. This modification was developed to help lessen the high incidence of marginal ulcers after BPD. The mechanism of weight loss is similar to that of BPD.

The first step is measurement of the terminal ileum. Notably, in the BPD-DS procedure, the common channel is 200 cm, and the entire alimentary tract is 350 cm. However, the major difference between BPD-DS and BPD is the gastrectomy and pyloric preservation. Instead of a distal hemigastrectomy, a sleeve gastrectomy is performed. This procedure is done as the initial part of the operation because if the patient exhibits any intraoperative instability, the operation can be discontinued after the LSG alone. A two-stage BPD-DS has been used in patients who have an extremely high BMI and are high operative risks. The LSG alone usually produces enough weight loss to make the second stage of the operation technically easier. This approach lowers the mortality rate despite the need to undergo two operative procedures. The first step of a laparoscopic BPD-DS is to perform the LSG with a stapling technique that begins at the mid-antrum, and a staple line is created parallel to the lesser curvature of the stomach with a 40- to 60-Fr Maloney dilator placed along the lesser curve to prevent narrowing. The staple line is created with multiple firings of the stapler until the angle of His is reached. The goal is to produce a lesser curvature gastric sleeve with a volume of 150 to 200 mL.

After LSG, the duodenum is divided with the stapler approximately 2 cm beyond the pylorus. The distal connections are performed as for BPD. The distal anastomosis is created at the 200-cm point proximal to the ileocecal valve. The proximal anastomosis is created between the proximal end of the 350 cm of terminal ileum and the first portion of the duodenum (creating a 150-cm alimentary limb, a 100- to 200-cm common channel, and an unmeasured biliopancreatic limb). The duodenoileostomy is an antecolic end-to-side anastomosis. This anastomosis is one of the most critical parts of the operation and can be performed either with a circular stapler or using a hand-sewn technique. If the end-to-end anastomosis (EEA) stapler is used, the anvil is directly inserted through the staple line of the duodenal stump through a gastrostomy under suture guidance or through an oral approach with a nasogastric tube.

Single Anastomosis Duodenal-Ileal Bypass With Sleeve Gastrectomy

The single anastomosis duodenal-ileal bypass with sleeve gastrectomy (SADI-S) is shown in Fig. 99.12. This modification was developed to help decrease the postoperative complications of vitamin deficiencies and malnutrition that can occur with the BPD-DS.

Port placement depends on whether a laparoscopic or robotic-assisted technique is used. For robotic-assisted SADI-S, which is our approach, we use a 12-mm port in the right mid-abdomen, 8-mm port in the left periumbilical position for the camera, 8-mm port in the left lateral abdomen, 12-mm port in the left

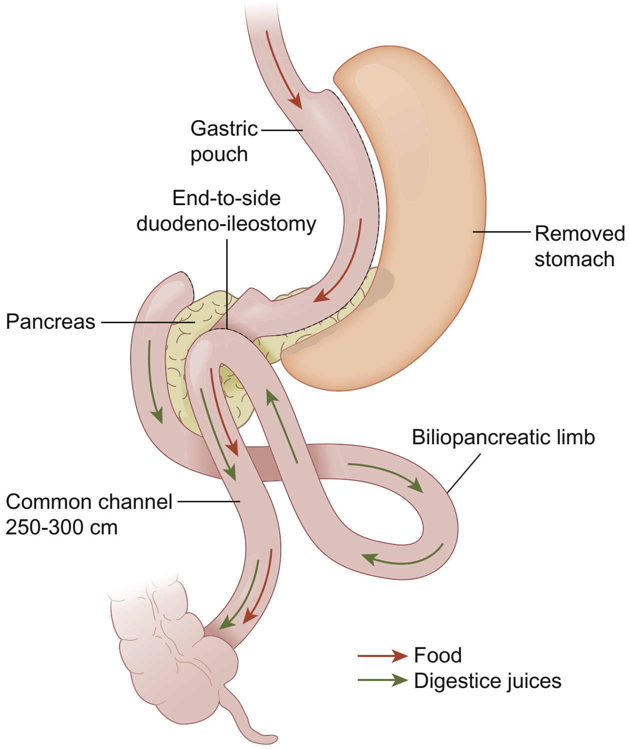

FIGURE 99.12 Anatomic configuration of the single anastomosis duodenal-ileal bypass with sleeve gastrectomy. (https://www.summahealth.org/medicalservices/weight-loss/weight-loss-surgery-options.)

hemi-abdomen between the two 8-mm ports, and a 12-mm port in the right lateral abdomen for assistance. The first step of the procedure is measurement from the terminal ileum. In the SADI-S, the common channel is typically 250 to 350 cm, and the biliopancreatic limb is unmeasured. Next, the sleeve gastrectomy is performed as described earlier. This is done by first taking down the omentum from the greater curve of the stomach with a vessel sealing device. A 38- to 40-Fr bougie is then used to loosely size the sleeve, and the stomach is divided from 5 cm proximal to the incisura to the angle of His by sequential firings of a reinforced stapling device. The greater omentum is then taken down distally past the antrum. The first part of the duodenum is circumferentially dissected and transected approximately 3 cm distal to the pylorus. The marked ileum is then brought up into the duodenum, and enterotomies are made in both the duodenum and ileum. It is important to ensure there is no twisting of the ileal mesentery before the anastomosis is completed. An antecolic end-to-side duodenoileostomy is then created. We hand-sew the anastomosis with absorbable suture (posteriorly in two layers, anteriorly in one layer). This can alternatively be completed with a circular or linear stapler. We perform an upper endoscopy and air-leak test to ensure the integrity of the anastomosis.

Laparoscopic Sleeve Gastrectomy

LSG is now recognized as a primary procedure, and a *Current Procedural Terminology* code was assigned to the procedure in 2010. From 2008–17, there was a precipitous increase in the number of LSG procedures (0.9%–59.4% of the total number of bariatric procedures), which is approximately the current percentage of bariatric procedures performed in the United States (Table 99.6).[32] Advantages of LSG are the technical simplicity of the procedure, preservation of the pylorus (avoidance of dumping), metabolic reduction of ghrelin levels, no need for serial adjustments (as for LAGB), reduction in internal hernias (seen after LRYGB, BPD-DS, and SADI-S), reduction in malabsorption (seen with LRYGB, BPD-DS, and SADI-S), and ability to later modify the gastric sleeve to either an LRYGB or a BPD-DS configuration in a second stage of the operation. The trocar placement can be identical to that of LRYGB (see Fig. 99.3). We now often use a 5-mm trocar in the left upper quadrant, a 5-mm trocar left of the umbilicus, a 15-mm trocar right of the umbilicus, and a 5-mm trocar in the right upper quadrant, with a Nathanson retractor placed via an epigastric incision. As a primary procedure, the surgeon takes down the entire greater curvature, leaving intact the tissue within 3 to 5 cm of the pylorus and up to the angle of His and exposing the left crus of the diaphragm. Then, using a 38- or 40-Fr bougie, the stomach is divided from the antrum to

the angle of His by sequential firings of the stapler (Fig. 99.13). It is vitally important in this procedure to preserve the left gastric vessels and lesser curve blood supply and prevent twisting or spiraling of the gastric tube. Major controversy exists about techniques to reinforce the staple line to prevent bleeding or leaks from the staple line (Table 99.7).

POSTOPERATIVE CARE AND FOLLOW-UP

Laparoscopic Adjustable Gastric Banding

Patients undergoing LAGB experience an operation that may last as little as 1 hour in experienced hands. Same-day discharge is the norm. The band is initially placed without adding any saline to distend it. Saline is added in 1.0- to 1.5-mL increments to produce a desired weight loss of 1 to 2 kg/week. Excess weight loss (EWL) may lead to actual removal of a small amount of saline, whereas inadequate weight loss is an indication for the addition of more saline to the system to increase the restriction of the band. The incidence of nutritional deficiencies is low after LAGB because there is no disruption of the normal GI tract. Slippage of the lap band can result in acute strangulation of the stomach, necessitating emergency surgical removal of the band, but is more likely to present with symptoms of dysphagia, regurgitation, heartburn, and aspiration. Plain abdominal radiographs show that the normally located 7 o'clock to 2 o'clock band position is either vertical or horizontal. Barium swallow demonstrates a slip of the band, which should be followed by either explantation or revision.

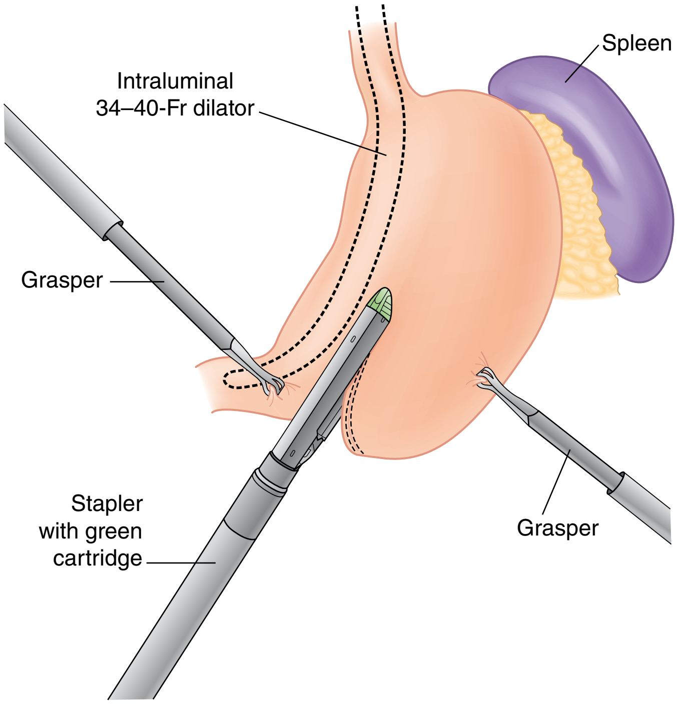

FIGURE 99.13 Creation of the sleeve gastrectomy.

Roux-en-Y Gastric Bypass, Biliopancreatic Diversion With Duodenal Switch, Single Anastomosis Duodenal-Ileal Bypass With Sleeve Gastrectomy, and Laparoscopic Sleeve Gastrectomy

Excellent surgical outcomes require the appropriate selection of patients, thorough preoperative preparation, technically well-performed operations, and attentive postoperative care. A bariatric patient requires particularly attentive postoperative care in several areas above and beyond that of the average surgical patient. The most dreaded complication after bariatric surgery is a leak from the GI tract. Tachycardia, at times accompanied by tachypnea or agitation, is often the only manifestation of this severe intraabdominal problem. A severely obese patient may not be subject to the development of fever or signs of peritonitis, as would a patient with a normal body habitus. A high index of suspicion for leak must be present for postoperative patients who demonstrate sustained tachycardia, fever, or increased pain. If a leak is suggested, a CT scan with oral administration of a contrast agent, upper GI swallow, or possibly laparoscopy may be needed to establish the diagnosis before overwhelming sepsis occurs.

Patients undergoing laparoscopic surgery usually have much less third space and operative blood loss than patients undergoing open surgery and can be managed with 4 mL/kg/hour of intravenous (IV) fluids. Urine output intraoperatively is normally low because of the pneumoperitoneum and usually improves in the recovery room area. Some patients who have been taking diuretics chronically may not produce adequate urine output without diuretic use, but the surgeon must ensure that the patient is adequately volume resuscitated before giving diuretics. Higher-than-expected fluid requirements, oliguria, and tachycardia are a constellation of postoperative findings suggesting intraabdominal problems.

Adequate pain control is essential via a multimodal approach. An Enhanced Recovery After Surgery (ERAS) protocol is recommended. We use IV acetaminophen followed by a scheduled PO regimen. We also use an additional scheduled nonnarcotic agent, such as pregabalin or gabapentin, and an as-needed (pro re nata [PRN]) narcotic (e.g., oxycodone). We recommend avoiding a patient-controlled analgesia pump.

Care pathways and ERAS protocols have been implemented in bariatric surgery, emphasizing nonnarcotic multimodality pain control, limitation of IV fluids, and early ambulation. One-night hospitalization and discharge on a bariatric full liquid diet are routine for patients undergoing LSG and RYGB and for some experienced clinicians performing BPD-DS and SADI-S.

TABLE 99.7 Technical Considerations During Laparoscopic Sleeve Gastrectomy

TECHNIQUE	RECOMMENDATION	RATIONALE
Bougie size	34–40 Fr	Smaller bougie size associated with gastroesophageal reflux disease Larger associated with weight regain
Staple line extent	5 cm proximal to the pylorus	Improved long-term weight loss; do not narrow the incisura
Staple line reinforcement	Surgeon preference	Some studies show increase in leak rate with staple line reinforcement but decrease in bleeding complications

BARIATRIC SURGERY RESULTS

Across the world, bariatric surgery has improved results, with declines over time in operative mortality, hospital stay, and postoperative morbidity. In the United States, Europe, and Asia, operative mortality is nil for LAGB, and the operative mortality for LRYGB and sleeve gastrectomy has fallen to under 0.1%, coming up against operative mortality associated with many other common procedures, such as laparoscopic cholecystectomy or joint replacement (Table 99.8).[33–35] Moreover, a large series reviewing the outcomes in countries or healthcare systems shows that there are significant reductions in comorbidities (diabetes, hypertension, dyslipidemia, sleep apnea, asthma, arthritis, and GERD) and an increase in weight-related QOL and physical HRQOL scores.[11,12,15,36,37]

Laparoscopic Adjustable Gastric Banding

As can be seen in Table 99.6, lap band operations rapidly increased in the early 2000s, peaked in 2011, and declined to 2.8% in 2017, largely secondary to a high rate of reinterventions and inadequate weight loss.[32] During the early 2000s, laparoscopic gastric bypass was associated with high mortality and complication rates, so a number of surgeons adopted the lap band procedure as a much simpler procedure with a dramatically lower morbidity and mortality rate. The early results with lap band were almost uniformly excellent, with modest weight loss and very little morbidity or mortality. Results of the LAGB procedure show no 30-day mortality and reasonable weight loss, as shown in Table 99.8, in select centers.[33,34]

Roux-en-Y Gastric Bypass

RYGB has an established record of accomplishment that is longer than that of any other bariatric operation. Its performance has been modified over the years, and the results presented in Table 99.9 reflect data from studies in the era of its performance as a laparoscopic procedure. Resolution of comorbid conditions after LRYGB has been excellent and sustained in long-term studies, as demonstrated in Table 99.9.[36,37] It has been commonly thought that gastric bypass has been associated with higher morbidity and mortality in older individuals and that older individuals would not benefit from surgery long term. However, Adams and colleagues identified a reduction in long-term mortality in older patients (55–80 years of age) when the patients were operated on at a center specializing in bariatric surgery. The demonstration of acceptable morbidity and mortality in older individuals, coupled with improvements in long-term survival, has led most bariatric surgeons to consider operating on older individuals if they meet criteria for operation.

Another important advantage of LRYGB is a decrease in the incidence of wound complications and incisional hernia seen after open RYGB. Long-term follow-up of a prospective randomized trial comparing laparoscopic and open gastric bypass found a much higher rate of incisional hernias in the open-surgery group. There was, however, no difference in the rate of resolution of comorbid conditions or weight loss between the two procedures. The duration of hospitalization has decreased in all patients undergoing RYGB. Patients undergoing LRYGB are usually hospitalized for, on average, 1 night.

RYGB has also been shown to resolve the symptoms of pseudotumor cerebri as well as to cure the difficult problem of venous stasis ulcers. Immediate resolution of symptoms of GERD occurs in more than 90% of cases. The extremely small gastric pouch has a limited reservoir for holding gastric juice, and the cardia is a low-acid-producing area of the stomach, so the Roux-en-Y reconstruction diverts gastric acid away from the esophagus immediately after surgery, thus accounting for its efficacy in alleviating heartburn.

Age has been shown previously to be an important determinant of operative morbidity and mortality. However, a matched-pair analysis of the MBSAQIP database of 3371 patients older than age 60 years matched to 3371 patients younger than 60 with similar BMI and comorbidities showed that there was comparable mortality between older individuals and younger individuals in both LSG and LRYGB. These data should not be misinterpreted to mean that older individuals have the same mortality risk as younger ones but to suggest that the surgeon can identify older patients most likely to benefit from bariatric surgery and can expect good short- and long-term outcomes.[38]

Biliopancreatic Diversion With Duodenal Switch and Single Anastomosis Duodenal-Ileal Bypass With Sleeve Gastrectomy

Most malabsorptive procedures performed in the United States are the DS modification of BPD or the SADI-S, so this section discusses the results of both operations. EWL (65%–80%) after BPD/DS and SADI-S is the highest of the bariatric operations discussed in this chapter, with a slightly higher EWL in the BPD/DS group. BPD/DS and SADI-S have been highly effective in treating comorbid conditions, including hypertension (remission >80%), diabetes (remission >85%%), lipid disorders (remission >75%), GERD (remission >75%), and obstructive sleep apnea (remission >80%).[35,39]

Thus, some surgeons argue that superobese patients maintain weight loss better in the long term after undergoing BPD/DS or SADI-S than after other bariatric operations. Others point out that serious complications, such as deficiency in vitamin D, vitamin K, and zinc; reoperation for correction of protein malnutrition, hernia, or bowel obstruction; and overall morbidity are much higher with BPD/DS; therefore, the incremental improvements in EWL are not justified. However, many of these complications are slightly lower with the SADI-S. Outcomes between BPD/DS and SADI-S are compared in Table 99.10.

After BPD/DS and SADI-S, patients typically have between two and four bowel movements per day. Excessive flatulence and foul-smelling stools are common. Malabsorption of starch and fat provides the major mechanism of weight loss and creates vitamin deficiencies in fat-soluble vitamins (K, A, D, and E).

Surgeons caring for these patients must be alert to measure protein levels for confirmation of adequate absorption. When protein malnutrition does occur, the common channel may need to be lengthened with a reoperation. This is less common with the SADI-S because of the longer common channel. Patients must also be aware that their ability to absorb simple sugars, alcohol, and short-chain triglycerides is good and that overindulgence in sweets, milk products, soft drinks, alcohol, and fruit may produce excess weight gain.

Major considerations for achieving excellent results in patients offered BPD/DS include the ability to monitor these patients and to confirm that they are compliant with the recommendations to take appropriate vitamin supplements. Supplements include multivitamins as well as at least 2 g of oral calcium per day. Supplemental fat-soluble vitamins, including D, K, and A, are indicated monthly as well.

Laparoscopic Sleeve Gastrectomy

Advantages of LSG are the technical ease of the procedure, induction of satiety through reduction in ghrelin levels, reduced need for postoperative adjustments as opposed to LAGB, preservation of the pylorus and avoidance of dumping, reduced risk of malabsorption, and apparent safety of the procedure in high-risk individuals. Use of LSG is advantageous for some populations of patients, as outlined in Table 99.11.[16–18]

TABLE 99.12 Comparison of Laparoscopic Sleeve Gastrectomy Versus Laparoscopic Roux-en-Y Gastric Bypass: 5-Year Outcomes in the SLEEVEPASS and SM-BOSS Randomized Trials

MEASURE	LSG	LRYGB	COMMENTS
Percentage excess weight loss	49%	57%	LRYGB had more weight loss but not statistically significant
BMI at 5 years (kg/m^2)	31.6–36.5	32.5–35.4	No significant difference between procedures
Remission of type 2 diabetes mellitus	12%–61.5%	25%–67.9%	No significant differences
Remission of hypertension	29%–62.5%	51%–70.3%	LRYGB in the SLEEVEPASS trial had increased remission rate
LDL cholesterol (mg/dL)	104.3–116.1	96.5–101.1	LDL level significantly lower after LRYGB
Quality of life (QOL)	Improved	Improved	Both procedures improved QOL
Remission of GERD	25%	60.4%	LRYGB associated with greater remission of GERD; in the SLEEVEPASS trial, 7/10 reoperations were done for severe reflux
Late complications	14.9%–19%	17.3%–26%	No difference between techniques

BMI, Body mass index; *GERD*, gastroesophageal reflux disease; *LDL*, low-density lipoprotein; *LRYGB*, laparoscopic Roux-en-Y gastric bypass; *LSG*, laparoscopic sleeve gastrectomy; *SM-BOSS,* Swiss Multicentre Bypass or Sleeve Study.

LSG was developed because of a high incidence of morbidity and mortality (23% and 7%, respectively) in patients with a BMI greater than 60 kg/m^2 undergoing laparoscopic DS. Surgeons developed the two-stage DS, with sleeve gastrectomy alone performed as the first stage to decrease morbidity in this population of superobese patients. The Clinical Issues Committee of the ASMBS performed a comprehensive review of the subject, which demonstrated a lower rate of complications for DS in this population of high-risk patients (leak rate of 1.2%, bleeding rate of 1.6%, and mortality of 0.24%). The ASMBS concluded that LSG could be used in high-risk patients to reduce perioperative complications and also to induce weight loss as a standalone procedure. Modifications to LSG, including reduced bougie size and extension of the LSG into the antrum, made LSG a primary bariatric procedure.

Five-year results after LSG in the STAMPEDE trial show good weight loss (−18.6% baseline) and remission of diabetes in 23.4% (Table 99.12).[18] O'Brien reported the collective series of LSG across the globe and reported a weighted mean of 58.3% EWL after LSG.[34] Two excellent RCTs give us comparative data on the outcomes 5 years after LSG and LRYGB, as shown in Table 99.12. The SLEEVEPASS trial shows that LRYGB has a greater percentage of weight loss than LSG (57% vs. 49%), but there was no statistically significant difference in HgbA1c (6.6% vs. 6.6%), dyslipidemia, QOL improvement, and late morbidity. There was a significant improvement in the resolution of hypertension based on medication use in LRYGB (51% vs. 29% resolution).[17] The Swiss Multicentre Bypass or Sleeve Study (SM-BOSS) randomized trial found no significant difference in percentage of BMI loss (68.3% vs. 61.1%), complete remission of type 2 diabetes mellitus (67.9% vs. 61.5%), hypertension remission (70.3% vs. 62.5%), improvement in QOL, or late complications (see Table 99.12).[16]

COMPLICATIONS OF BARIATRIC SURGERY

The various procedures are associated with complications that can occur with any intraabdominal operation. However, each operation has unique complications as well as different incidences of some of the shared common complications seen after any abdominal operation.

It is now well accepted that laparoscopic and robotic procedures are much safer than open gastric bypass in 30-day mortality (e.g., overall complication rates, surgical site infection, and pulmonary complications). The benefits touted for laparoscopic surgery go beyond the cosmetic benefits and really do influence postoperative complication rates, which makes the laparoscopic or robotic technique our preferred approach in every patient, including reoperative operations.

Laparoscopic Adjustable Gastric Banding

Although many centers have shown a very low (approaching zero) 30-day morbidity and mortality rate, long-term complications such as esophageal dilation, lap band slippage, lap band erosion, and failure to lose weight have been the Achilles heel of this operation. High-resolution manometry of the esophagus in patients who present for LAGB removal has shown that three-fourths of patients have abnormal esophageal peristalsis, including simultaneous or failed peristalsis. It has been noted that removal of the lap band in patients who have developed pseudoachalasia or megaesophagus will improve; therefore, surgeons should be vigilant regarding patients with lap bands who might have either a slip or significant esophageal motility disorders who need deflation and/or explantation of the band.

The 10-year outcomes of a prospective randomized trial of LAGB versus LRYGB demonstrated poor long-term weight loss with the LAGB procedure (LAGB 27.4 kg vs. LRYGB 42.4 kg), higher reoperation rate (LAGB 31.4% vs. LRYGB 8.1%), and lower rate of remission of comorbidities.[40] The natural history of LAGB was defined by a study of the French standardized national database of 53,000 patients, which demonstrated that 20% of the 52,868 patients underwent removal of the band, and by 7 years, 71% of the patients underwent revisional surgery. Many of the revisional procedures were conversions to either LSG or LRYGB for either lap band slippage or failure of weight loss with LAGB. The authors of the French study questioned whether the lap band was a viable procedure given the high rate of removal and complications.[41]

Although a few centers that specialize in LAGB have demonstrated much lower reoperation rates with much improved durable weight loss, the authors of this chapter no longer offer LAGB in their practices because the current surgical practices of LSG and LRYGB have low morbidity, much improved long-term weight loss, and improved resolution of comorbidity.

Roux-en-Y Gastric Bypass

The laparoscopic revolution has fundamentally changed the outcomes of many surgical procedures, but in particular, it has reduced operative mortality and morbidity significantly. The

TABLE 99.13 **Complications After Laparoscopic Roux-en-Y Gastric Bypass**

CRITERIA	COURCOULAS[37]	KUMAR[42]	CLAPP[43]

NR, Not reported.

most recently reported mortality rates after LRYGB have generally been in the 0.1% to 0.3% range for a large series, as shown in Table 99.13.

Mortality rates are influenced heavily by patient selection. Male sex was associated with an increased risk for morbidity and mortality in older series but not in the most recent experience. Almost all studies have identified BMI and history of VTE as independent predictors of complications.

Complications specific to RYGB include anastomotic leaks from the proximal or distal anastomosis. They typically present early with signs of shock, including tachycardia, tachypnea, and abdominal pain. They can be diagnosed clinically or with CT with PO contrast. Leaks from the gastrojejunostomy are more common and are generally the cause of a significant percentage of the life-threatening complications and deaths. Whereas the older studies found a leak rate of 2.2% in open and LRYGB, the more recent LRYGB studies report anastomotic leak rates of under 1.0%.[38,44] These investigators found no difference in leak rates by type of anastomosis or stapling instrument used. Leak rate may be slightly higher in the buttressing group but with lower postoperative bleeds.[44] Early leaks are treated with sepsis control, which often means operative management, whereas later leaks in clinically stable patients can be managed nonoperatively.

Pulmonary embolism is one of the most feared complications after any form of bariatric surgery, and its incidence in large reported series of open RYGB sometimes exceeds 1%. Thrombotic complications such as DVT and pulmonary embolism are less frequently associated with laparoscopic surgery than with open gastric bypass but still account for 17% of deaths, and up to 80% of patients who die after bariatric surgery have evidence of VTE. Emphasis on DVT prophylaxis using SCDs, early ambulation, and low-molecular-weight heparin has reduced the incidence of VTE to 0.23% in both LSG and LRYGB, as evidenced by the latest reports from the MBSAQIP.[42]

Although nausea and vomiting are not unusual in isolated circumstances after RYGB, especially in relation to a patient's adaptation to food restriction, if persistent, these symptoms can lead to the obvious problem of dehydration. This must be aggressively treated in the postoperative period or in association with a viral or other GI illness compounding the problem and further limiting oral intake. IV fluids are indicated when in doubt. This is the case for all bariatric operations, not just RYGB.

One specific problem that may arise with persistent vomiting after *any* of the bariatric operations and that is *imperative* for the surgeon to treat is Wernicke's encephalopathy. This neurologic deficit is preventable with appropriate administration of parenteral thiamine (vitamin B_1) when the patient has persistent and severe vomiting. If the neurologic symptoms become significant, they may often not be fully reversed despite thiamine therapy.

Because depression is so frequent in the population of patients undergoing bariatric surgery, severe postoperative depression may develop after any of the bariatric operations as well. When it does occur, the patient may completely stop eating, thereby producing what at first seems like a wonderful response, but if unrecognized, it can progress to loss of critical visceral and musculoskeletal protein mass, which can be life threatening.

Another specific life-threatening complication that may result after RYGB is bowel obstruction. Patients who have a clinical or radiographic picture of small bowel obstruction after RYGB need a reoperation. The potential for internal hernias after this operation makes strangulation obstruction a frequent presentation. Patients with bowel obstruction are best diagnosed by an oral and IV contrast-enhanced CT scan of the abdomen to visualize the bypassed stomach and small bowel that may be obstructed or the mesenteric twist with volvulus of the Roux limb. These patients *must* be promptly treated before retrograde distention of the biliopancreatic limb and distal part of the stomach results in rupture of the distal gastric staple line with subsequent peritonitis. Closure of the mesenteric defects has been shown to reduce the incidence of internal hernia from 4% to 17% to 0% to 7% or by approximately 70% and adds only minimal operative time.[45] It is our practice to perform antecolic LRYGB, and we close both the jejunojejunostomy and Petersen's defect.

Stenosis of the gastrojejunostomy may occur after RYGB and has been reported in 2% to 7% of patients in various series. The higher incidence seems to be associated with a circular stapler versus sutured anastomoses. Postoperative anastomotic stenosis is usually manifested at 4 to 6 weeks postoperatively as progressive intolerance to solids and then liquids. The problem is successfully treated with endoscopic balloon dilation. Unless a marginal ulcer is associated with the stenosis, the problem does not usually require a reoperation.

A marginal ulcer occurs after 2% to 14% of RYGB procedures. The incidence can be decreased by preoperative treatment of patients for *Helicobacter pylori* colonization of the stomach. Patients with a marginal ulcer typically have continuous boring epigastric pain. Larger pouch size was associated with increased marginal ulceration. For each 5-cm^3 increase in pouch size, patients had 2.4 times the odds of increase in marginal ulcer formation.[46] Presumably, the additional size of the pouch had more parietal cells secreting acid, which increased the risk of marginal ulceration. Treatment of marginal ulcer consists of medical therapy with proton pump inhibitors and avoidance of nonsteroidal anti-inflammatory drugs and smoking. Medical treatment resolves most of the marginal ulcers unless a fistula has formed to the lower part of the stomach, which creates an ongoing source of acid, thus exacerbating the ulcer. Surgery to divide the fistula is necessary to effect healing of the ulcer.

Iron and vitamin B_{12} deficiencies are the two most common long-term metabolic complications of RYGB. The incidence of iron insufficiency varies among reported series. Iron is preferentially absorbed in the duodenum and proximal jejunum. Hence, RYGB bypasses the area of maximal iron absorption in the gut.

The iron deficiency, based on serum values, is between 15% and 40%, whereas actual iron deficiency anemia occurs in as many as 20% of patients after RYGB. This problem is treated in most cases with oral iron supplements. The gluconate form of iron is best absorbed in a nonacid environment.

The incidence of vitamin B_{12} deficiency after RYGB is reported as being 15% to 20%, although it rarely causes anemia. Vitamin B_{12} deficiency is a result of inefficient absorption because of delayed mixing with intrinsic factor. Thus, B_{12} deficiency can develop despite plentiful oral administration. Several preparations include intrinsic factor, which maximizes absorption in the terminal ileum. Other routes of vitamin B_{12} administration include sublingual medication, nasal spray, and parenteral injections.

Biliopancreatic Diversion With Duodenal Switch and Single Anastomosis Duodenal-Ileal Bypass With Sleeve Gastrectomy

The most significant and specific long-term complication seen after BPD/DS is protein malnutrition, which occurs in 8% of patients. Treatment is hospitalization with 2 to 3 weeks of parenteral nutrition. This particular problem is usually manifested within the first few months after surgery, but it can occur sporadically, although less frequently, and may even require reoperation to lengthen the common channel. This occurs more frequently in BPD/DS patients because the common channel is shorter.

Malabsorption of fat-soluble vitamins is one of the major problems associated with BPD/DS and SADI-S. However, one of the main benefits of SADI-S is a lower rate of vitamin deficiencies. In one single institution study comparing BPD/DS to SADI-S, the rates of vitamin A (36.4% vs. 13.5%,), vitamin D (55.3% vs. 36.5%), calcium (36% vs. 12.4%), iron (41.1% vs. 19.1%), and copper (6% vs. 1.7%) deficiency were all significantly higher in the BPD/DS group. The overall rate of long-term complications was also higher in the BPD/DS group (13.1% vs. 4.4%), with higher rates of incisional hernia and internal hernias but lower rates of symptomatic GERD. Diarrhea may also be less frequent after SADI-S.[35,39]

Although the complication of protein malnutrition and poor intake is theoretically most likely to occur soon after BPD/DS, the fact that late deaths occur from protein malnutrition and Wernicke's encephalopathy suggests that these patients are always at risk for these problems. Marginal ulcers are a distinct problem of BPD, which has been addressed with the DS modification and SADI-S preserving the pylorus. Finally, mortality rates in recent studies are also low for both BPD/DS and SADI (0.3%–0.5%) but still higher than those of LSG and LRYGB.[35,39,43]

Although still low in total procedures performed, the rates of DS and SADI-S are slowly on the rise, reaching 2.8% of bariatric operations nationally in 2021. Further studies are needed to elucidate long-term outcomes and assess whether the excitement for SADI-S as a safer alternative to BPD/DS with better weight loss and comorbidity resolution than LRYGB is merited.

Laparoscopic Sleeve Gastrectomy

The mortality rate after LSG ($\sim$0.1%) is slightly lower than that of LRYGB (Table 99.14).[38,42,47] The morbidity associated with LSG, including infections and reoperation rates, is slightly below that of LRYGB but with similar rates of VTE. Malabsorption of vitamins and nutrients is much less for LSG compared with LRYGB or the laparoscopic DS and makes LSG ideally suited for patients with preexisting vitamin disorders or those who need full absorption of lifesaving medications. Moreover, studies of 30-day morbidity and mortality show that there has been a continual decline in postoperative complications associated with increased surgical experience.

TABLE 99.14 **Complications After Laparoscopic Sleeve Gastrectomy**

CRITERIA	KUMAR[42]	JANIK[38]	ABOUEISHA[47]
Number of patients	93,062	3371	513,354
Age	Median = 44	>60	Median = 44.2
Mortality	0.1%	0.12%	<0.1%
Leak perforation	0.8%	0.5%	0.4%
Surgical site infection	0.2%	0.2%	0.2%–0.3%
Pulmonary embolus/venous thromboembolism	0.1%	0.1%	0.2%
Reoperation	1.2%	0.9%	0.8%–0.9%
Bleeding	0.6%	1.0%	0.5%–0.6%

The long-term morbidity of LSG is related to reoperation, primarily conversion to RYGB for severe GERD, which is exacerbated by the high-pressure system created by LSG in addition to decreased gastric compliance, disruption of gastric sling fibers, and increased transient lower esophageal sphincter relaxations. The SLEEVEPASS 10-year follow-up study showed that there was a high incidence of GERD in patients who underwent LSG, with 11.6% requiring conversion to RYGB. Moreover, of the 90 patients who underwent endoscopy postoperatively, 20% never experienced GERD symptoms, 18% had symptoms similar to preoperatively, and 13% had symptoms alleviated, but 49% had worsened symptoms.[48]

The most feared complications postoperatively after LSG are stenosis and leak. Stenosis occurs in less than 1% of cases but is most typically at the incisura. It typically presents with obstructive symptoms and may be diagnosed on esophagogastroduodenoscopy (EGD) or upper GI series. It is often treated with serial endoscopic dilation but may require revision to RYGB.[17,47] Leaks occur in approximately 0.3% to 0.5% of cases and typically present 1 to 4 weeks after surgery. They may present more indolently with infection and abscess but without frank shock and can be diagnosed by CT scan with oral contrast. Sleeve leaks are often a result of stricture or narrowing at the incisura, leading to proximal leak. Early leaks (within 48 hr) are more often related to stapler misfires or tissue trauma (and behave more like a post-RYGB anastomotic leak), whereas late leaks are related to ischemia and high intragastric pressure, particularly when there is a distal stenosis. Management of leaks includes sepsis control with adequate drainage and antibiotics as well as initial nil per os (NPO) with supplemental nutrition. They may require a combination of drainage (externally and intraluminally), stenting, or intraluminal wound vacuum placement, as discussed later.

REOPERATIVE SURGERY

A controversial topic is the appropriateness of performing repeated bariatric operations for recurrent weight gain or inadequate weight loss. It is well established that there is heterogeneity in postoperative weight loss outcomes. Long-term recurrent weight gain is also possible despite attention to diet and physical activity; thus, long-term follow-up is recommended. The absolute definition of a failure is unclear, but most surgeons would accept the criteria listed in

Box 99.2 as appropriate when considering reoperation in patients with inadequate weight loss (<50% EWL at 18 months), recurrent weight gain (>10%), or recurrence of comorbidities. Complications of procedures, such as stenosis causing gastric outlet obstruction after vertical banded gastroplasty or metabolic complications after jejunoileal bypass, are obvious indications for revisional surgery.

In assessing a patient for the appropriateness of reoperative surgery, the surgeon must determine whether the original bariatric operation is intact and anatomically still appropriate for maintaining weight loss. If not, consideration for reoperation is appropriate. The incidence of infection, organ ischemia, anastomotic leakage, blood transfusion, and other severe intraabdominal complications is increased in revisional surgery.

All bariatric operations have some incidence of failure, which includes inadequate weight loss, inadequate resolution of medical comorbid conditions, development of side effects negatively influencing lifestyle and satisfaction, development of complications requiring medical or surgical intervention, and complications requiring alteration or reversal of the operation. Analysis of the 449,753 bariatric operations in the Bariatric Outcomes Longitudinal Database (BOLD) showed that 4.4% were corrective operations (i.e., operations that addressed complications or incomplete treatment effect of the primary bariatric operation), and 1.9% were conversions (i.e., operations in which the primary bariatric procedure was converted to another bariatric procedure).[49] Only 6.3% of bariatric operations needed reoperation, and even fewer needed conversion to another bariatric procedure, which points out the relative efficacy of the common bariatric procedures being performed currently. Moreover, the reoperations had a low mortality rate of 0.12% to 0.21% and a 1-year EWL of 36% to 39%.[49] The data suggest that reoperations for failure are not that common; the clinical results are acceptable, albeit less predictable with less EWL; and have similar mortality rates. This should negate the bias among some primary care providers as well as insurance companies that reoperative bariatric surgery is risky and not worth the benefits. Nevertheless, appropriate counseling is necessary to set patient expectations.

ENDOSCOPIC PROCEDURES IN BARIATRIC SURGERY

Endoscopy has become an important part of management of complications after bariatric surgery, and in addition, a plethora of endoscopic weight loss procedures are being used or are in development.

Preoperative Use of Endoscopy

The ASMBS published guidelines on this topic in 2021 and concluded that EGD in preoperative patients may indeed guide treatment of modifiable conditions or identify anatomic abnormalities or conditions that would alter treatment. Moreover, clinical evaluation by symptoms alone does not reliably diagnose or rule out GERD. A comprehensive review of 28 studies and 12,385 patients identified that the majority (92.4%) of preoperative endoscopic findings did not alter management; however, 7.6% of patients had findings that delayed or altered surgery.[50] Therefore, the ASMBS states that EGD before bariatric surgery should be done at the surgeon's discretion. We recommend endoscopy for symptomatic patients before bariatric surgery, and consideration should be given to preoperative endoscopy in asymptomatic patients.

Intraoperative Endoscopy

Many surgeons will do an intraoperative leak test in the operating room at the time of the procedure to prevent complications after the procedure. The method of leak test varies from using methylene blue through an orogastric tube to air insufflation with a tube or an endoscope. When using an insufflation test, the staple line of the stomach and any proximal anastomosis is submerged under sterile saline, and air is insufflated into the gastric pouch. One then looks for air bubbles to assess whether the staple lines are airtight under hyperdistention. The benefit of the endoscope is that it can be both diagnostic and therapeutic at the time of surgery. If a leak is noted, it may be able to be managed with endoscopic clips or externally placed sutures under endoscopic guidance. In addition, if bleeding is noted along any staple lines, it can be managed immediately rather than with a potential return to the operating room later once the bleed becomes clinically evident. Finally, endoscopy allows the surgeon to assess the postsurgical anatomy more thoroughly to ensure it looks as intended.

Postoperative Endoscopy

Once a patient has had altered anatomy for a weight loss procedure, endoscopy is invaluable in evaluating patients who return with abdominal complaints, suffer from weight regain, or develop a complication of their procedure. Understanding the postsurgical anatomy after a bariatric procedure can be challenging, especially if the surgery was many years ago. The most common procedures one should recognize are the gastric bypass, LSG, gastric banding, DS, and SADI-S.

Endoscopic Management of Complications After Bariatric Surgery

Leaks after bariatric surgery are one of the most dreaded complications, as discussed earlier, and carry a high mortality. One of the most commonly used interventions for a leak is the use of a fully covered stent. This endoscopically placed stent traverses the perforation, thereby decreasing ongoing contamination. However, a major issue with this treatment method is stent migration. To avoid this, multiple methods of prevention have been described, including suturing it or clipping the stent in place. Stents are left in place for 4 to 6 weeks. Sutures can be placed endoscopically, but these devices are sometimes bulky in this small space. Fluoroscopy is essential to ensure proper stent placement. Leaks after LSG can be particularly challenging because the stents available in the United States are not long enough to traverse the entire sleeve. Many use two stents placed overlapping to mitigate this problem.

Another approach to leak management is the use of over-the-scope clips. This technology generally does not work for these leaks in the acute setting unless the hole is very small with fresh edges. Usually, this technology works better for chronic leaks that are small or fistulas that are less than 1 cm.

Endoscopic vacuum-assisted closure is now being used for the closure of large leaks. This technique involves placing the vacuum sponge on the end of an orogastric tube into the cavity external to the leak. Over time, this allows closure of this area. This works for encapsulated leaks. This technique is very labor intensive because the device must be changed every few days, similar to any external wound vacuum device. Generally, patients will require 8 to 12 procedures over a period of weeks. The benefit is this can actually shorten the healing time compared with traditional methods.

If the hole is small but the external cavity of the leak is on the larger side, internal drainage with a double pigtail stent can also be used. This allows internal drainage of the extraluminal cavity. This is very helpful, particularly when the placement of an external drain is difficult. If the opening is small, an endoscopic septotomy has also been performed to allow better drainage of an extraluminal cavity.

Strictures After Bariatric Surgery

Strictures can occur at the outlet of a pouch after gastric bypass procedures or at the incisura angularis after LSG. After a gastric bypass, the anastomotic strictures can often be managed with through-the-scope balloons. These range from 5 to 20 mm in diameter. They are placed through the scope and across the stricture. If the scope cannot traverse the stricture, the balloon can be placed over a wire or with fluoroscopic guidance to avoid perforation. These strictures may require multiple dilations because one should not try to dilate the stricture more than 3 to 5 mm at any one sitting. In addition, the underlying cause of the stricture should be identified and addressed to avoid recurrence. Common causes include smoking and nonsteroidal medication use. Strictures after LSG are most often at the incisura angularis. These have been managed with endoscopic balloon dilation and stent placement. Unfortunately, these methods are not always successful, and conversion to a gastric bypass for management may be necessary.

Recurrent Weight Gain After Bariatric Surgery

Recidivism after bariatric surgery occurs around 10% to 15% of the time. Conversion of a primary procedure such as LAGB to sleeve or RYGB, conversion from sleeve to RYGB or DS, or revising an RYGB to a distal bypass can be done. Endoscopic suturing for pouch outlet reduction after gastric bypass procedure is another described procedure but has yet to demonstrate substantial results. An endoscopic suturing device that allows full-thickness bites is used to decrease the size of the gastrojejunostomy. The smaller-diameter anastomosis allows for longer retention of food within the pouch, leading to greater satiety and reduced food intake. The endoscopic procedure is accompanied by lifestyle counseling to improve dietary and exercise habits and has been able to obtain marginal weight loss at 6 months, but longer-term studies are needed.

Primary Endoscopic Weight Loss Procedures

Currently, for those overweight, diet and exercise are recommended. For those with severe obesity, weight loss surgery is an option. For those in between, few interventions were available before the introduction of GLP-1 RAs. In addition, many patients do not wish to undergo an anatomically altering weight loss surgery. Now there are several endoscopic options for weight loss that work in various ways, which include space filling devices and the endoscopic sleeve gastroplasty.

Space filling devices can come in single- and multiple-balloon systems. The most common is the Orbera balloon (Apollo Endosurgery, Inc., Austin, TX). Over 300,000 of these balloons have been placed, with reasonable success. This balloon is placed endoscopically, remains in place for 6 months, and then is removed endoscopically. Throughout this time and the ensuing 6 months, the patient receives dietary and lifestyle counseling. Patients learn how much food they can live on while the balloon is in place, and the ongoing counseling is to help them maintain that lifestyle once the balloon is removed. Patients can lose up to 30 to 50 lb, but this weight loss is often not sustained. Other balloon systems are air filled or use multiple balloons to minimize the nausea that is encountered at initial placement. Newer balloons are on the horizon that do not require endoscopy for placement or removal.

The other endoscopic procedure that has gained popularity is the endoscopic sleeve gastroplasty. The stomach walls are sutured together to collapse the stomach using an endoscopic suturing device. By doing so, the only lumen left behind emulates a sleeve gastroplasty. The weight loss reported in the short term in small series is greater than that from medical therapy, and long-term controlled trials are needed to evaluate the potential of this approach.

Other endoscopic procedures include liners that decrease absorption or reduce gastric emptying, thereby inducing fullness in the patient. In addition, even magnets are being used to create bypasses endoscopically. All these procedures have minimal data, and their durability is unclear. Their long-term use may be further challenged by the success of incretin-mimetic drugs like GLP-1 RAs that are now flooding the market. These endoscopic procedures will likely not attain the effectiveness of surgery; however, they can provide a bridge to surgical procedures. They can also be an intervention that some patients can accept to facilitate weight loss that is less invasive than surgery.

CONCLUSION

Surgical treatment of morbid obesity is now a component of surgical residency training programs and represents the fastest-growing area of general surgery. Although patient demand for the procedure has vastly increased, at present, surgeons operate annually on less than 2% of the eligible patients who would benefit from bariatric surgery. This chapter has discussed all aspects of the performance of bariatric surgery in current surgical practice, including the most commonly performed procedures at this time. The disease process of morbid obesity is unfortunately incompletely understood, but morbid obesity is increasing in prevalence worldwide. Surgical therapy has been shown to reduce long-term mortality and aid in control of diabetes largely because surgery has proven to be a more effective intervention for weight loss than nonsurgical options. Recent randomized clinical trials of bariatric surgery versus medical treatment in obese diabetic patients have shown bariatric surgery to be more effective in the treatment of severe obesity, type 2 diabetes mellitus, hypertension, and dyslipidemia. With the positive results of bariatric surgery becoming more widely known, there has been a movement by multiple medical societies to recognize the need for referral to a bariatric surgeon for evaluation. It is hopeful that these data will also encourage the government and insurance companies to add or expand bariatric and metabolic surgery coverage.

Aminian A, Zajicheck A, Arterburn DE, et al. Association of metabolic surgery with major adverse cardiovascular outcomes in patients with type 2 diabetes and obesity. *JAMA*. 2019;322:1271-1282.

This study involved a 1:5 matched cohort of patients with type 2 diabetes and obesity and compared major adverse cardiovascular events (MACEs) between patients undergoing metabolic surgery (2287 patients) and nonsurgical patients (11,435) in the Cleveland Clinic Health System. The primary end point was incidence of extended MACE (composite of six outcomes), defined as first occurrence of all-cause mortality, coronary artery events, cerebrovascular events, heart failure, nephropathy, and atrial fibrillation, and secondary end points were the three-component MACE (i.e., myocardial infarction, ischemic stroke, and mortality) and the six individual

components of the primary end point. The study found that the surgical group experienced a primary end point in only 30.8% of patients compared with 47.7% in the nonsurgical group (p <0.001), with an absolute risk reduction of 16.9%. Surgical patients had a lower three-component MACE compared with nonsurgical patients as well (17.0% vs. 27.6%, HR 0.62, 95% CI 0.53–0.72). Metabolic surgery was also associated with significantly lower incidence of each individual primary component, including heart failure (HR 0.38), coronary artery disease (HR 0.69), cerebrovascular disease (HR 0.67), nephropathy (HR 0.40), and atrial fibrillation (HR 0.78). Therefore, among patients with type 2 diabetes and obesity, metabolic surgery was associated with significantly lower risk of incident MACE.

Carlsson LMS. Sjoholm K, Jacobson P, et al. Life expectancy after bariatric surgery in the Swedish Obese Subjects Study. *N Engl J Med*. 2020;383:1535-1543.

This study compared a group of patients undergoing bariatric surgery with a group of matched control subjects and monitored them for 10.9 years. This is the long-term follow-up at median 22 and 24 years for the surgical and control groups. The study found a significant decrease in the weight and risk of death in individuals in the surgical weight loss group compared with control patients not undergoing surgery (HR 0.77, 95% CI 0.68–0.87). The corresponding HR for death from cardiovascular disease was 0.7 (95% CI 0.57–0.85), and that from cancer was 0.77 (95% CI 0.31–0.96). The median life expectancy in the surgery group was 3.0 years longer than in the control.

Khalid SI, Maasarani S, Wiegmann J, et al. Association of bariatric surgery and risk of cancer in patients with morbid obesity. *Ann Surg*. 2022;275:1-6.

This study compared 28,908 patients who underwent vertical sleeve gastrectomy (VSG) or RYGB or who met bariatric surgery eligibility criteria between 2010 and 2018 in a 1:1:1 matched cohort. It found that patients who underwent VSG or RYGB had a significantly lower risk of developing any cancer compared with bariatric surgery–eligible patients who did not undergo an intervention (VSG OR 0.74, 95% CI 0.64–0.86; RYGB OR 0.78, 95% CI 0.67–0.90). Bariatric surgery patients also had lower odds of developing lung cancer, ovarian cancer, and uterine cancer compared with nonsurgical patients. Moreover, compared with nonsurgical patients, patients undergoing an RYGB had lower odds of colorectal cancer (OR 0.47, 95% CI 0.30–0.75), and those undergoing VSG had lower odds of liver cancer (OR 0.44, 95% CI 0.22–0.89). The authors conclude that bariatric surgery may lower the postoperative cancer rates in obese patients compared with bariatric-eligible patients who do not undergo surgical intervention.

Salminen P, Helmio M, Ovaska J, et al. Effect of laparoscopic sleeve gastrectomy vs laparoscopic Roux-en-Y gastric bypass on weight loss at 5 years among patients with morbid obesity: the SLEEVEPASS Randomized Clinical Trial. *JAMA*. 2018;319:241-254.

Comparison of laparoscopic LRYGB to LSG in an RCT demonstrated that weight loss was slightly better (57% vs. 49%, respectively) and resolution of hypertension was improved after LRYGB compared with LSG. The difference in weight loss between procedures did not have clinical significance. The study also noted that both procedures had improved HRQOL and no difference in late complications. The majority (7/10) of reoperations after LSG were performed for severe reflux. The results of this trial and the SM-BOSS RCT show LSG to be an effective bariatric procedure that compares favorably to LRYGB at 5 years after surgery.

Schauer PR, Bhatt DL, Kirwan JP, et al. Bariatric surgery versus intensive medical therapy for diabetes—5-year outcomes. *N Engl J Med*. 2017;376:641-651.

The authors randomized 150 obese (BMI 27–43) uncontrolled diabetics (HbA1c >7.0%) to intensive medical therapy or to LSG or laparoscopic RYGB. Surgical groups had significant improvement in HbA1c, weight loss, and dyslipidemia and a reduction in the number of antihypertensive, lipid-lowering, and diabetic medications used at 1, 2, 3, and 5 years after randomization. The surgical patients also had a significant improvement in QOL, whereas there was no change in the QOL for the medically treated patients. They concluded, "Bariatric surgery represents a potentially useful strategy for the management of type 2 diabetes, allowing many patients to reach and maintain therapeutic targets of glycemic control that otherwise would not be achievable with intensive medical therapy alone." This study, now with a 5-year follow-up showing sustained improvements for the surgical groups, adds to the strong evidence supporting bariatric surgery as a safe and effective therapy for treatment of type 2 diabetes.
